Library of Congress Cataloging-in-Publication Data

Names: Marcel Grossmann Meeting on General Relativity (16th : 2021 : Online) | Ruffini, Remo, editor. | Vereshchagin, Gregory, editor.

Title: The sixteenth Marcel Grossmann meeting on recent developments in theoretical and experimental general relativity, astrophysics, and relativistic field theories : proceedings of the MG16 meeting on general relativity online, 5–10 July 2021 / editors: Remo Ruffini, University of Rome "La Sapienza", Rome, Italy, International Center for Relativistic Astrophysics Network (ICRANet), Pescara, Italy, Gregory Vereshchagin, International Center for Relativistic Astrophysics Network (ICRANet), Pescara, Italy.

Other titles: Proceedings of the MG16 meeting on general relativity online, 5–10 July 2021

Description: New Jersey : World Scientific, [2023] | Includes bibliographical references.

Identifiers: LCCN 2022047088 | ISBN 9789811269769 (set ; hardcover) | ISBN 9789811266584 (v. 1) | ISBN 9789811266591 (v. 2) | ISBN 9789811266607 (v. 3) | ISBN 9789811266614 (v. 4) | ISBN 9789811269776 (set ; ebook)

Subjects: LCSH: General relativity (Physics)--Congresses. | Gravitation--Congresses. | Quantum gravity--Congresses. | Cosmology--Congresses. | Astrophysics--Congresses.

Classification: LCC QC173.6 .M37 2021 | DDC 523.01--dc23/eng/20220929

THE MARCEL GROSSMANN MEETINGS

Series Editor: REMO RUFFINI

Publications in the Series of Proceedings

Proceedings of the Sixteenth Marcel Grossmann Meeting on General Relativity
(Virtual Meeting, 2021)
Edited by G. Vereshchagin, R. Ruffini
World Scientific, 2022

Proceedings of the Fifteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2018)
Edited by E.S. Battistelli, R.T. Jantzen, R. Ruffini
World Scientific, 2022

Proceedings of the Fourteenth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2015)
Edited by M. Bianchi, R.T. Jantzen, R. Ruffini
World Scientific, 2017

Proceedings of the Thirteenth Marcel Grossmann Meeting on General Relativity
(Stockholm, Sweden, 2012)
Edited by K. Rosquist, R.T. Jantzen, R. Ruffini
World Scientific, 2015

Proceedings of the Twelfth Marcel Grossmann Meeting on General Relativity
(Paris, France, 2009)
Edited by T. Damour, R.T. Jantzen, R. Ruffini
World Scientific, 2012

Proceedings of the Eleventh Marcel Grossmann Meeting on General Relativity
(Berlin, Germany, 2006)
Edited by H. Kleinert, R.T. Jantzen, R. Ruffini
World Scientific, 2007

Proceedings of the Tenth Marcel Grossmann Meeting on General Relativity
(Rio de Janiero, Brazil, 2003)
Edited by M. Novello, S. Perez-Bergliaffa, R. Ruffini
World Scientific, 2005

Proceedings of the Ninth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 2000)
Edited by V.G. Gurzadyan, R.T. Jantzen, R. Ruffini
World Scientific, 2002

Proceedings of the Eighth Marcel Grossmann Meeting on General Relativity
(Jerusalem, Israel, 1997)
Edited by T. Piran
World Scientific, 1998

Proceedings of the Seventh Marcel Grossmann Meeting on General Relativity
(Stanford, USA, 1994)
Edited by R.T. Jantzen and G.M. Keiser
World Scientific, 1996

Proceedings of the Sixth Marcel Grossmann Meeting on General Relativity
(Kyoto, Japan, 1991)
Edited by H. Sato and T. Nakamura
World Scientific, 1992

Proceedings of the Fifth Marcel Grossmann Meeting on General Relativity
(Perth, Australia, 1988)
Edited by D.G. Blair and M.J. Buckingham
World Scientific, 1989

Proceedings of the Fourth Marcel Grossmann Meeting on General Relativity
(Rome, Italy, 1985)
Edited by R. Ruffini
World Scientific, 1986

Proceedings of the Third Marcel Grossmann Meeting on General Relativity
(Shanghai, People's Republic of China, 1982)
Edited by Hu Ning
Science Press – Beijing and North-Holland Publishing Company, 1983

Proceedings of the Second Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1979)
Edited by R. Ruffini
North-Holland Publishing Company, 1982

Proceedings of the First Marcel Grossmann Meeting on General Relativity
(Trieste, Italy, 1975)
Edited by R. Ruffini
North-Holland Publishing Company, 1977

FREEDOM OF MOVEMENT FOR SCIENTISTS

The Marcel Grossmann Meetings were founded with the premise that scientists of all nations have a right to meet to exchange knowledge independent of national borders.

ACKNOWLEDGEMENTS

We acknowledge the outstanding job done before, during and after the meeting by the ICRANet/ICRA administrative and secretarial staff: Cristina Adamo, Silvia Latorre, Elisabetta Natale, and Cinzia di Niccolo. Finally this meeting and its proceedings could not have functioned without the dedicated IT support of the ICRANet system manager Gabriele Brandolini, with some temporary assistance from Domenico La Selva and Damiano Verzulli. We would like to thank Linda Kwan from World Scientific for valuable assistance during preparation of these proceedings.

ORGANIZING BODIES OF THE SIXTEENTH MARCEL GROSSMANN MEETING

INTERNATIONAL ORGANIZING COMMITTEE

Blair David, Choquet Bruhat Yvonne, Damour Thibault, De Bernardis Paolo, Everitt C. W. Francis, Fryer Chris, Haensch Theodor, Henneaux Marc, Jones Christine, Kerr Roy, Kleinert Hagen, Kunz Jutta, Laemmerzahl Claus, Longair Malcolm, Mirabel Felix, Mirzoyan Razmik, Piran Tsvi, Rueda Jorge, Ruffini Remo (chair), Sasaki Misao, Sato Humitaka, Sunyaev Rashid, 't Hooft Gerard, Weinberg Steven, Yau Shing-Tung, Zhang Bing

LOCAL ORGANIZING COMMITTEE

Adamo Cristina, Bianco Carlo Luciano, Brandolini Gabriele A., di Niccolo Cinzia, Latorre Silvia, La Selva Domenico, Li Liang, Loppini Alessandro, Natale Elisabetta, Verzulli Damiano, Vereshchagin Gregory (chair), Wang Yu

INTERNATIONAL COORDINATING COMMITTEE

ALBANIA: Hafizi M. - ARGENTINA: Arguelles C., Scoccola C., Reula O., Romero G.E. - ARMENIA: Sahakyan N. - AUSTRALIA: Blair D., Ju L., Lun A., Manchester D., Melatos A., Quinn P., Scott S.M., Steele J.D. - AUSTRIA: Aichelburg P.C., Schindler S. - BELARUS: Kilin S., Prakapenia M., Siutsou I. - BELGIUM: Henneaux M. - BOLIVIA: Aguirre C.B. - BOSNIA: Pasic V. - BRAZIL: Barres de Almeida U., Coelho Goulart J., Dalmolin F.T., de Lima Rafael C.R., Guzzo M., Maia C., Malheiro M., Romero Filho C.A., Shellard R.C., Zen Vasconcellos C. - BULGARIA: Yazadjiev S. - CANADA: Singh D., Smolin L., Turok N. - CHILE: Bauer F., Bunster W.C., Giacomini A. - CHINA (MAINLAND): Cai R., Cai Y., Cao Z., Chang J., Chen J., Chen X., Dai Z., Feng L.-L., Han W., Jing Y., Li T.-P., Lin W., Lou Y.-Q., Luo J., Mei J., Tam T., Wang A., Wang Y., Wu X.-P., Wu Y.-L., Yuan Y.-F., Zhang B.-B., Zhang S.-N., Zhao G. - CHINA (TAIWAN): Chen Chiang-Mei, Chen Pisin, Lee Da-Shin, Lee Wo-Lung, Ni Wei-Tou - COLOMBIA: Bargueño de Retes P., Gonzalez G., Higuera Garzon M.A., Núñez L., Romano A.E., Valenzuela Toledo C.A., Zuluaga J.I. - CROATIA: Dominis Prester D., Karlica M., Milekovic M., Smolcic V., Smolic I., Suric T. - CUBA: Perez Martinez A., Pérez Rojas H. - CZECH REPUBLIC: Bicak J., Stuchlik Z. - DENMARK: Naselsky P. - ECUADOR: Contreras E. - EGYPT: Tawfik A.N., Wanas M.I. - ESTONIA: Einasto J., Saar E. - FINLAND: Poutanen J., Volovik G. - FRANCE: Brillet A., Buchert T., Chardonnet P., Coullet P., de Freitas Pacheco J.A., Deruelle N., Iliopoulos J., Lamanna G., Mignard F. - GEORGIA: Lavrelashvili George, Machabeli Giorgi - GERMANY: Biermann P., Blumlein J., Di Piazza A., Fritzsch H., Genzel R., Gilmozzi R., Hasinger G., Hehl F., Keitel C., Kiefer C., Mirzoyan R.,

Neugebauer G., Nicolai H., Renn J., Ringwald A., Ruediger A. - GREECE: Batakis N.A., Cotsakis S., Vagenas E.C. - HUNGARY: Fodor G., Levai P. - ICELAND: Bjornsson G., Jakobsson P. - INDIA: Chakrabarti S.K., Iyer B., Padmanabhan T., Souradeep T. - IRAN: Baghram S., Bavarsad E., Eslam Panah B., Firouzjahi H., Haghighat M., Mansouri R., Mashhoon B., Shakeri S., Sobouti Y., Taghi Mirtorabi M. - IRELAND: O'Murchada N. - ISRAEL: Milgrom M., Nakar E., Pe'er A., Piran T. - ITALY: Belinski V., Bianchi M., Bianco C.L., Cherubini C., Della Valle M., Falciano S., Filippi S., Haardt F., Menotti P., Merafina M., Pani P., Ricci F., Treves A., Vereshchagin G.V., Vitale S., Xue S.- S. - JAPAN: Fujimoto M.-K., Makishima K., Nakamura T., Sato K., Shibata M. - KAZAKHSTAN: Abishev M., Aimuratov Y., Boshkayev K., Mychelkin E.G., Spitaleri C. - KOREA (PYEONGYANG): Kim J.S. - KOREA (SEOUL): Kim S.P., Kim S.-W., Lee H.K., Lee H.-W., van Putten M. - KYRGYZSTAN: Gurovich V.Ts. - LIBYA: Gadri M. - MEXICO: Breton N., Cervantes-Cota J.L., Fraija Cabrera N.I., García-Diaz A.A., Macías Alvarez A., Mielke Eckehard W., Quevedo H., Rodriguez L.F. - NETHERLANDS: Slagter R. - NEW ZEALAND: Visser M., Wiltshire D. - NORWAY: Elgaroy O., Fonseca Mota D., Knutsen H. - PAKISTAN: Qadir A., Qamar S. - PERU: Vargas T. - POLAND: Belczynski K., Demianski M., Lewandowski Jerzy, Nurowski P., Sokolowski L. - PORTUGAL: Costa M., Da Silva A., Lemos J.P.S., Lobo F., Moniz P., Silva L.O. - ROMANIA: Visinescu M. - RUSSIA: Aksenov A., Arkhangelskaja I., Bisnovatyi-Kogan G., Blinnikov S., Chechetikin V.M., Cherepaschuk A.M., Khriplovich I., Lipunov V.M., Lukash V.N., Novikov I., Rudenko V.N., Starobinsky A.A. - SERBIA: Djordjevic G., Jovanovic P., Knezevic Z., Pankov-Hzvojevic M., Popovic L., Prodanovic T., Sijacki D., Simic S. - SLOVAKIA: Balek V. - SLOVENIA: Cadez A., Gomboc A., Zavrtanik D. - SOUTH AFRICA: Larena J., Maharaj S. - SPAIN: Elizalde E., Ibanez J., Perez M.J., Verdaguer E. - SWEDEN: Abramowicz M.A., Marklund M., Ryde F. - SWITZERLAND: Durrer R., Jetzer P. - TURKEY: Aliev A., Gurses M. - UKRAINE: Novosyadlyj B., Zaslavskii O., Zhuk A. - UNITED ARAB EMIRATES: Fernini I. - UNITED KINGDOM: Cruise A.M., Frenk Carlos S., Green M., Mavromatos N., Perry M., Willingale R. - USA: Abel T., Ashtekar A., Bardeen J., Carlstrom J., Cornish N., Dermer C., Fan X., Flanagan E., Fraschetti F., Fryer C., Incera V., Jantzen R.T. (chairperson), Kolb R., Laguna P., Lousto C., Madau Piero, Mathews Grant, Matzner Richard, Melia Fulvio, Mester John, Michelson Peter, Nordtvedt Kenneth, Parker Leonard, Pretorius F., Pullin J., Shapiro I., Shapiro S., Shoemaker D., Smoot G., Stiavelli M., Teukolsky S., van Nieuwenhuizen P., Zhang B. - UZBEKISTAN: Ahmedov B., Zalaletdinov R.M. - VATICAN CITY: Gionti G. - VENEZUELA: Fuenmayor E. - VIETNAM: Long H.N.

MARCEL GROSSMANN AWARDS

Sixteenth Marcel Grossmann Meeting

Institutional Awards

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

Individual Awards

DEMETRIOS CHRISTODOULOU
"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

GERARD 't HOOFT
"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

TSVI PIRAN
"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".

STEVEN WEINBERG
"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Each recipient is presented with a silver casting of the TEST sculpture by the artist A. Pierelli. The original casting was presented to His Holiness Pope John Paul II on the first occasion of the Marcel Grossmann Awards.

15th Marcel Grossmann Meeting
July 2018, Rome, Italy

Institutional Awards

PLANCK SCIENTIFIC COLLABORATION (ESA)
"for obtaining important constraints on the models of inflationary stage of the Universe and level of primordial non-Gaussianity; measuring with unprecedented sensitivity gravitational lensing of Cosmic Microwave Background fluctuations by large-scale structure of the Universe and corresponding B-polarization of CMB, the imprint on the CMB of hot gas in galaxy clusters; getting unique information about the time of reionization of our Universe and distribution and properties of the dust and magnetic fields in our Galaxy"

- presented to Jean-Loup Puget, the Principal Investigator of the High Frequency Instrument (HFI)

HANSEN EXPERIMENTAL PHYSICS LABORATORY AT STANFORD UNIVERSITY
"to HEPL for having developed interdepartmental activities at Stanford University at the frontier of fundamental physics, astrophysics and technology"

- presented to Research Professor Leo Hollberg, HEPL Assistant Director

Individual Awards

LYMAN PAGE
"for his collaboration with David Wilkinson in realizing the NASA Explorer WMAP mission and as founding director of the Atacama Cosmology Telescope"

RASHID ALIEVICH SUNYAEV
"for the development of theoretical tools in the scrutinising, through the CMB, of the first observable electromagnetic appearance of our Universe"

SHING-TUNG YAU
"for the proof of the positivity of total mass in the theory of general relativity and perfecting as well the concept of quasi-local mass, for his proof of the Calabi conjecture, for his continuous inspiring role in the study of black holes physics"

14th Marcel Grossmann Meeting
July 2015, Rome, Italy

Institutional Award

EUROPEAN SPACE AGENCY (ESA)
"for the tremendous success of its scientific space missions in astronomy, astrophysics, cosmology and fundamental physics which have revolutionized our knowledge of the Universe and hugely benefited science and mankind"

- presented to its Director General Johann-Dietrich Woerner

Individual Awards

KEN'ICHI NOMOTO
"for heralding the role of binary systems in the evolution of massive stars"

MARTIN REES
"for fostering Research in black holes, gravitational waves and cosmology"

YAKOV G. SINAI
"for applying the mathematics of chaotic systems to physics and cosmology"

SACHIKO TSURUTA
"for pioneering the physics of hot neutron stars and their cooling"

FRANK C.N. YANG
"for deepening Einstein's geometrical approach to physics in the best tradition of Paul Dirac and Hermann Weyl"

T.D. LEE (award received by Yu-Qing Lou on behalf of Prof. T.D. Lee)
"for his work on white dwarfs motivating Enrico Fermi's return to astrophysics and guiding the basic understanding of neutron star matter and fields"

13th Marcel Grossmann Meeting
July 2012, Stockholm, Sweden

Institutional Award

ALBANOVA
for its innovative status as a joint institute established by Stockholm University and the Royal Institute of Technology and for fostering contributions to cosmology and astrophysics in the profound scientific tradition established by Oskar Klein.

- presented to the Rector of Stockholm University, Prof. Kåre Bremer.

Individual Awards

DAVID ARNETT
for exploring the nuclear physics and yet unsolved problems of the endpoint of thermonuclear evolution of stars, leading to new avenues of research in physics and astrophysics.

VLADIMIR BELINSKI and I.M. KHALATNIKOV
for the discovery of a general solution of the Einstein equations with a cosmological singularity of an oscillatory chaotic character known as the BKL singularity.

FILIPPO FRONTERA
for guiding the Gamma-ray Burst Monitor Project on board the BeppoSAX satellite, which led to the discovery of GRB X-ray afterglows, and to their optical identification.

12th Marcel Grossmann Meeting
July 2009, Paris, France

Institutional Award

INSTITUT DES HAUTES ÉSTUDES SCIENTIFIQUE (IHÉS)
for its outstanding contributions to mathematics and theoretical physics, and notably for having renewed basic geometrical concepts, and having developed new mathematical and physical aspects of spacetime.

- presented to Prof. Jean-Pierre Bourguignon

Individual Awards

JAAN EINASTO
for pioneering contributions in the discovery of dark matter and cosmic web and fostering research in the historical Tartu Observatory.

CHRISTINE JONES
for her fundamental contributions to the X-ray studies of galaxies and clusters tracing their formation and evolution and for her role in collaborations using clusters to study dark matter and in analyzing the effects of outbursts from supermassive black holes on the intracluster gas.

MICHAEL KRAMER
for his fundamental contributions to pulsar astrophysics, and notably for having first confirmed the existence of spin-orbit precession in binary pulsars.

11th Marcel Grossmann Meeting
July 2006, Berlin, Germany

Institutional Award

FREIE UNIVERSITÄT BERLIN
for the successful endeavor of re-establishing — in the spirit of the Humboldt tradition — freedom of thinking and teaching within a democratic society in a rapidly evolving cosmos

- presented to Dr. Dieter Lenzen, President of FUB

Individual Awards

ROY KERR
for his fundamental contribution to Einstein's theory of general relativity: "The gravitational field of a spinning mass as an example of algebraically special metrics."

GEORGE COYNE
for his committed support for the international development of relativistic astrophysics and for his dedication to fostering an enlightened relationship between science and religion.

JOACHIM TRUMPER
for his outstanding scientific contributions to the physics of compact astrophysical objects and for leading the highly successful ROSAT mission which discovered more than 200,000 galactic and extragalactic X-ray sources: a major step in the observational capabilities of X-ray astronomy and in the knowledge of our universe.

10th Marcel Grossmann Meeting
July 2003, Rio de Janeiro, Brazil

Institutional Award

CBPF (Brazilian Center for Research in Physics)
for its role as a teaching and research institution and as a place originating fundamental physics ideas in the exploration of the universe.

- presented to its founders Cesar Lattes, Josè Leite Lopez and Jayme Tiomno

Individual Awards

YVONNE CHOQUET-BRUHAT AND JAMES W. YORK, JR.
for separate as well as joint work in establishing the mathematical framework for proving the existence and uniqueness of solutions to Einstein's gravitational field equations.

YUVAL NE'EMAN
for his contributions to science, epistimology, mathematics and physics from subnuclear to space sciences.

9th Marcel Grossmann Meeting
July 2000, Rome, Italy

Institutional Award

SOLVAY INSTITUTES
for identifying and recording in discussions by the protagonists the crucial developments of physics and astrophysics in the twentieth century.

- presented to Jacques Solvay

Individual Awards

CECILLE AND BRYCE DEWITT
for promoting General Relativity and Mathematics research and inventing the "summer school" concept.

RICCARDO GIACCONI
for opening, five successive times, new highways for exploring the Universe.

ROGER PENROSE
for extending the mathematical and geometrical foundations of General Relativity.

8th Marcel Grossmann Meeting
June 1997, Jerusalem

Institutional Award

HEBREW UNIVERSITY
for its role as a cradle of Science and Humanities and for hosting the manuscripts of Albert Einstein.

- presented to M. Magidor, President of the Hebrew University of Jerusalem

Individual Awards

TULLIO REGGE
for his contributions to the interface between mathematics and physics leading to new fields of research of paramount importance in relativistic astrophysics and particle physics.

FRANCIS EVERITT
for leading the development of extremely precise space experiments utilizing superconducting technology to test General Relativity and the Equivalence Principle.

7th Marcel Grossmann Meeting
June 1994, Stanford, USA

Institutional Award

SPACE TELESCOPE SCIENCE INSTITUTE
for its critical role in the direction and operation of the Hubble Space Telescope, a truly unique international laboratory for the investigation and testing of general relativity in the context of modern astrophysics and cosmology.

- presented to Peter Stockman

Individual Awards

SUBRAHMANYAN CHANDRASEKHAR
for his contributions to the analysis of gravitational phenomena from Newton to Einstein and especially for leading the way to relativistic astrophysics with the concept of critical mass for gravitational collapse.

JIM WILSON
for having built on his experience in nuclear physics, thermonuclear reactions, and extensive numerical simulation to create a new testing ground for the novel concepts of relativistic astrophysics.

6th Marcel Grossmann Meeting
June 1991, Kyoto, Japan

Institutional Award

RITP
for keeping alive first in Hiroshima and them in Kyoto research in relativity, cosmology, and relativistic field theory and the development of a school of international acclaim.

- presented to Professor K. Tomita

Individual Awards

MINORU ODA
for participating in the pioneering work of the early sixties in X-ray astronomy and for his subsequent molding of an agile and diversified Japanese scientific space program investigating the deepest aspects of relativistic astrophysics.

STEPHEN HAWKING
for his contributions to the understanding of spacetime singularities and of the large scale structure of the Universe and of its quantum origins.

5th Marcel Grossmann Meeting
August 1988, Perth, Australia

Institutional Award

THE UNIVERSITY OF WESTERN AUSTRALIA
for its contributions to relativistic astrophysics.

- presented to the Vice Chancellor, Professor Robert Smith

Individual Awards

SATIO HAYAKAWA
for his contributions to research in gamma, X-ray and infrared radiation as well as cosmic rays.

JOHN ARCHIBALD WHEELER
for his contributions to geometrodynamics and Einstein's visions.

4th Marcel Grossmann Meeting
July 1985, Rome, Italy

Institutional Award

THE VATICAN OBSERVATORY
for its contributions to the origin and development of astrophysics.

- presented to His Holiness Pope John Paul II

Individual Awards

WILLIAM FAIRBANK
for his work in gravitation and low temperature physics.

ABDUS SALAM
for his work in unifying fundamental interactions.

Institutional Awards for the Spektrum-Roentgen-Gamma (SRG) mission

"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance".

S.A. LAVOCHKIN ASSOCIATION
- presented to its Designer General **Alexander Shirshakov**

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
- presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
- presented to Professor **Rashid Sunyaev,** Principal Investigator of SRG Observatory in Russia

S.A. LAVOCHKIN ASSOCIATION
presented to its Designer General **Alexander Shirshakov**

Dr Alexander Shirshakov

S.A. Lavochkin Association created the Navigator space platform carrying German eRosita and Russian ART-XC X-Ray Telescopes, organized the launch of SRG Orbital X-Ray Observatory to the second Lagrangian point of the Sun-Earth system at a distance of 1.5 million km from the Earth and managed the observatory flight and the daily reception of its scientific data on Earth for 23.5 months.

Dr Alexander Shirshakov, Designer General of the S.A. Lavochkin Association, is specialized in design, manufacture, testing, launch and control of S/C for scientific purposes. Among those S/C launched, there are the «Radiostron» Astrophysical Observatory (2011) and the «Spektr-RG» space observatory (2019), while the planned S/C launches are «Luna-25» and «Exomars».

Dr Shirshakov started his career in 1973, working as an engineer of the State Unitary Enterprise «NPO named by S.A. Lavochkin» in Khimki (Russian Federation). Starting from 1989 he has played multiple roles within the Lavochkin Association, been appointed head of the group, head of the sector, head of department, deputy head of the complex, head of the branch, director of the center, deputy head of the Design Bureau, deputy General Designer and deputy General Director.

Dr Shirshakov is an editorial board Member of the reviewed edition of «Vestnik of Lavochkin Association». Since 2017, he is also member of the General Designer council. He has been awarded Honored Mechanical engineer of the Russian Federation as well as Agency-level award of the Russian Federal Space Agency.

MAX PLANCK INSTITUTE FOR EXTRATERRESTRIAL PHYSICS (MPE)
presented to Professor **Peter Predehl**, Principal Investigator of eROSITA

Professor Peter Predehl

eROSITA is the soft X-ray telescope on-board the Russian-German Spektr-RG mission which was successfully launched from Baikonur on July 13, 2019 and placed in a halo orbit around the L2 point. 30 years after ROSAT, eROSITA performs an all-sky survey with an unprecedented sensitivity, spectral and angular resolution. Clusters of galaxies are the largest collapsed objects in the Universe. Their formation and evolution is dominated by gravity, i.e. Dark Matter, while their large scale distribution and number density depends on the geometry of the Universe, i.e. Dark Energy. X-ray observations of clusters of galaxies provide information on the rate of expansion of the Universe, the fraction of mass in visible matter, and the amplitude of primordial fluctuations which are the origin of clusters of galaxies and the whole structure of the universe. eROSITA has been designed to detect at least 100.000 clusters of galaxies and to detect systematically more than 3 million obscured accreting Black Holes. eROSITA will also allow to study the physics of galactic X-ray source

populations, like pre-main sequence stars, supernova remnants and X-ray binaries. The eROSITA telescope consists of seven identical Wolter-1 mirror modules. A novel detector system has been developed by MPE on the basis of the successful XMM-Newton pn-CCD technology. MPE is the scientific lead institute of eROSITA, responsible for the development of the instrument, the operation, the analysis software and data archive. Peter Predehl led this development as Principal Investigator of eROSITA and German lead scientist of the SRG mission for more than 15 years until the completion of the first of eight surveys in 2020. At this time eROSITA has already discovered more than 1 million X-ray sources, more than all X-ray observatories of the last 50 years together. This demonstrates that the design goals of the mission will easily be fulfilled.

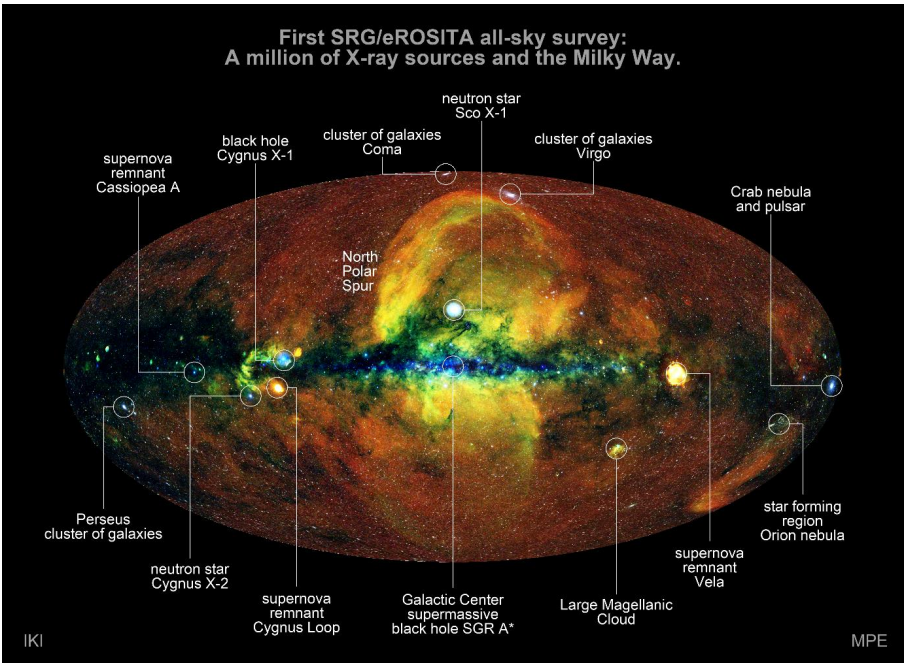
SPACE RESEARCH INSTITUTE (IKI) OF THE RUSSIAN ACADEMY OF SCIENCES
presented to Professor **Rashid Sunyaev**

Professor Rashid Sunyaev

Space Research Institute (IKI) of the Russian Academy of Sciences was responsible for developing the overall concept and scientific program of the SRG Orbital observatory and played a leading role in developing the ART-XC telescope and the entire SRG observatory as part of the Russian space science program carried out by Roskosmos Corporation in the interests of the Russian Academy of Sciences.

During the flight to the L2 point of the Sun-Earth system, SRG with German (eRosita) and Russian (ART-XC named after Mikhail Pavlinsky) X-ray Telescopes aboard performed calibrations and long duration Performance Verification observations of a dozen of targets and deep fields. Starting in the middle of December 2019, the SRG scanned the whole sky three times. During these scans, SRG discovered two million point X-ray sources: mainly quasars, stars with hot and bright coronae, and more than 30 thousand clusters of galaxies. There is a competition and synergy in the search for clusters of galaxies between SRG and the ground-based Atacama Cosmology and South Pole Telescopes, which are searching for clusters of galaxies in microwave spectral band using Sunyaev-Zeldovich effect. SRG provided the X-Ray map of the whole sky in hard and soft bands, the last is now the best among existing. The huge samples of the X-ray selected quasars at the redshifts up to z = 6.2 and clusters of galaxies will be used for well-known cosmological tests and detailed study of the growth of the large scale structure of the Universe during and after reionization. SRG/eRosita is discovering every day several extragalactic objects which increased or decreased their brightness more than 10 times during half of the year after the previous scan of the same one-degree wide strip on the sky. A significant part of these objects has observational properties similar to the Events of Tidal Disruption of a star orbiting in the vicinity of the supermassive black hole. ART-XC discovered a lot of bright galactic and extragalactic transients.

Rashid Sunyaev is the Principal Investigator of SRG mission in Russia, director-emeritus of the Max-Planck Institute for Astrophysics and Maureen and John Hendricks distinguished visiting professor of the Institute for Advanced Study, Princeton.



Individual Awards

Professor **DEMETRIOS CHRISTODOULOU**

"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."

Professor Demetrios Christodoulou

It was back in 1967 that Achille Papapetrou mentioned the case of the 16-year-old Demetrios Christodoulou to John Archibad Wheeler. Wheeler interviewed Demetrios in Paris and brought him immediately to Princeton where he was registered as an undergraduate at the university. After one year he entered the graduate school and started collaborating with me. At the time I was working with Wheeler on the effective potential approach to geodesics co-rotating and counter-rotating (see e.g. reference in The Classical Theory of Fields (Landau and Lifshitz, 1980) in the Kerr metric (later renamed as ISCO; see e.g. (Gravitation Misner, Thorne, Wheeler. 1973). In parallel, Frank Zerilli was working on the gravitational radiation emitted by the fall of a test particle in a Schwarzschild black hole (Zerilli 1970). From these limited conceptual arena Charles Misner and later Kip Thorne launched a program for the detection of gravitational waves on the Earth; see e.g. Misner 1974, Abbott et al. 2016, Abbott et al. 2017. See however Davis et al. 1972, Rodriguez et al. 2018 and J.A. Rueda et al. 2018.

A new approach started with the arrival of Demetrios: he was just creating mathematics following his needs. We identified the reversible and irreversible transformations of a Kerr black hole. Wheeler advanced a thermodynamic analogy. I addressed the need of identifying the concept of irreducible mass (from the Italian "irriducibile"), and was Demetrios's contribution to integrate, overnight, the differential equation for infinitesimal reversible transformations which led to the finite mass-energy formula of a Kerr black hole. That evening, while walking back home through IAS woods, I expressed to Wheeler the great relevance of the newly found formula by Demetrios and proposed to let Demetrios be the single author of this article, admiring his great mathematical talent. Wheeler agreed. The Editor of PRL objected since in that two pages article the Fig. 2 by Wheeler and myself was still unpublished. Actually that Fig. 2 followed a discussion I previously had with Penrose in Florence (Penrose 1961) which allowed us to present there, for the first time, a "Penrose Process". Some difficulties in achieving this process were obvious from the example in Fig. 2, which Roger later recognized himself (Penrose & Floyd 1971). The Editor finally agreed on our written request and the paper appeared on September 17, 1970 (Christodoulou, 1970). On January 1971 appeared my article with Johnny introducing the Black Hole (Ruffini & Wheeler, 1971), with the new physics we were developing in Princeton, including the concept of the "ergosphere". On march 1 1971 we submitted the mass formula of the Kerr Newmann metric, including the relation between the surface area of the horizon and the irreducible (Christodoulou & Ruffini, 1971). On March 11, 1971 the same results were independently confirmed by Steven Hawking, extending further the applicability of our equation (Hawking 1971).

The thesis was successfully discussed by a committee including Eugene Wigner (see Fig. 1), one of the closest collaborators of Albert Einstein and David Wilkinson (see Fig. 2), the head of the NASA WMAP mission, and Johnny and myself as supervisors. The new message was clear: Black Holes, far from being a sink of energy, were energy sources emitting "in principle" 50% of their mass energy, being extractable (Christodoulou & Ruffini, 1971).

Fig. 1 and Fig. 2: Demetrios during his thesis presentation with Eugene Wigner (Fig. 1) and David Wilkinson (Fig.2). Johnny and I were supervisors, ready to intervene in case of need, but no need of intervention was necessary! Wigner elaborated the aphorism of Niels Bohr "Interesting = wrong" in the most definite "very interesting if true = totally wrong".

Demetrios turned soon to the study of partial differential equations and mathematical physics, to which he dedicated for the rest of his career and results were published in four monographs: (Christodoulou and Klainerman 1994, Christodoulou 2007, Christodoulou 2009, Christodoulou 2019). In 1968, Johnny proposed to Demetrios the collapse of a "geon" composed of massless scalar field as a second topic for his thesis. It took almost forty years for him to solve this problem, extended by Demetrios to the focusing of gravitational waves leading to black hole formation (Christodoulou 2009).

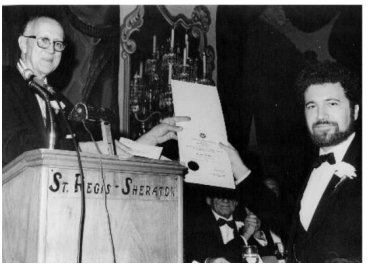


Fig. 3: Prof. Remo Ruffini receiving the Cressy Morrison Award of the New York Academy of Sciences, 1972 for the discovery of the first Black Hole in our galaxy Cygnus X1.

A "long march" started on 12 December 1970 with the launch of the Uhuru satellite by Riccardo Giacconi. Early in 1971 an almost daily conversation with him and Herb Gursky at the Smithsonian Astrophysical Observatory, leading to the discovery of binary X-ray sources. This was soon followedby the announcement of Cygnus X1 identified as the first black hole in our galaxy (Ruffini 1973); see e.g. Gursky & Ruffini 1975, which contained as well the first publicannouncement of the Discovery of Gamma Ray burst, as well as Giacconi & Ruffini 1980, 2009; see Figs. 3 and 4).

Fig. 4: In the second row, from left to right, there are, among others: E. T. Newman, S. Chandrasekhar (Nobel 1983), R. Giacconi (Nobel 2002), R. Ruffini, A. Treves, A. Hewish (Nobel 1974), D. Arnett, J.H. Taylor (Nobel 1993), J. Wilson, R. Penrose (Nobel 2020), as well as J. Bahcall, T. Damour, T. Piran et al.

Today, after fifty years, this "long march" has reached a definite result: through the grandest observational multi-wavelength effort in the history of mankind, from space, ground and underground observatories, we are finally finding evidence that black holes are "alive" and their "extractable energy" in our mass formula (Christodoulou & Ruffini, 1971), is the energy source of the most energetic cosmological sources: gamma ray bursts (GRBs),the active galactic nuclei (AGNs) as well as the ultra-high energy cosmic rays (UHECRs) (Ruffini et al. 2021 and references therein). Their "inner engine", has three independent components: 1) a Kerr black hole which is neither in a stationary state nor in vacuum, 2) a background magnetic field aligned with the black hole rotation axis, and 3) an extremely diluted fully ionized plasma (Moradi et al. 2021).There is no role in this inner engine for ISCO. Indeed a new electro dynamical field equations describe the synchrotron radiation emitted close to the black hole horizon, they point to a discrete and repetitive emission of "blackholic quanta" in the MeV and in the GeV. The magnitudes and the emission time scales of these quanta, for M87 and GRB 130427A, are expressed as a function of the above three parameters (Rueda & Ruffini, 2021). A long lasting GeV emission with a luminosity decreasing as a temporal power law, allows for the first time in GRBs, the determination of the black hole mass and spin as well as their time evolution perfectly fulfilling our mass energy formula (Christodoulou & Ruffini, 1971): a long lasting emission process profoundly different from the traditional process of continued gravitational contraction.

Remo Ruffini

Professor **GERARD 't HOOFT**

"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon".

Professor Gerard 't Hooft

Prof. Gerard 't Hooft has been a full Professor at the Utrecht University (the Netherlands), since 1977. Nowadays, he is an Emeritus Professor at that University. During his career, he has paid extended scientific visits to CERN (Geneva), Harvard, Stanford, Princeton and Duke University, NC. In 1999, together with M. Veltman, he received the Nobel Prize in Physics, awarded by The Royal Swedish Academy of Sciences, *"For elucidating the quantum structure of electroweak interactions in physics"*.

Prof. 't Hooft's main subjects of research includes:

– Gauge Theories for the sub-atomic particles and forces, various aspects and ingredients of what is now called "The Standard Model of the sub-atomic particles: renormalizability, topological features such as magnetic monopoles and instantons, 1/N expansions.

– Theories for the quantization of the gravitational force and black holes: producing models for the quantum properties of a black hole, as derived from Standard Model and General Relativity alone; its topological features such as antipodal identification.

– Fundamental theories underlying quantum mechanics, in particular returning determinism and reality to the dynamics of the tiniest material entities in his universe.

Prof. 't Hooft has been awarded the Wolf Prize of the State of Israel (1982), the Pius XI Medal (Vatican City, 1983), the Lorentz Medal (KNAW Amsterdam, 1986) as well as the Spinoza Premium (Netherlands Organization for Scientific Research NWO, 1995).

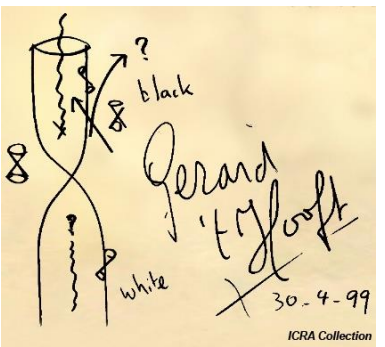

Fig. 2: The signature of Gerard 't Hooft on the wall of ICRA Room 301 (April 4, 1999).

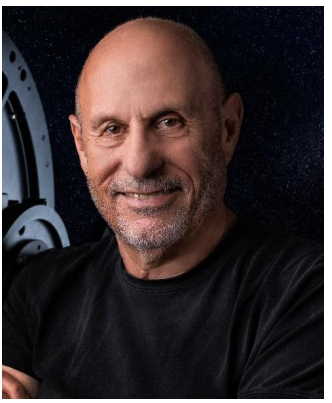
A special event took place at ICRA on April 30, 1999. Prof. Ruffini invited Gerard 't Hooft to Rome to discuss a boundary condition for a quantum field on the black hole horizon, a topic Prof. Ruffini discussed in a previous article "Black-hole evaporation in the Klein-Sauter-Heisenberg-Euler formalism" with Thibault Damour (Phys. Rev. D 14, 332, 1976), but which needed to be examined in more detail. Prof. Ruffini planned to direct Gerard's attention to some specific aspects of this problem. Because we have traditionally been very attentive in spending ICRA travel funds, ICRA offered Gerard to come to Rome on a reduced fare weekend ticket arriving Friday and departing Monday. He had a great relaxing weekend together with Prof. Ruffini following his seminar, which among other things allowed Gerard to sign the wall in our ICRA Room (see Fig. 2), and during this splendid Rome spring weekend he also was able to find a missing factor of 2 in a formula in Prof. Ruffini's 1971 paper with Demetri Christodoulou on the black hole mass formula. The following October, Gerard received the Nobel prize, which meant that we could no longer get away with bringing him to Rome on a cheap ticket! Ever since Gerard has been in our MG IOC helping us with the preparation of the meetings. We are very happy to announce this MG16 Award to Gerard 't Hooft with the motivating phrase *"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon"*.

Remo Ruffini

Professor **TSVI PIRAN**

"for extending relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory".



Professor Tsvi Piran

Tsvi Piran is the emeritus Schwartzmann professor at the Hebrew University of Jerusalem. He obtained his PhD in Physics, in 1976 from the Hebrew University working on the collisional Penrose process. Piran returned to the Hebrew University at 1981after being a post doc at Oxford and Texas and a long-term member at the IAS at Princeton. In 1982 he initiated and directed the first ever summer school on Gravitational Waves that took place at Les Houches. Piran was a visiting professor at Harvard, Columbia and New York and a Moore scholar at Caltech.

Piran's research deals with numerous aspects of relativistic astrophysics, ranging from the foundation of numerical relativity to modeling of observer relativistic phenomena and analytic work on the fate of gravitational collapse. Piran's research work focuses mostly on black holes and in particular on gamma-ray bursts. He was among the first to point out their cosmological origin and their association with merging neutron stars and heavy r-process nucleo synthesis. Piran's achievements were recognized in the 2019 EMET prize for Physics.

Professor **STEVEN WEINBERG**

"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory".

Professor Steven Weinberg. Photo courtesy of Matt Valentine.

Steven Weinberg is a member of the Physics and Astronomy Departments at The University of Texas at Austin. His research has covered a broad range of topics in quantum field theory, elementary particle physics and cosmology. He has been honored with numerous awards, including the Nobel Prize in Physics, the National Medal of Science, the Heinemann Prize in Mathematical Physics and in 2020, the Breakthrough Prize. He is a member of the US National Academy of Sciences, Britain's Royal Society, and other academies in the USA and abroad. The American Philosophical Society awarded him the Benjamin Franklin Medal, with a citation that said he is "considered by many to be the preeminent theoretical physicist alive in the world today." His books for physicists include *Gravitation and Cosmology*, the three-volume work *The Quantum Theory of Fields*, *Cosmology* and published in April of 2021, *Foundations of Modern Physics*. Educated at Cornell, Copenhagen, and Princeton, he also holds honorary degrees from sixteen other universities. He taught at Columbia, Berkeley, M.I.T., and Harvard, where he was Higgins Professor of Physics, before coming to Texas in 1982.

Fig. 1: Chuo Pei Yuan and Cheng Ning Yang at MG2 in Trieste, Italy (1979).

The Sixteenth Marcel Grossmann Meeting (MG16) is a very special one in many respects: it will take place during a pandemic and in spite of the many difficulties, we have decided not to postpone it but to organize it as a virtual meeting. As described on the MG series webpage, these meetings started in 1975 with the first meeting at the International Centre for Theoretical Physics (ICTP) in Trieste (Italy) that I organized with Nobel Prize winner Abdus Salam. A second meeting followed in 1979, with a significantly larger participation including Nobel Laurate Cheng Ning Yang and a Chinese delegation led by Chuo Pei Yuan (see Fig. 1), including Fang Li-Zhi who had accompanied me during my entire first visit to China in 1979. The first truly international MG meeting followed in 1982 in Shanghai (China):this represented an especially important step forward both for the meeting and for China. A multi-millennia *"motto"* in China, which was then proclaimed on banners everywhere, read *"Friends from all over the world are welcomed"*.

We were soon at an impasse over the participation of scientists from Israel, since no diplomatic relations existed between China and Israel at that time and the Israeli scientists were not to be allowed to attend the meeting. A long negotiation began. The boundary conditions were clearly set by Steven Weinberg, a member of the present MG16 IOC: no MG meetings on Einstein's theory of general relativity could occur without the participation of Israeli scientists. The intervention of Yuval Ne'emann, also a member of the MG IOC then as well as the Minister of Science of Israel (see Fig.2), proposed a compromise that would admit at least one Israeli scientist. I went to Beijing alone, meeting every morning for a week with 12 Chinese representatives led by Chuo Pei Yuan going over all possible options. I stayed in an isolated villa not far from Tiananmen Square, accompanied by the 3 volumes of Matteo Ricci (RI MA TO) to keep me company. No solution was in sight the entire week. At the last moment, just before my departure, an agreement was finally reached allowing two Israeli scientists into China. The historic compromise would admit Gerard Tauber and Tsvi Piran into China using a special ICRA travel document I had proposed for them to be able to participate in the meeting, accepted by the Chinese Ambassador in Rome. This modified the thousand-year Chinese *"motto"* to read *"Scientists from all over the world are welcomed"*. The event was extremely beneficial for China and signaled the truly international nature of the MG meetings.

Fig. 2: From right to left: Chaim Weizmann, President of Israel; Yuval Ne'emann, Minister of Science of Israel; R. Ruffini.

I kept on meeting Tauber in the years which followed (see Fig. 3). Soon after, Yuval Ne'emann visited China. The development of bilateral relations, including military cooperation and economical tights, grow exponentially until the establishment of normal diplomatic relations between Israel and China in 1992.

Fig. 3: From right to left: Arrigo Finzi, Remo Ruffini, Gerard Tauber and Konrad Bleuler.

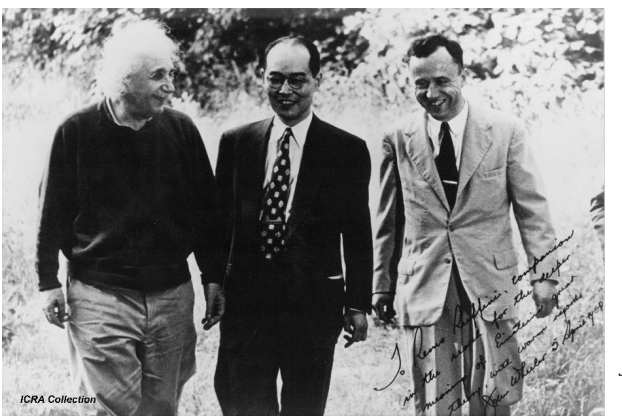


Fig. 4: Albert Einstein, Hideki Yukawa and John. A. Wheeler with a hand-written dedication to Remo Ruffini "To Remo Ruffini, companion in the search for the deeper meaning of Einstein great theory. With warm regards, John Wheeler 5 April 1968".

Given their key role played in the foundations of the MG meetings, I am very happy to propose on behalf of the MG16 IOC, two special Marcel Grossmann Individual Awards: one to Steven Weinberg for *"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory"* and another one to Tsvi Piran, *"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory"*, in the words of John A. Wheeler's photo dedication to me (see Fig. 4).

Remo Ruffini

PREFACE

Since 1975, the Marcel Grossmann Meetings on Recent Developments in Theoretical and Experimental General Relativity, Gravitation, and Relativistic Field Theories have been organized in order to provide opportunities for discussing recent advances in gravitation, general relativity and relativistic field theories, emphasizing mathematical foundations, physical predictions and experimental tests. The objective of these meetings is to elicit exchange among scientists that may deepen our understanding of spacetime structures as well as to review the status of ongoing experiments aimed at testing Einstein's theory of gravitation either from the ground or from space. Previous meetings have been held in Trieste (MG1: 1975) and (MG2: 1979), Shanghai (MG3: 1982), Rome (MG4: 1985, MG9: 2000), Perth (MG5: 1988), Kyoto (MG6: 1991), Stanford (MG7: 1994), Jerusalem (MG8: 1997), Rio (MG10: 2003), Berlin (MG11: 2006), Paris (MG12: 2009), Stockholm (MG13: 2012), MG14 in 2015 and MG15 in 2018 both in Rome.

Due to the COVID-19 pandemic spreading in the last two years the decision was taken to organize the Sixteenth Marcel Grossmann meeting for the first time in history entirely online. Despite numerous challenges, related to the organization of large worldwide event, MG16 showed the strongest ever interest from the scientific community with a record-breaking number of almost 1200 registered participants and of more than 1000 speakers.

The traditional six-day schedule has been modified to account for different time zones of the speakers and each day the program of the meeting was divided in three blocks with the reference to the Central European Summer Time. The first block was starting at 06:30 in the morning, allowing comfortable time for speakers from Asia and Oceania. The second block was held in the daytime in Europe and Africa. The third block was starting in the afternoon and ending at 19:30 allowing accommodation of the speakers from the Americas. Each day the blocks of plenary sessions were interchanging with the blocks of about 30 parallel sessions each, making this one of the most intense MG meetings ever. All this was possible thanks to recent developments in communication technologies. The Indico open-source software was selected as a web platform for this meeting, while Zoom platform was adopted for the video-conferencing. The meeting was streamed on ICRANet YouTube channel.

The meeting started on Monday July 5 with the Award ceremony. The individual awards went to Demetrios Christodoulou, Tsvi Piran, Gerard 't Hooft and Steven Weinberg, while the Institutional Awards went to the S.A. Lavochkin Association, to the Max Planck Institute for Extraterrestrial Physics – MPE and to the Space Research Institute IKI of the Russian Academy of Sciences. Overall there were 54 plenary talks, 4 public lectures and 5 roundtables and about 90 parallel sessions. The plenary session "Events in Relativistics Astrophysics" on Monday have seen the contributions from Rashid Sunyaev, Michael Kramer, James Miller-Jones, Felix Mirabel. The public lectures were delivered by Razmik Mirzoyan, Asghar Qadir

and Mohammad Bagheri. Plenary talks on Tuesday session "Black holes and the Quantum" by Juan Maldacena, Ahmed Almheiri, Gerard 't Hooft, Mihalis Dafermos, Sergiu Klainerman, Abhay Ashtekar and Frank Wilczek were bracketed by two roundtables on "New results from SRG/eRosita" with the participation of Andrea Merloni, Prof. Rashid Sunyaev, Alexander Lutovinov, Chandreyee Maitra, Esra Bulbul and "Solar neutrinos and Borexino" with the participation of Gianpaolo Bellini and Wick Haxton. Plenary talks on Wednesday in the session "Lambda CDM tensions" by George Efstathiou, Scolnic Daniel, Marc Kamionkowski, Wendy Freedman, Priya Natarajan and Licia Verde were followed by the roundtable "Precision cosmology" with the participation of Licia Verde, Marc Kamionkowski, Piero Rosati, and the public lecture by Francis Halzen. Two blocks of Thursday plenary sessions "Black holes in GRBs" and "Precision tests" included the talks by Roy Kerr, Yuan Ha, Lorenzo Amati, Elena Pian, Carlos Raúl Argüelles, Di Li, Jianglai Liu, Claus Lämmerzahl, Gerhard Heinzel and Ignazio Ciufolini and were followed by the roundtable "GRB 170817A and GRB 190829A" with the participation of Eleonora Troja, Liang Li, Rahim Moradi, Jorge Armando Rueda Hernandez. Two plenary blocks on Friday "Massive stars" and "Physics behind stellar collapse" included the talks by Selma de Mink, Norbert Langer, Jiri Bicak and Tomáš Ledvinka, Ivan De Mitri, Rahim Moradi and Giancarlo Cella. Finally, two plenary blocks on Saturday "Current and future missions" have seen the talks by Shuang-Nan Zhang, Weimin Yuan, Makoto Tashiro, Ruoyu Liu, Jean-Luc Atteia, Jim Hinton and Nicholas White and were followed by the roundtable "What is in our Galactic center" with the participation of Reinhard Genzel, Carlos Raúl Argüelles, Andreas Krut, Jorge Armando Rueda Hernandez, Eduar Becerra Vergara. The program of the meeting can be found at the official website http://www.icra.it/mg/mg16 and at ICRANet Indico website https://indico.icranet.org/event/1/.

These proceedings include about 400 papers containing the results presented at the Sixteenth Marcel Grossmann meeting. The plenary papers from the meeting have been published in International Journal of Modern Physics D as they were submitted. The table of contents includes also the links to YouTube videos with talks given at the meeting and cover plenary talks, public lectures, roundtables and all parallel sessions. The general link to the videos from MG16 is: https://www.youtube.com/watch?v=QFe1lsSid-o&list=PLr5RLbSWSonsaOnZukBDs0qsNIWM8AvRF.

As the editors we would like to express our gratitude to all the chairpersons of the parallel sessions at MG16, who peer-reviewed the papers submitted for these proceedings, as well as to the ICRANet secretariat office and in particular to Cinzia di Niccolo, Elisabetta Natale and Yasmina Di Domizio, as well as to ICRANet system manager Gabriele Brandolini for their help in preparation of this publication.

Preface xxxvi

PART A
PLENARY SESSIONS

New results from testing relativistic gravity with radio pulsars
Michael Kramer 3

Dragging of inertial frames by matter and waves
Jiří Bičák and Tomáš Ledvinka 22

Probes of the progenitors, engines and physics behind stellar collapse
Chris L. Fryer 39

The observation of high-energy neutrinos from the cosmos: Lessons learned for multimessenger astronomy
Francis Halzen 59

The first results of PandaX-4T
Jianglai Liu on behalf of the PandaX Collaboration 85

XRISM: X-ray imaging and spectroscopy mission
Makoto S. Tashiro and the XRISM team 95

The SVOM mission
J.-L. Atteia, B. Cordier and J. Wei on behalf of the SVOM Collaboration 104

Quantum field theory with boundary conditions at the horizons
Gerard 't Hooft 133

The development of general relativity and the cosmological constant
Asghar Qadir 143

The irreducible mass of Christodoulou-Ruffini-Hawking mass formula
Yuan K. Ha 154

Reshaping our understanding on structure formation with the quantum nature of the dark matter
C. R. Argüelles, E. A. Becerra-Vergara, A. Krut et al. 164

First results of LHAASO
Ruo-Yu Liu for the LHAASO Collaboration 180

On the MG16 awards 2021
Remo Ruffini 196

The white dwarf binary merger model of GRB 170817A
J. A. Rueda, R. Ruffini, Liang Li et al. 217

PARALLEL SESSIONS

Accretion

• MHD Processes Near Compact Objects
Chairperson: Sergey Moiseenko
YouTube link: https://youtu.be/2WMTg06ZmV8

A semi-implicit multidimensional unstructured gas dynamical solver for astrophysical applications
Ilya A. Kondratyev and Sergey G. Moiseenko 242

Magnetized neutron stars propagating through a non-uniform ISM
O. D. Toropina, M. M. Romanova and R. V. E. Lovelace 255

Calculation of the kinetic coefficients of arbitrary degenerate electrons in magnetized dense matter
M. V. Glushikhina and G. S. Bisnovatyi-Kogan 264

Modeling of magnetic fields of accretion discs, using no-z- and RZ-approximations
M. V. Pashentseva and E. A. Mikhailov 272

• Accretion Discs and Jets
Chairpersons: Audrey Trova and Shokoufe Faraji
YouTube link: https://youtu.be/29Wj9RCVEKw

Limiting effects in tori clusters
D. Pugliese and Z. Stuchlik 280

Hydrodynamical transport of angular momentum in accretion disks in the presence of nonlinear perturbations due to noise
Subham Ghosh and Banibrata Mukhopadhyay 295

Properties of accretion disc models in the background quadrupole
Shokoufe Faraji 307

Magnetized tori around a uniformly accelerating black hole
Shokoufe Faraji and Audrey Trova 317

Multifrequency behaviour of high mass X-ray binaries (Time lag between optical and X-ray outbursts)
Franco Giovannelli 321

Active Galactic Nuclei

• The Black Hole in M87
Chairpersons: Brian Punsly and Jorge Rueda
YouTube link: https://youtu.be/l1lTgksyJag

Rotation of the crescent image of M87* and polarization of its ESE hotspot
Krzysztof Nalewajko 339

Magnetic reconnection in jet-accretion disk systems
Chandra B. Singh, Elisabete M. de Gouveia Dal Pino, Luis H. S. Kadowaki et al. 344

• Machine Learning in Astronomy: AGN, Transient Events, Cosmology and Others
Chairpersons: Rahim Moradi and Yu Wang
YouTube link: https://youtu.be/ErqrmMZQsBk

Exact fractal model of the universe and possible machine learning methods for the verification of the fractality
A. A. Kirillov, E. P. Savelova and P. O. Vladykina 352

Estimating the photometric redshifts of galaxies and QSOs using regression techniques in machine learning
A. Momtaz, M. H. Salimi and S. Shakeri 368

Deep learning in quasar physics
F. Rastegar Nia, M. T. Mirtorabi, R. Moradi, Y. Wang and A. Vafaei Sadr 382

Cosmological density field emulation and gravitational wave inference based on dimensionality reduction and supervised machine learning
Miguel Conceição, António da Silva and Alberto Krone-Martins 391

Unsupervised photometric detection of galaxy cluster candidates in large surveys
Ana Carvalho, Alberto Krone-Martins and Antonio da Silva 409

• Multiwavelength and Multi-Messenger Observations of Active Galactic Nuclei
Chairpersons: Paolo Giommi and Narek Sahakyan

YouTube link: https://youtu.be/-Hyu2NQsExg

Time-dependent lepto-hadronic modeling of the emission processes in blazar jets
S. Gasparyan, D. Bégué and N. Sahakyan 429

G. Harutyunyan and D. Israyelyan 445

Alternative Theories

• Extended Theories of Gravity and Quantum Cosmology
Chairpersons: Yi-Fu Cai and Wentao Luo

YouTube links: https://youtu.be/ADRr9DfV5zM
https://youtu.be/eOzpiC1cFkU
https://youtu.be/kYzJds_JIp8

Quantum gravity phenomenology from thermodynamics of spacetime
A. Alonso-Serrano and M. Liška 462

Gauge theory of gravity based on the correspondence between the 1^{st} and the 2^{nd} order formalisms
David Benisty 479

$U(1)$ local strings in hybrid metric-Palatini gravity
Tiberiu Harko, Francisco S. N. Lobo and Hilberto M. R. da Silva 485

Inflationary supersymmetric FRLW quantum cosmology
N. E. Martínez-Pérez, C. Ramirez and V. M. Vázquez-Báez 499

Effective $f(R)$ actions for modified loop quantum cosmologies
Ana Rita Ribeiro, Daniele Vernieri and Francisco S. N. Lobo 517

Probing multiverse using gravitational wave observations
Moe Kukihara and Kazuhiro Hayama 531

Operator ordering ambiguity in observables of quantum cosmology
Harkirat Singh Sahota and Kinjalk Lochan 538

Decoupled quark stars in self-interacting Brans-Dicke gravity
M. Sharif and Amal Majid 548

Big-bounce in projectively invariant Nieh-Yan models: The Bianchi I case
Flavio Bombacigno, Simon Boudet, Gonzalo J. Olmo and Giovanni Montani 561

Late time cosmology with derivatives of matter Lagrangian
Shahab Shahidi 576

On the semiclassical and quantum picture of the Bianchi I polymer dynamics
E. Giovannetti, G. Montani and S. Schiattarella 588

Quantum corrections to the Bianchi II transition under local rotational invariance
Sara F. Uria, David Brizuela and Ana Alonso-Serrano 597

• **Mathematical Problems of Relativistic Physics: Classical and Quantum**
Chairpersons: A. Shadi Tahvildar-Zadeh and Michael Kiessling

YouTube links: https://youtu.be/9Dr3M9Kb2jo
https://youtu.be/gMOykpapJ5A

The hypercomplex medium as storage of physical equations
Alexander P. Yefremov 605

The Maxwell-Bopp-Landé-Thomas-Podolsky-Einstein system for a static point source
Érik Amorim 619

On recent developments in the theory of relativistic dissipative fluids
V. Hoang 627

Adiabatic solutions in general relativity as null geodesics on the space of boundary diffeomorphisms
Emine Şeyma Kutluk 635

The point spectrum of the Dirac Hamiltonian on the zero-gravity Kerr-Newman spacetime
M. Kiessling, E. Ling and A. S. Tahvildar-Zadeh 648

Causal fermion systems: Classical gravity and beyond
Felix Finster 661

Newman-Penrose-Debye formalism for fields of various spins in pp-wave backgrounds
Aleksandr Kulitskii and Elena Yu Melkumova 679

Gravitational geometric phase
Banibrata Mukhopadhyay, Tanuman Ghosh and Soumya Kanti Ganguly 689

Retarded potentials and radiation in odd dimensions
D. V. Gal'tsov and M. Khlopunov 699

Wave propagation in the anti-deSitter optical metric
D. García-Peláez and C. S. López-Monsalvo 713

New approaches to constrained dynamics and Hamilton-Jacobi procedures in general relativity
D. Salisbury, J. Renn and K. Sundermeyer 719

Orientability of space from electromagnetic quantum fluctuations
N. A. Lemos and M. J. Rebouças 725

Essential self-adjointness of Dirac operators under the influence of general-relativistic gravity
Michael K.-H. Kiessling, A. Shadi Tahvildar-Zadeh and Ebru Toprak 736

• **Wormholes, Energy Conditions and Time Machines**
Chairpersons: Francisco Lobo and Diego Rubiera-Garcia

YouTube links: https://youtu.be/tu_3Wqcd9Ys
https://youtu.be/NqN1c-2fv8Y

Relic magnetic wormholes as possible source of toroidal magnetic fields in galaxies
A. A. Kirillov and E. P. Savelova 743

Wormhole geometries induced by action-dependent Lagrangian theories
Ismael Ayuso, Francisco S. N. Lobo and José P. Mimoso 756

Gravitational lensing by wormholes in binary systems
S. Pietroni 774

Hyper-fast positive energy warp drives
E. W. Lentz 779

From black-bounce to traversable wormhole, and beyond
Alex Simpson 787

Tractor beams, pressor beams, and stressor beams within the context of general relativity
Matt Visser, Jessica Santiago and Sebastian Schuster 808

A singularity theorem for evaporating black holes
E.-A. Kontou, B. Freivogel and D. Krommydas 822

Circularly symmetric thin-shell wormholes in F(R) gravity with (2+1)-dimensions
Cecilia Bejarano, Ernesto F. Eiroa and Griselda Figueroa-Aguirre 831

Warp drive dynamic solutions considering different fluid sources
Osvaldo L. Santos-Pereira, Everton M. C. Abreu and Marcelo B. Ribeiro 840

Symmetries and geometry of spacetime: Towards a new paradigm
Francisco Cabral, Francisco S. N. Lobo and Diego Rubiera-Garcia 856

• Theories of gravity: Alternatives to the cosmological and particle standard models
Chairpersons: Stefano Bellucci and Orlando Luongo

YouTube links: https://youtu.be/-aQcrYoQfBM

Thermodynamics of scalar-tensor gravity: A new approach
Valerio Faraoni 876

Two body dynamics in a quadratic modification of general relativity
Soham Bhattacharyya 883

Alternatives to Λ: Torsion, generalized couplings, and scale invariance
C. J. A. P. Martins, C. M. J. Marques, C. B. D. Fernandes et al. 907

Model-independent test of scalar-tensor gravity theory by reconstructing scalar mode of GW170817
Yuya Gushima and Kazuhiro Hayama 921

Cosmology in the novel scalar-tensor representation of $f(R,T)$ gravity
Tiago B. Gonçalves, João Luís Rosa and Francisco S. N. Lobo 932

On the interaction between electromagnetic, gravitational, and plasma related perturbations on LRS class II spacetimes
P. Semrén 943

Condition for expansion-collapse duality between Einstein and Jordan frames
Dipayan Mukherjee, H. K. Jassal and Kinjalk Lochan 958

The model of dark energy based on the quantum-mechanical uncertainty relation
Yu. V. Dumin 967

• Conformal Dilaton Gravity and Related Issues
Chairperson: Reinoud Jan Slagter

YouTube link: https://youtu.be/A3Ygi3YBs5A

Conformal dilaton gravity, antipodal mapping and black hole physics on a warped spacetime
R. J. Slagter 978

From neutrino masses to the full size of the universe — Some intriguing aspects of the tetron model
B. Lampe 999

Summary parallel session AT5
Reinoud Jan Slagter 1014

• Horava-Lifshitz Gravity
Chairperson: Anzhong Wang

YouTube links: https://youtu.be/vPT1dH1zITE
https://youtu.be/5z7zhpiDOpw

Boundary conditions for the Klein-Gordon field on Lifshitz spacetimes
Lissa de Souza Campos 1017

Dynamical system analysis of Bianchi-I spacetimes in $f(R)$ gravity
Saikat Chakraborty, Kazuharu Bamba and Alberto Saa 1026

Cosmological implications in modified Hořava-Lifshitz gravity
Abdul Jawad, Kazuharu Bamba and Farwa Khurshid 1038

Finite action principle and wormholes
Jan Chojnacki and Jan Kwapisz 1046

Strange quark stars in Hořava gravity
Grigoris Panotopoulos 1054

Shadows of Kerr-like black holes in $4D$ Einstein–Gauss–Bonnet gravity and constraints from EHT observations
Sushant G. Ghosh and Rahul Kumar Walia 1069

Wormhole interaction in 2d Horăva-Lifshitz quantum gravity
Jan Ambjørn, Yuki Hiraga, Yoshiyasu Ito and Yuki Sato 1084

Nature of singularities in vector-tensor theories of gravity
V. H. Satheeshkumar 1095

Hořava-Lifshitz and Einstein-Æther gravity in the light of Event Horizon Telescope observations of M87*
Emmanuel N. Saridakis 1104

Hořava-Lifshitz gravity in $(3 + 1)$ dimensions coupled with anisotropic matter and possible constraints from GRB 170817A
Tao Zhang and Fu-Wen Shu 1112

Summary of the parallel session AT6
Anzhong Wang 1119

• Ghost-Free Models of Modified Gravity: Massive Gravity, Horndeski and DHOST Theories, Other Related Models; Their Properties and Solutions
Chairpersons: Dmitry Gal'tsov and Michael Volkov

YouTube links: https://youtu.be/l8KHUPnT2D8
https://youtu.be/48OHIKpgNqs

Non-local R^2-like inflation, gravitational waves and Non-Gaussianities
K. Sravan Kumar 1124

Palatini kinetic scalar-tensor theory: Analytical and numerical solutions
D. V. Gal'tsov and D. S. Bushuev 1136

PART B

Black Holes: Theory and Observations/Experiments

• Theoretical and Observational Studies of Astrophysical Black Holes
Chairperson: Alexander Zakharov

YouTube links: https://youtu.be/fiv_MH-N2kw
https://youtu.be/GYoOb17GvE8

Reconstruction of a star motion in the vicinity of black hole from the redshift of the electromagnetic spectrum
S. O. Komarov and A. K. Gorbatsievich 1151

Shadows of hairy Kerr black holes and constraints from M87*
Sushant G. Ghosh and Misba Afrin 1167

Displacement memory and BMS symmetries
Shailesh Kumar 1179

Physical black holes in semiclassical gravity
Sebastian Murk and Daniel R. Terno 1196

• Black Hole Thermodynamics
Chairperson: Hernando Quevedo

YouTube links: https://youtu.be/XmZDf5mrXQk
https://youtu.be/amseL2qykfk

Information recovery from evaporating rotating charged black holes
Zhi-Wei Wang, Samuel L. Braunstein and Saurya Das 1212

Black hole thermodynamics from entanglement mechanics
S. Mahesh Chandran and S. Shankaranarayanan 1223

Thermodynamics of charged black hole
M. Sharif and Amjad Khan 1238

Rindler trajectories and Rindler horizons in the Schwarzschild spacetime
Kajol Paithankar and Sanved Kolekar 1250

Linear growth of the two-point function for the Unruh state in $1+1$ dimensional black holes
Paul R. Anderson, Zachary P. Scofield and Jennie Traschen 1255

Stress-energy tensor for a quantized scalar field in a four-dimensional black hole that forms from the collapse of a null shell
Shohreh Gholizadeh Siahmazg, Paul R. Anderson, Raymond D. Clark and Alessandro Fabbri 1265

Microscopic model building for black hole membranes from constraints of symmetry
Swastik Bhattacharya and S. Shankaranarayanan 1275

Einstein-Maxwell-Dilaton-Axion mass formulas for black holes with struts and strings
Dmitri Gal'tsov, Gérard Clément and Igor Bogush 1291

• Black Holes in Alternative Theories of Gravity
Chairpersons: Jutta Kunz and Kamal Hajian

YouTube links: https://youtu.be/FRNGJKhiw7c
https://youtu.be/Tjfmuut1Eo0

Holography for rotating black holes in $f(T)$ gravity
Masoud Ghezelbash 1308

Infinitely degenerate exact Ricci-flat solutions in $f(R)$ gravity
Semin Xavier, Jose Mathew and S. Shankaranarayanan 1319

Universe in a black hole with spin and torsion
Nikodem Popławski 1327

Asymptotically flat black hole solution in modified gravity
Surajit Kalita and Banibrata Mukhopadhyay 1337

Shadow of a charged black hole surrounded by an anisotropic matter field
Javier Badía and Ernesto F. Eiroa 1343

Constraining modified gravity theories with physical black holes
Sebastian Murk 1351

Penrose suggestion as to pre-Planck-era black holes showing up in present universe data sets discussed, with a possible candidate as to GW radiation which may provide initial CMBR data
A. W. Beckwith 1359

Summary of the parallel session BH3
Kamal Hajian and Jutta Kunz 1372

Binaries

• **Explosive Events Associated with Compact-Object Binary Mergers**
Chairpersons: Chris Belczynski and Jorge Rueda

YouTube links: https://youtu.be/Dwq1ZU3gKrg
https://youtu.be/nw02ylI6R2M

Uncertainties in kilonova modeling
C. L. Fryer, C. J. Fontes, O. Korobkin et al. 1391

• **Post-Newtonian and Post-Minkowskian Corrections for Binary Gravitating Systems**
Chairperson: Johannes Bluemlein

YouTube link: https://youtu.be/wfiLG5r08yE

Tutti-Frutti method: Recent developments in the PN/PM/SF treatment of the gravitational two-body problem
Donato Bini and Andrea Geralico 1405

• **Multichannel Studies of Nonstationary Relativistic Stars**
Chairperson: Vladimir Lipunov

YouTube link: https://youtu.be/usn2PlU_qFA

GRB observations on cubesate satellites in the Universat–SOCRAT project
Sergey I. Svertilov, Michail I. Panasyuk, Vitaly V. Bogomolov et al. 1412

Multiwavelength observations of GRB160625B by MASTER, Lomonosov, Konus-Wind and three stage collapse
V. M. Lipunov, V. A. Sadovnichy, M. I. Panasyuk et al. 1429

The role of the magnetic fields in GRB outflows
N. Jordana-Mitjans, C. G. Mundell, S. Kobayashi et al. 1449

MASTER optical observations of the blazar TXS0506+056 during the IC170922A
V. M. Lipunov, K. Zhirkov, V. G. Kornilov et al. 1467

Boson Stars

• Scalar Fields in Cosmology
Chairpersons: Carlos Herdeiro and Alfredo Macias

YouTube links: https://youtu.be/SyLoguueGKk
https://youtu.be/f9nuo8Jvw-w

A short review on nonlinear perturbation theory of structure formation for modified gravity
Jorge L. Cervantes-Cota and Alejandro Aviles 1474

Testing modified gravity theories with marked statistics
Alejandro Aviles 1494

Dark matter as condensed phase of generic bosons
Elías Castellanos and Jorge Mastache 1513

Cosmic Microwave Background

• Cosmic Backgrounds from Radio to Far-IR
Chairperson: Carlo Burigana

YouTube link: https://youtu.be/4e3Cj5wahck

New Planck tSZ map and its cosmological analysis
H. Tanimura, M. Douspis and N. Aghanim 1527

The CMB dipole: Eppur si muove
R. M. Sullivan and D. Scott 1532

High angular resolution Sunyaev Zel'dovich observations: The case of MISTRAL
E. S. Battistelli, E. Barbavara, P. de Bernardis et al. 1542

Cosmological and astrophysical results exploiting magnification bias with high-z sub-millimetre galaxies
L. Bonavera, M. M. Cueli and J. Gonzalez-Nuevo 1557

The impact of the Lorentz symmetry violation on the CMB polarization
Seddigheh Tizchang, Rohoollah Mohammadi and She-Sheng Xue 1571

Cosmic backgrounds from the radio to the far-infrared: Recent results and perspectives from cosmological and astrophysical surveys
Carlo Burigana, Elia Sefano Battistelli, Laura Bonavera et al. 1579

• **New Horizons in Cosmology with CMB Spectral Distortions**
Chairpersons: Jens Chluba and Andrea Ravenni

YouTube links: https://youtu.be/uBYLO4Smw3o
https://youtu.be/5oAPfzAe35k

CMB μT cross-correlations as a probe of PBH scenarios
Ogan Özsoy and Gianmassimo Tasinato 1609

Theoretical and numerical aspects of CMB spectral distortions from non-thermal energy injections
Sandeep Kumar Acharya, Jens Chluba and Abir Sarkar 1628

BISOU: A balloon project to measure the CMB spectral distortions
B. Maffei, M. H. Abitbol, N. Aghanim et al. 1633

Cosmic microwave background spectral distortions constraints on decaying dark matter particles and axion-like particles using *COBE/FIRAS* and *EDGES*
Boris Bolliet 1645

The COSmic Monopole Observer (COSMO)
S. Masi, E. Battistelli, P. de Bernardis et al. 1654

• **Status of the $\mathbf{H_0}$ and $\boldsymbol{\sigma_8}$ Tensions: Theoretical Models and Model-Independent Constraints**
Chairpersons: Joan Solà Peracaula and Adrià Gómez-Valent

YouTube links: https://youtu.be/VNWZ1Bzjus4
https://youtu.be/zEBOCwvetKE
https://youtu.be/nzgC7qV9H_Y

Measuring the Hubble constant H_0 from gravitational lensing
Liliya L. R. Williams 1672

Extra components consistency in the Hubble tension and BBN
Osamu Seto and Yo Toda 1686

Gravitational anomalies, axions and a string-inspired running vacuum model in Cosmology
Nick E. Mavromatos 1693

Early and not so early dark energy. What do cosmological observations tell us about them?
Adrià Gómez-Valent, Ziyang Zheng, Luca Amendola, Valeria Pettorino and Christof Wetterich 1713

Renormalized $\rho_{\rm vac}$ without m^4 terms
Cristian Moreno-Pulido and Joan Solà Peracaula 1733

BD-ΛCDM and running vacuum models: Theoretical background and current observational status
Javier de Cruz Pérez, Joan Solà Peracaula, Adrià Gómez-Valent and Cristian Moreno-Pulido 1752

Cosmological tensions: Hints for a new concordance model?
E. Di Valentino 1770

Solving both H_0 and σ_8 tensions in $f(T)$ gravity
Emmanuel N. Saridakis 1783

Precision Cosmology and Hubble tension in the era of LSS surveys
G. Fanizza 1792

• **Effects of Primordial Perturbations Enhancement: From Black Holes Formation to CMB Anomalies**
Chairpersons: Antonio Enea Romano and Krzysztof Turzynski
YouTube link: https://youtu.be/frjjONXbd1M

Primordial black holes arise when the inflaton falls
Keisuke Inomata 1803

Effects of the modification of gravity on the production of primordial black holes
Sergio Andrés Vallejo Peña 1809

Cosmic Strings

• **Cosmic Strings**
Chairpersons: Reinoud Jan Slagter and Batool Imtiaz
YouTube link: https://youtu.be/ZpaU82ZUHzM

$U(1)$ local strings in generalized hybrid metric-Palatini gravity
Hilberto M. R. da Silva, Tiberiu Harko, Francisco S. N. Lobo and João Luís Rosa 1820

New evidence of the azimuthal alignment of quasars spin vector in Large Quasar Groups and cosmic strings
R. J. Slagter 1835

Summary parallel session cosmic strings I
Reinoud Jan Slagter and Batool Imtiaz 1848

• **From Cosmic Strings to Superstrings**
Chairpersons: Carlos Martins and Ivan Rybak
YouTube link: https://youtu.be/LJFtV_4aSAg

Scaling solutions of wiggly cosmic strings
A. R. R. Almeida and C. J. A. P. Martins 1851

High resolution calibration of string network evolution
J. R. C. C. C. Correia and C. J. A. P. Martins 1871

Radiation from Global Cosmic Strings using adaptive mesh refinement
Amelia Drew and E. P. S. Shellard 1891

Analysing the scaling density of axion strings
A. Lopez-Eiguren 1898

Electroweak axion string and superconductivity
Yu Hamada, Yoshihiko Abe and Koichi Yoshioka 1912

Dark Energy and Large Scale Structure

• **Dark Energy and the Accelerating Universe**
Chairpersons: Alexei Starobinky and David Polarski
YouTube links: https://youtu.be/JZEPRS_rqbE
https://youtu.be/3aG_AT4UzWE
https://youtu.be/ZlTWquG-pFk

Hints for the $H_0 - r_d$ tension in uncorrelated Baryon Acoustic Oscillations dataset
Denitsa Staicova 1923

Observational constraints on nonlinear matter extensions of general relativity
E.-A. Kolonia and C. J. A. P. Martins 1935

Constraining the dark energy-dark matter interaction model using low-redshift observations
Archana Sangwan, Joseph P. J. and S. Shankaranarayanan 1948

On the evolution of inhomogeneous perturbations in the ΛCDM model and $f(R)$ modified gravity theories
T. Schiavone and G. Montani 1961

Soft dark energy and soft dark matter
Emmanuel N. Saridakis 1970

A simple parametrisation for coupled dark energy
Vitor da Fonseca, Nelson J. Nunes and Tiago Barreiro 1979

• **Cosmography with Gravitational Lensing**
Chairpersons: Claudio Grillo and Mimoza Hafizi
YouTube link: https://youtu.be/FXplIAvUDBM

A tale of two double quasars: Hubble constant tension or biases?
L. J. Goicoechea and V. N. Shalyapin 1990

Dark Matter

• **Interacting Dark Matter**
Chairpersons: Nikolaos Mavromatos
YouTube links: https://youtu.be/zOshKJlwD-Y
https://youtu.be/JR44dh2GYik

Dark energy and dark matter unification from dynamical space time: BBN constraints
D. Benisty 2005

Entropy and irreversible processes in gravity and cosmology
Llorenç Espinosa-Portalés and Juan García-Bellido 2013

LHC experiments for long-lived particles of the dark sector
Vasiliki A. Mitsou 2029

Constraining the interactions in the dark sector with cosmological data
Adrià Gómez-Valent, Valeria Pettorino and Luca Amendola 2050

Running vacuum interacting with dark matter or with running gravitational coupling. Phenomenological implications
Joan Solà Peracaula 2069

Dark matter properties from the Fornax globular cluster timing: Dynamical friction and cored profiles
D. Blas 2089

Growth of linear perturbations in a universe with superfluid dark matter
S. Banerjee, S. Bera and D. F. Mota 2101

Interacting dark sector in the late Universe: Mapping fields and fluids, and observational signatures
Joseph P. J. and S. Shankaranarayanan 2119

The role of self interactions in the cosmological evolution of warm dark matter
R. Yunis, C. R. Argüelles, D. López Nacir et al. 2127

Interaction energy between a charged medium and its electromagnetic field as a dark matter candidate
Mayeul Arminjon 2139

• Dark Matter Searches with Liquid Xenon and Argon Detectors and Self Gravitating Systems and Dark Matter
Chairpersons: Marco Merafina and Soroush Shakeri and She-Sheng Xue

YouTube link: https://youtu.be/H9oGYnGq9pI

The maximum mass of dilute axion stars
Pierre-Henri Chavanis 2149

A dark matter solution for the XENON1T electron excess and the galactic center 511 keV line
Yasaman Farzan 2174

Preliminary results of rich galaxy clusters' spatial distribution analysis on CfA2 Redshift Survey data: Compact objects or dark matter presence at redshift less 0.032
I. V. Arkhangelskaja, A. M. Galper, L. N. Khanh and D. N. Dorosheva 2189

• Dark Matter: Beyond ΛCDM
Chairpersons: Carlos Argüelles and Andreas Krut

Primordial black holes as dark matter candidates in the Galactic halo
Lindita Hamolli, Mimoza Hafizi, Francesco De Paolis and Achille A. Nucita 2319

Giant cosmic ray halos around M31 and the Milky Way
S. Recchia, S. Gabici, F. A. Aharonian and V. Niro 2335

A nearly complete census of intergalactic gas using the kinematic Sunyaev-Zel'dovich effect
Chaves-Montero, Jonás 2345

Searching for Intermediate Mass Black Holes in the Milky Way's galactic halo
A. Franco, A. A. Nucita, F. De Paolis, F. Strafella and M. Maiorano . . . 2352

Virial clouds evolution from the last scattering up to the formation of first stars
Noraiz Tahir, Asghar Qadir, Muhammad Sakhi and Francesco De Paolis 2360

Testing Weyl-modified gravity on M31 and Milky Way
Muhammad Bilal and Asghar Qadir 2365

PART C

Education

• **Teaching Einsteinian Physics to School Students**
Chairpersons: David Blair and Matteo Luca Ruggiero
YouTube links: https://youtu.be/W-WV6J8kprg
https://youtu.be/UHYpwKQ09SU

Teaching relativity: A paradigm change
F. Herrmann and M. Pohlig 2371

Teaching relativity: Computer-aided modeling
F. Herrmann and M. Pohlig 2381

Solstices and Equinoxes in 1703 at the meridian line of St. Maria degli Angeli in Rome, and the stellar aberration of Sirius
Costantino Sigismondi and Silvia Pietroni 2388

Positional astrometry at arcsecond accuracy using historical instruments, with light equipment
Costantino Sigismondi and Lorenzo Ricciardi 2398

Daily, seasonal, and equinoctial solar paths on a school soccer field
Costantino Sigismondi 2411

Teaching relativity at the AstroCamp
C. J. A. P. Martins 2415

Sungrazing comets as General Relativistic gravitational probes
Silvia Pietroni and Costantino Sigismondi 2424

The three Summer solstice's markers of 1721 unveiled in the Basilica of Santa Maria degli Angeli in Rome
Costantino Sigismondi 2428

Einstein-First: Bringing children our best understanding of reality
A. Popkova, K. Adams, S. Boublil et al. 2438

Exact Solutions

• **Exact Solutions in Four and Higher Dimensions**
Chairpersons: David Blair and Matteo Luca Ruggiero

YouTube link: https://youtu.be/GHZUS5-4gVQ

Kundt spacetimes in the Einstein–Gauss–Bonnet theory
R. Švarc, J. Podolský and O. Hruška 2453

Exact decoupled solutions in curvature-matter coupled gravity
M. Sharif and Fizza Furqan 2464

Tolman-Oppenheimer-Volkov conditions beyond spherical symmetry
José P. Mimoso, Alan Maciel and Morgan Le Delliou 2479

A spherically symmetric stiff fluid spacetime in light of cosmic structure formation
Daniele Gregoris 2497

• **Exact Solutions (Including Higher Dimensions)**
Chairperson: Susan Scott

YouTube link: https://youtu.be/-hJjJvmmOew

Three-parameter solution for the null-surface formulation in 2+1 dimensions
Tina A. Harriott and J. G. Williams 2510

New exact stationary cylindrical anisotropic fluid solution of GR
M.-N. Célérier 2522

Early Universe

• **Quantum Fields**
Chairperson: Andrei Lebed

YouTube links: https://youtu.be/BLaTp0r0TkQ
https://youtu.be/ZifgaSDy5Vc

Hydrodynamic representation and energy balance for the Dirac and Weyl fermions in curved space-times
Tonatiuh Matos, Omar Gallegos and Pierre-Henri Chavanis 2533

Breakdown of the Equivalence Principle for a composite quantum body
A. G. Lebed 2551

Extended DeWitt-Schwinger subtraction scheme, heavy fields and decoupling
Antonio Ferreiro and Jose Navarro-Salas 2557

Renormalization and decoupling for the Yukawa model in curved spacetime
Sergi Nadal-Gisbert, Antonio Ferreiro and José Navarro-Salas 2562

Trace anomaly and evaporation of spherical black holes
P. Meda 2573

On decay of the false Unruh vacuum
A. Shkerin 2587

Behaviour of noise kernel in de Sitter and FRW space-times
Ankit Dhanuka and Kinjalk Lochan 2600

Breaking Buchdahl: Ultracompact stars in semiclassical gravity
Julio Arrechea, Carlos Barceló, Raúl Carballo-Rubio and Luis J. Garay 2608

Einstein anomaly with tensors of odd order in six dimensional curved space
Kohei Yamamoto and Satoshi Yajima 2619

Quantum memory and BMS symmetries
Sanved Kolekar and Jorma Louko 2623

• Topological Methods, Global Existence Problems, and Spacetime Singularities
Chairperson: Spiros Cotsakis

YouTube link: https://youtu.be/H8Itnc_C10c

Gravitational singularities, scattering maps for bouncing, and structure-preserving algorithms
Philippe G. LeFloch 2630

Brane-world asymptotics in a nonlinear fluid bulk
I. Antoniadis, S. Cotsakis and Ifigeneia Klaoudatou 2645

Primordial synchronization of Mixmaster spatial points
Spiros Cotsakis 2657

• The Early Universe
Chairperson: Stefano Ansoldi

YouTube links: https://youtu.be/m80hHWgOlFs
https://youtu.be/6tyaZ8MMVtw

Quintessential inflation from Lorentzian slow roll
David Benisty 2663

Condensed light, quantum black holes and L-CDM cosmology: Experimentally suggested and tested unified approach to dark matter, dark energy, cosmogenesis and two-stage inflation
Victor Borsevici 2672

Helical magnetic fields lead to baryogenesis
Ashu Kushwaha and S. Shankaranarayanan 2692

Polymer Quantization of the Isotropic Universe: Comparison with the Bounce of Loop Quantum Cosmology
G. Barca, E. Giovannetti, F. Mandini and G. Montani 2700

General relativistic evolution equations for density perturbations in open, flat and closed FLRW universes and the problem of structure formation

New results from testing relativistic gravity with radio pulsars

Michael Kramer

Max-Planck-Institut für Radioastronomie
Auf dem Hügel 69, 53177 Bonn, Germany
mkramer@mpifr-bonn.mpg.de

We experience a golden era in testing and exploring relativistic gravity. Whether it is results from gravitational wave detectors, satellite or lab experiments, radio astronomy plays an important complementary role. Here one can mention the cosmic microwave background, black hole imaging and, obviously, binary pulsars. This talk will concentrate on the latter and new results from studies of strongly self-gravitating bodies with unrivalled precision. This presentation compares the results to other methods, discusses implications for other areas of relativistic astrophysics and will give an outlook of what we can expect from new instruments in the near future.

Keywords: Pulsars; Neutron stars; Black holes; Gravitational-wave astrophysics; Experimental tests of gravitational theories

PACS numbers: 97.60.Gb; 97.60.Jd; 97.60.Lf; 04.30.Tv; 04.80.Cc

1. Introduction

The latest Marcel-Grossmann Meeting has showed once more that gravity can be explored and tested in many different ways. Whether it is via lab experiments on Earth, in the Solar system or in outer space. Whether it is via radio astronomy, optical/infrared astronomy, high-energy observations or gravitational wave detectors. Nearly all experiments use techniques that were not even remotely thinkable at the time, when Einstein conceived general relativity (GR). And yet, all these experiments that the theory has been confronted with, seem to confirm GR's predictions. Obviously, the phenomena of Dark Matter and Dark Energy, or the incompatibility of GR with quantum physics, justify the search for alternatives and the continuing search for experiments that may eventually show a flaw in Einstein's theory.

In this endeavour it is important to complement the different approaches as they test different regimes of gravity, in each of which one may find a deviation for a given theory. This is illustrated in Figure 1. In the solar systems, gravity tests are made in the quasi-stationary weak-field regime, often involving satellite experiments of high precision (e.g. Ref. 1). The quasi-stationary strong-field regime can be probed with experiments such as stellar orbits around Sgr A* (e.g. Ref. 2) or radio images of black holes (Ref. 3). But also pulsar experiments contribute to this regime, and indeed they already allow precision tests of the radiative properties of gravity (e.g. Ref. 4), as we also show in the following. Using radio pulsars

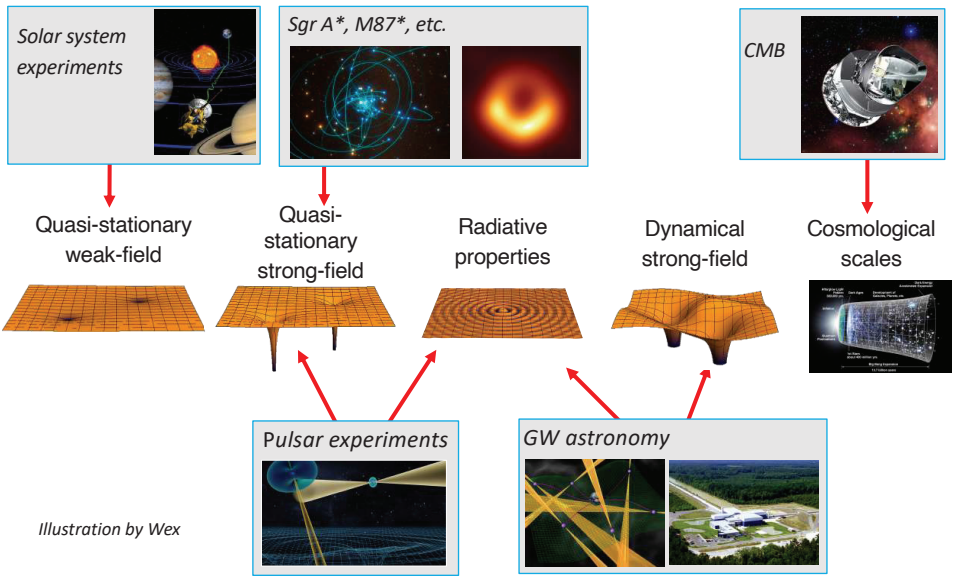

Fig. 1. Different regimes of gravity tests and examples of methods and experiments that allow tests in those.

also as galaxy-sized gravitational wave (GW) detectors (e.g. Refs. 5), one also enters the dynamical strong-field regime, where obviously also the Earth-bound GW detectors are operating (e.g. Ref. 6). Finally, theories should also be tested on the largest scales, which can be done, for instance, with studies of the cosmic microwave background (CMB).

We note that in most of these experimental methods (certainly in those examples given here) radio astronomy plays a crucial role. In the following, we will concentrate on recent results involving radio pulsars.

2. Testing gravity with pulsars

The most common, and most well known way, of testing gravity with pulsars is via a technique called pulsar timing.[7] Less common but still powerful is the usage of pulse structure data that allow us to probe precessional effects when the line-of-sight through the emission beam is changing, modifying the observed pulse properties like width or generally pulse shape.[8] In extreme cases, the pulsar may completely disappear from our view after a while.[9,10])

In pulsar timing one makes use of the often very stable rotation of a pulsar that leads to a regularity in the emitted pulsed signal, caused by a lighthouse effect, that rivals the best atomic clocks on Earth. As an observer on Earth, we can measure the arrival time of the pulses at the telescope and infer from it the motion of the

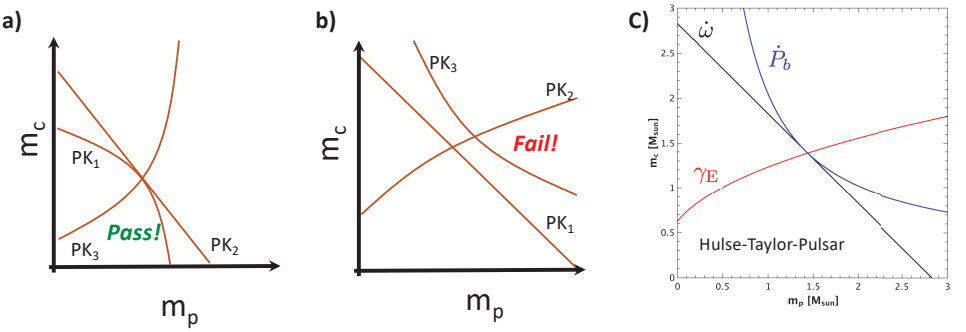

Fig. 2. Gravity tests using binary pulsars performed via the measurements of Post-Keplerian (PK) parameters and their graphical representation in a mass-mass diagram. a) all PK parameter lines insect in a single point: the test is passed. b) the lines do not intersect in a single point: the theory fails the test. c) Example for the Hulse-Taylor pulsar, here shown for general relativity.

pulsar in a binary orbit. The timing precision that is attainable (i.e. better than 100 ns in many cases) is provided by following the rotational phase of the pulsar in a coherent fashion, making measurements more precise as the time baseline increases. In a similar way, tracking the orbital phase reveals periodic and secular deviations from a simple Keplerian orbit, expressed in the so called Post-Keplerian (PK) parameters.[8,11,12] Those can typically be expressed as functions of the Keplerian parameters and the two unknown masses of the binary system. Once two PK parameters can be measured, the two masses can be determined within the framework of a given theory and the value of further PK parameters can be predicted. Once that is done, the predictions can be compared with similar measurements and the theory, hence, can be tested.

One can express such a test in a graphical form, where each PK parameter describes a line in a diagram with the values of two unknown masses as its axes. Two PK parameter lines define an intersection point through which every other PK parameter line must pass. If that is not the case, the theory determining the lines is falsified and needs to be rejected. The measurement uncertainties in the PK parameters is expressed as the width of the PK lines in the mass-mass diagram. See Figure 2.

2.1. *The Double Pulsar*

We demonstrate the power of pulsar timing using the best laboratory currently known, the so called "Double Puslar".[13,14] The system consists of two active radio pulsars – a currently still unique feature of the system – orbiting each other in 147 min. The recycled (old) pulsar (A) in the system has a period of 23 ms, the non-recycled (young) pulsar (B) a period of 2.8 s. An important feature of the system is its edge-on geometry (see Figure 3) that also leads to 30-s long eclipses and our

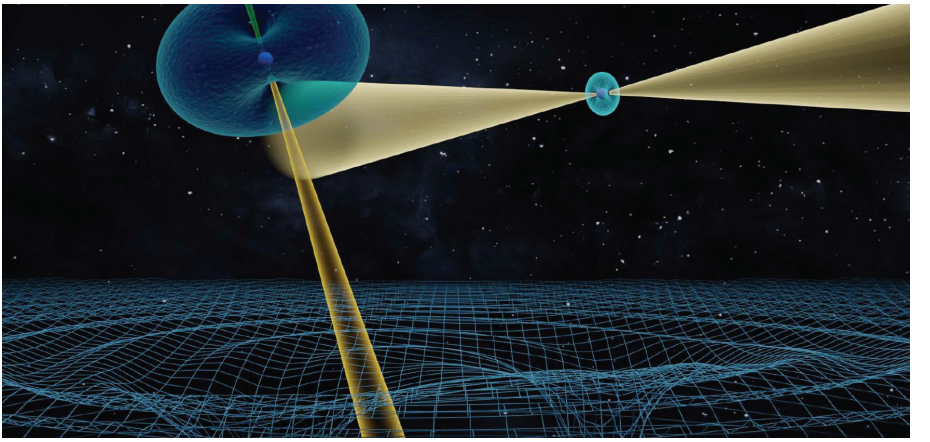

Fig. 3. Artistic impression of the Double Pulsar. Here, two active radio pulsars orbit each other in 147 min in a slightly eccentric orbit ($e = 0.09$). One pulsar is old and recycled ($P = 23$ ms), while the second pulsar is young ($P = 2.8$ s). Figure is not to scale.

ability to measure light-propagation effects (see below). The previous gravity tests with the system made usage of the ratio of the masses of the two pulsars, that can be directly (i.e. theory independently to 1PN order) measured from the two semi-major axes the pulsars' orbit around the common centre of mass.[4] Meanwhile the data have improved very significantly in both precision and length. The latest results were presented by Kramer et al. (Ref. 15), reporting the measurement of, in total, seven PK parameters.

What is important and different to previous experiments, the measurement precision is now so high that for the first time higher-order contributions need to be taken into account for some of the PK parameters. This includes the contribution of the A pulsar's effective mass loss (due to spin-down) to the observed orbital period decay, a relativistic deformation of the orbit, and the effects of the equation of state of super-dense matter on some of the observed PK parameters via relativistic spin-orbit coupling. The system also provides the currently most precise test of general relativity's quadrupolar description of GWs, validating GR's prediction at a level of 1.3×10^{-4} with 95% confidence.[15] As indicated, the impact of the mass loss due to rotational spin-down is taken into account in this result. Interestingly, as the pulsar is losing rotational energy, and while $E = m\,c^2$, the slow-down corresponds to a mass loss of 8.4 Million tons per second or 3.2×10^{-21} of the mass of A per second.

2.1.1. *Light propagation*

The edge-on geometry of the system allows not only a test of relativistic spin-precession as discussed in Section 3, but it also leads to a "Shapiro-delay", i.e. the a delay in the measured arrival time as the photons have to propagate in the curved

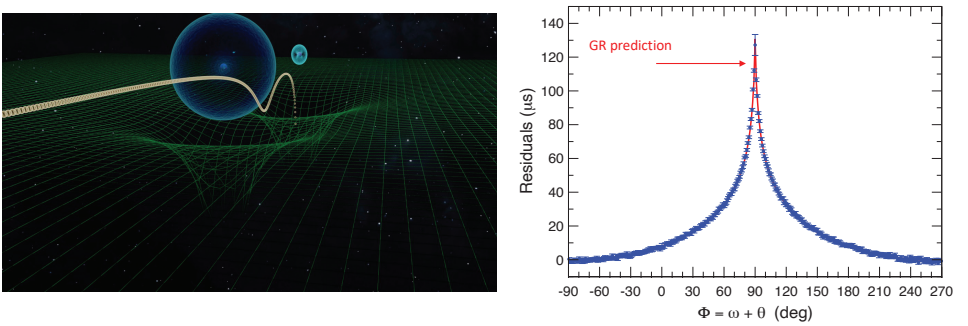

Fig. 4. Shapiro delay measurement in the Double Pulsar. The curvature of spacetime around the companion B (see artistic impression on the left, not to scale) leads to a delay in the arrival times of the pulses of pulsar A (right).

spacetime near the companion pulsar. We illustrate this effect in Figure 4. The data points follow the prediction of GR (red line) remarkable well (at a level of 4×10^{-4} with 95% confidence.[15] This agreement with the data is, however, only achieved when next-to-leading order effects are taking into account: at the 1.5PN limit one has to take into account that the speed of light is finite and that pulsar B moves during the flight time of the photos across the orbit. See Figure 5.

When comparing the Shapiro delay curve with precision data, another effect needs to be considered which relates to the fact the pulsar is indeed a lighthouse rather than a pulsating or oscillating object. This effect is aberration, which for pulsar timing means in principle a delay in arrival time that depends on orbital phase and on the orientation of the pulsar with respect to the orbit and the observer.[12,16] Due to the geometry of the Double Pulsar that does, however, not lead to separately measurable, additional PK parameters.[15] Nevertheless and most interestingly, given the precision obtained in the measurements, the curved spacetime encountered by the photons near superior conjunction leads to a deflection of the signal in the gravitational field of pulsar B. This gravitational signal deflection leads to a small change in the proper angle of emission, which in turn leads to a lensing correction to the classical ("longitudinal") aberration. See Ref. 15 for details. As a result, only those photons reach the observer on Earth that are emitted slightly earlier (or later, respectively) in pulsar rotational phase, before (and after, respectively) superior conjunction. The measurement shown in Figure 6 not only demonstrates the lighthouse character of pulsars but also indicates a prograde alignment of the pulsar spin relative to the total angular momentum vector.

2.1.2. *Orbital deformation, lense-thirring effect and moment-of-inertia*

A further effect that is observed in the Double Pulsar and that is now required to be considered in the data analysis is a relativistic deformation of the orbit. The presence of the effect[11,12] was already seen by Weisberg & Huang (Ref. 17). In

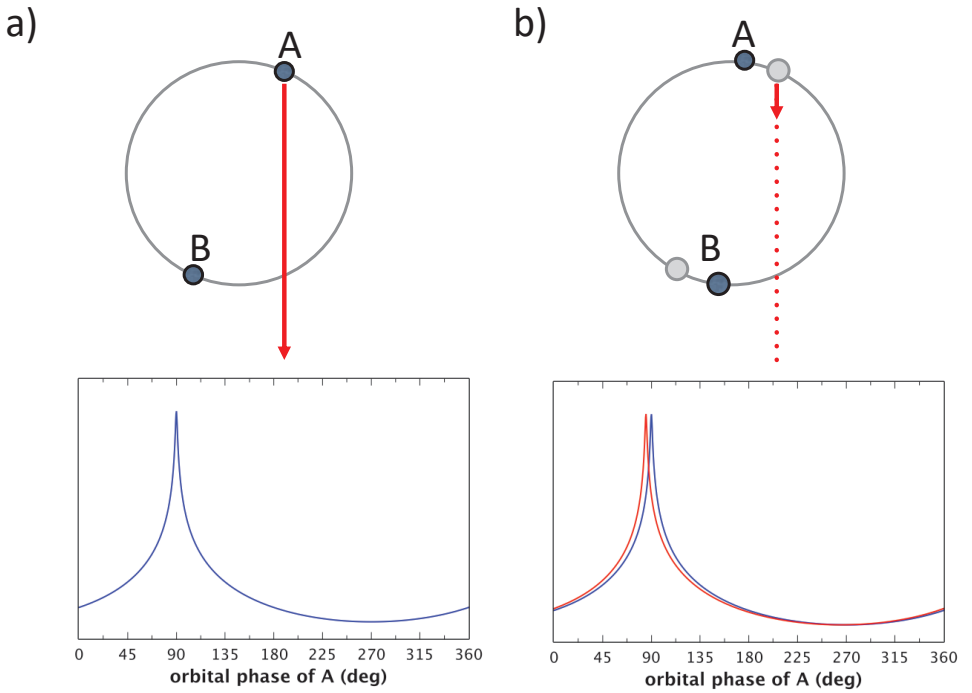

Fig. 5. Illustration of the physical origin and impact of the next-to-leading order (1.5PN) contribution to the Shapiro delay. a) Previously, a "static" Shapiro delay was implemented in timing formula, assuming the position of the companion pulsar B to be fixed during the propagation of A's photons. b) In reality, pulsar B moves during the flight time of the photons, which effectively leads to a small shift in the Shapiro delay curve at the 1.5PN level. Illustration by N. Wex.

this case, ignoring this subtle effect would (wrongly) suggest a tension between the measured "Einstein delay" and its prediction by GR. See Kramer et al. (Ref. 15) for details.

As already indicated, the extreme precision of the experiment now also needs to incooperate the effects of the equation of state (EoS) of super-dense matter on some of the observed post-Keplerian parameters via relativistic spin-orbit coupling. Indeed, the most precisely measured PK parameter, $\dot{\omega}$, representing the precession of the orbit, has a contribution from the Lense-Thirring effect due to the rotation of pulsar A at the 2PN level, which is more than 30 times larger than our measurement error. However, a calculation of the Lense-Thirring contribution requires the knowledge of the Moment-of-Inertia of pulsar A, $I_{\rm A}$, which comes with a significant uncertainty due to our imperfect knowledge of the EoS for neutron star matter. To constrain $I_{\rm A}$ one can use constraints on the EoS obtained from the double neutron star merger GW170817[18] and determine precise measurements for the pulsars. Alternatively, one can ignore any existing constraints on the EoS of neutrons stars to simultaneously determine the pulsar masses, $m_{\rm A}$, $m_{\rm B}$, and $I_{\rm A}$, assuming GR to be

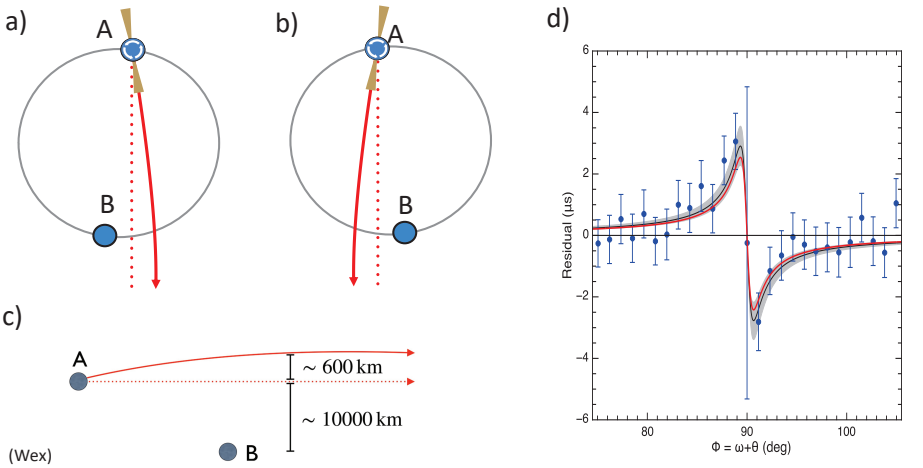

Fig. 6. Illustration and measurement of another next-to-leading order effect that needs to be taken into account for the Shapiro delay. In this case, aberrational light bending due to the curvature of spacetime around pulsar B is considered. a) Before superior conjunction, the photons have to be emitted at a slightly later rotational phase than usual to compensate for the light bending near B to reach the observer on Earth. b) After superior conjunction, the photons have to be emitted slightly earlier, respectively. c) The light bending contributes an additional 600 km to the total impact distance. d) Residuals observed near superior conjunction (i.e. periastron, $\Phi = 0$ deg), when this effect is *not* taken into account. The red curve shows the theoretical prediction arising from this effect, and the black curve corresponds to the best fit, with a 2σ range indicated by the light grey band. This effect allows us to infer the spin direction of pulsar A, indicating a prograde orientation. See Kramer et al. (2021) for details.

the correct theory of gravity. In this case, simply based on pulsar timing, one finds for the the MoI $I_{\rm A} < 3.0 \times 10^{45}\,{\rm g\,cm^2}$ with 90% confidence,[15] which in turn can be directly compared to the results derived from the GW170817 LIGO/Virgo merger and from NICER X-ray timing. Using a universal relation, like the one in Ref. 19, one can convert the obtained probability distribution of $I_{\rm A}$ into a probability distribution for A's radius. With 90% confidence, this gives an upper limit for A's radius of 22 km, a value outside any physically valid EoS but purely based on the arrival times measurements of pulses.[15]

In summary, the Double Pulsar allows to test conservative aspects of the orbital dynamics of two strongly self-gravitating masses up to 2PN order, including a $\sim 1\sigma$ constraint on the Lense-Thirring contribution, which in turn can be used to constrain the MoI of pulsar A under the assumption of GR. The experiments allow to test the propagation of photons in the gravitational field of a strongly self-gravitating (material) body, with next-to-leading-order contributions being clearly present in the timing data, confirmed with a precision of about 10%. We can also test the radiative aspects of GR, yielding a test at 2.5PN level in the equations of motion with a precision of 1.3×10^{-4} (95% C.L.). In terms of overall fractional precision, this is the most precise test of GR's predictions for GW emission

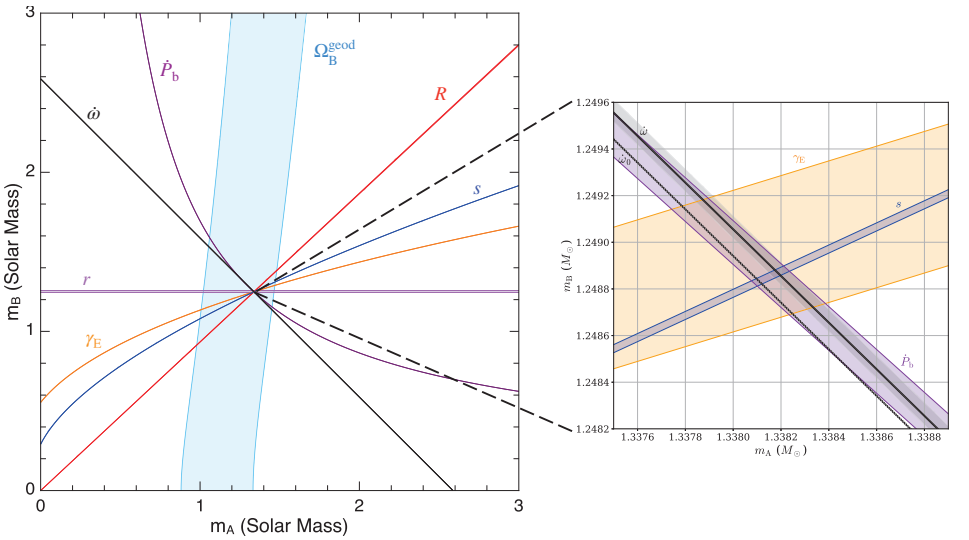

Fig. 7. Mass-mass diagram for the Double Pulsar as presented by Kramer et al. (2021). The right panel is a zoomed-in version of the intersection point of the PK parameter lines in the left panel. The shift of the line for the PK-parameter $\dot{\omega}$ when ignoring the Lense-Thirring effect ($\dot{\omega}_0$) is clearly visible. See text for details.

currently available. These tests are summarized in the mass-mass diagram shown in Figure 7.

3. Relativistic spin-precession

A gyroscope freely falling in curved spacetime suffers a precession with respect to a distant observer. Experiments made in Solar System provide precise weak-field tests and confirm it, e.g. with Lunar Laser Raning or GRAVITY Probe-B. In a binary pulsar system, the pulsar - also being a gyroscope - we observe, strictly speaking, a mixture of different contributions to relativistic spin-orbit coupling. One contribution comes from the motion of the first body around the centre of mass of the system (deSitter-Fokker precession), while the other comes from the dragging of the internal frame at internal frame at the first body due to the translational motion of the companion.[20] This resulting relativistic spin-precession causes nevertheless the expected effect: the pulsar precesses about the total angular momentum, which as a result changes the relative orientation of the pulsar towards Earth with potentially observable consequences as predicted by Damour & Ruffini in Ref. 21 even before the publication of the discovery of the Hulse-Taylor binary pulsar.[22] We note that the orbital angular momentum is expected to be much larger than that of a pulsar in the system, so that the orbital spin practically represents a fixed direction in space. Hence, effectively the pulsar precesses about the orbital angular momentum.

The precession rate, $\Omega_{\rm SO}$, is another PK as introduced above. Assuming GR to be valid, it is given by[23]

$$\Omega_{\rm SO} = T_\odot^{2/3} \left(\frac{2\pi}{P_{\rm b}}\right)^{5/3} \frac{m_{\rm A}(4m_{\rm B}+3m_{\rm A})}{2(m_{\rm B}+m_{\rm A})^{4/3}} \frac{1}{1-e^2}. \quad (1)$$

The effect of relativistic sin precession on pulsar timing is in principle measurable due to a change in the aberration parameters with time.[8] Much more obvious, and hence easier to measure, are the consequences of the changing line-of-sight as the pulsar precesses. We expect changes in the pulse shape (e.g. in simply the measured width, but also more dramatic changes) and especially in the measured linearly polarised emission which is a sensitive probe of the pulsar geometry.[21,24] Such measurements have indeed enabled the detection of spin precession in a number of relativistic binaries. After the first detection in the Hulse-Taylor pulsar B1913+16[9,25] and later in PSR B1534+12,[26,27] it is now possible to convert long-term observations in precise quantitative tests of spin precession and, hence, test of the "effacement" property of a spinning body.

3.1. *Spin precession in the Double Pulsar*

A prime example to study relativistic spin precession is, again, the Double Pulsar. Here, we have two active pulsars, both of which could, in principle show the effects of precession. However, it turns out that the supernova explosion creating the second-born pulsar, B, was a low-kick supernova which left the pre-Supernova orientation of the orbital angular momentum vector unchanged. The spin of pulsar A, having been aligned with the orbital spin during its recycling period, is therefore still aligned with it, so that precession for A is not expected. Indeed, so far, profile changes for A have not been detected, suggesting that A's misalignment angle is less than 3 deg.[28,29]

In contrast, secular changes in the pulse shape and the orbital visibility windows of pulsar B were observed soon after its discovery,[30] providing early evidence for spin precession of B. Around 2008, the pulsar vanished from our view when our line-of-sight moved out of the emission beam.[10] B will eventually re-appear. The exact epoch for this to happen depends on the actual beam shape, but despite a precession period of 71 years (see Table 1), it could happen relatively soon.[10,31]

Meanwhile, it has been possible to track the orientation of the spin axis of pulsar B in a rather fortuitous way: Breton et al. (Ref. 32) studied the time evolution of the $\sim$ 30-s long eclipses of A that are caused by the blocking rotating magnetosphere of B at superior conjunction. This absorption of the background emission, presumably by synchrotron self-absorption,[33] is not complete, but because of the torus-shaped dipolar magnetosphere[a] the light from the background pulsar A is visible every half-turn or full-turn of pulsar B, depending on the orientation of the spin-axis and,

[a]Deviations from a purely dipolar-shaped magnetosphere do exist and are observed. Indeed, about 50% of the magnetosphere is "missing" but for the remaining parts, the torus shape appears more than adequate, as the successful modelling shows. See, for instance Ref. 34.

hence, the magnetosphere. Applying a simple but successful geometrical model,[33] Breton et al. were able to explain the observed modulation of A's lightcurve during the eclipse phase in great detail. Model-fitting indicates a constant magnetic inclination angle and constant misalignment angle, while the azimuthal spin angle is changing with a rate of $\Omega_{\rm SO,B} = 4.77^{+0.66}_{-0.65}{}^{\circ}$ yr^{-1}, in agreement with general relativity[32] (see Table 1).

3.2. *PSR J1906+0746 – The currently best test*

A further observational consequence of relativistic spin precession is its impact on the polarisation properties of binary pulsars. Here, two separate but related aspects are observable.

The first aspect is due to the changing line-of-sight within the pulsar beam. According to the rotating vector model (RVM),[24] we expect an S-like swing of the position angle of the linearly polarised emission component of the studied pulsar. The closer the line-of-sight approaches the magnetic axis, the steeper is the expected S-swing. In general, the shape of the S-swing depends on four quantities: the magnetic inclination angle, α, between the spin and magnetic axes, the impact angle between our line-of-sight and the magnetic axis, β, the pulse phase, ϕ, and, finally, the absolute (reference) position angle, Ψ_0, which is obtained at $\phi = 0$ and identical to the orientation of the pulsar spin-axis projected on the plane of the sky. Such a measurement was first achieved for PSR B1534+12,[26,27] where the impact angle β was observed to change with time.

The second consequence is the change of Ψ_0 due to the changing orientation of the pulsar spin and the resulting projection on the sky.[35] This change of the absolute position angle is periodic, with a period equal to the precessional period. Note that there is also a small contribution due to orbital aberration, which we will ignore here. We note that the measured absolute position angle will be affected by Faraday rotation due to propagation in the magnetised ionised interstellar medium. But this effect can, in principle, be measured and removed.

It is the additional information provided by the change in absolute position angle that allows to break some degeneracies and to potentially determine the true orbital inclination angle, i (rather than $180-i$, as pulsar timing only provides $\sin i$). Modelling the evolution of the position angle swing in the described way requires in total only four free parameters, i.e. the precession rate, $\Omega_{\rm SO}$, the misalignment angle between pulsar spin and total angular momentum vector, δ, the precession reference phase, $\Phi^0_{\rm SO}$, and the magnetic inclination angle of the pulsar, α. A requirement for precession to occur is $\delta > 0$, a measurement of which is very useful to study the formation of the system (see Refs. 34 and 35 for a detailed discussion on this topic).

Both aspects just described are relevant for the beautiful case of PSR J1906+0746. This pulsar is an almost perfect orthogonal rotator, and so this pulsar was discovered with the emission from both magnetic poles being visible

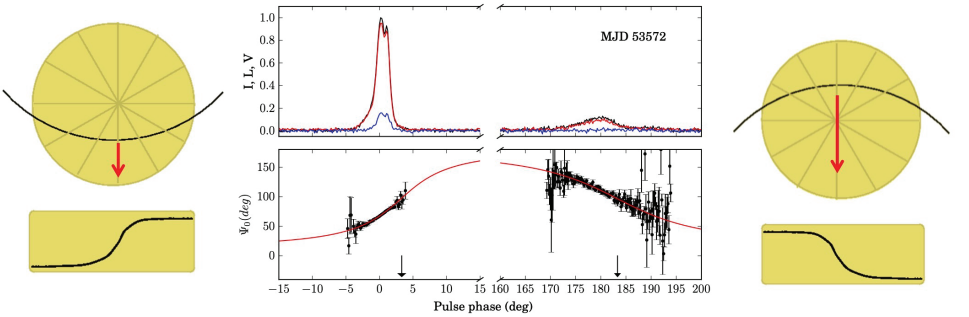

Fig. 8. Pulse profile of PSR J1906+0746 as observed by Desvignes et al. (2019) shown in the middle panel. Both magnetic poles (schematics left and right) were originally visible after discovery. Their observed emission is highly linearly polarised (red line), with a position angle swing (middle lower panel) that resembles a textbook-like rotating vector model. The pulsar also shows a modest amount of circularly polarised emission (middle upper panel, blue line). At the left pole, our line-of-sight moves out of the beam, while at the right pole our line-of-sight crossed the magnetic pole during the long-term monitoring of this source.

(see Figure 8). The emission's high degree of linear polarisation reveals a perfect RVM-like behaviour of the measured position angle that was studied by Desvignes et al. (Ref. 36). Fitting those to the RVM as a function of time using the precessional RVM model[35] described above, allows to measure the precession rate to $\Omega_{\rm SO} = 2.17 \pm 0.11$ deg/yr which is in perfect agreement with the expectation from GR (see Table 1). This test is the currently best test of relativistic spin-precession for strongly self-gravitating bodies.

The study of the position angle reveals even more: Apart from providing measurements of the geometry of the system ($i = 45 \pm 3$ deg, $\alpha = 99.4 \pm 0.2$ deg, $\delta = 104 \pm 9$ deg), the evolution of the position angle swing with time shows how its slope becomes steeper when our lines-of-sight approaches the magnetic pole. It also shows how it swaps sign in slope when crossing the pole, and how it becomes flatter again when moving away from the pole[36] (see right of Figure 9). This is the first unequivocal evidence that the RVM is correct and that the position angle swing of pulsars is in principle determined by the geometry of the pulsar and its fieldlines. Deviation may, however, still occur in cases due to propagation effects or modifications to the field line structure in the emission region.

Furthermore, we can reconstruct the emission beams of the pulsar as projected on the sky and as shown in the left two panels of Figure 9). As the light of sight crosses the two beams, we can obtain "tomographic" images, albeit incomplete ones due to lack of observations in part of the beam. We note from the middle panel, showing the pole that is responsible for the (initially) weaker pulse component in Figure 8, that the emission beam is active on either side of the pole, ruling out models that predict radio emission to be restricted to one side of the pole. Secondly, the emission pattern is not symmetric in the latitudinal direction relative

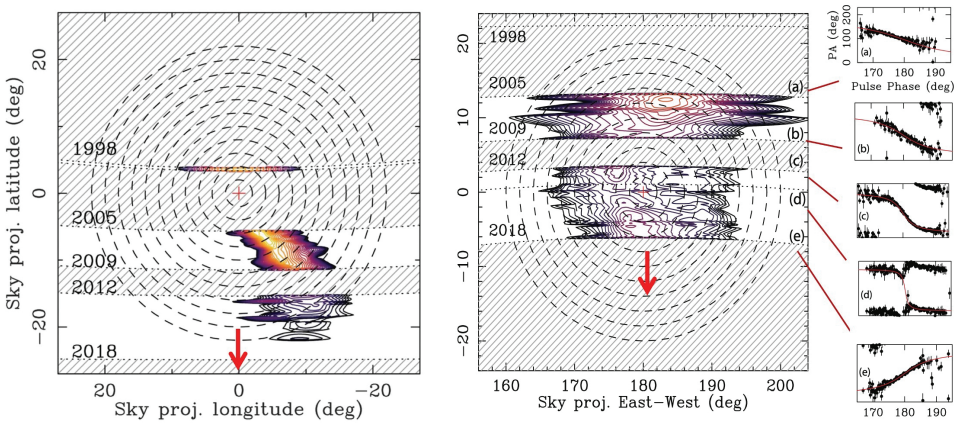

Fig. 9. Beam pattern of the two magnetic poles of PSR J1906+0746 as projected on the sky and observed by Desvignes et al.[36] The beams are reconstructed from observations spanning more than 10 years, when our line-of-sight moved in the indicated direction above both poles. For the right beam, our line-of-sight crossed the magnetic pole. The resulting position angle swing shown on the right evolves with time as expected from the rotating vector model (see text for details). For the left beam, the emission becomes weaker to the beam edge and the initially much stronger component (see Figure 8) is hardly detectable anymore and will soon vanish completely.

to the pole. When looking more closely at our data, we also notice that above the pole itself the emission is reduced, matching theoretical predictions for the current density in the polar cap for an orthogonal rotator.[37] What is also not visible in these total intensity plots shown here (see Ref. 36 for details) is an interesting behaviour of the polarisation characteristics more generally: the handedness of the circularly polarised emission changes when crossing the pole, the fractional linear polarization overall decreases with increasing distance to the beam centre, and finally, emission heights inferred from polarisation data increase from very low emission heights near the pole to emission heights of several hundreds of kilometres at the beam edge, again consistent with theoretical expectations[38] and inferred more indirectly from other pulsars.[39,40]

In summary, somewhat unexpectedly, an experiment designed to test theories of gravity and to tests predictions made by Thibault Damour and Remo Ruffini nearly 50 years ago, leads to unique insight into the emission physics of pulsars.

3.3. *Relativistic spin precession in other pulsars*

Today, spin precession has been routinely observed in all those binary pulsars, where we can expect the pulsar spin to be misaligned with the orbital momentum vector (i.e. systems where we observe the young pulsar or where the last supernova explosion in the system imparted a large kick onto the newly born neutron star) and where the precession rate is high enough due to a sufficient compactness of the orbit. Using the precession rate as given in GR, Eqn. 1, we provide a list of pulsars

where we would expect to observe spin precession. Table 1 gives the corresponding values, sorted by decreasing rate. We note that for the vast majority of sources, spin precession has been detected (see Ref 41). The second highest rate is expected for the highly accelerated binary pulsar J1757−1854 discovered with in the High Time Resolution Universe Survey.[42] As presented by Cameron et al. in this conference, first signs of profile changes may already be present but further data are needed. If this is confirmed, the first top-6 pulsars (and seven out of eight) have all been observed to undergo spin precession. The only other exception in the table is PSR J1756−2251. Here the spin may be aligned with the orbital momentum vector, but studies are in progress to revisit this pulsar with larger precision and longer time baseline.[43]

Table 1. Binary pulsar systems where relativistic spin precession is expected or observed, ordered according to the precession rate as expected from general relativity. Pulsars marked with an asterisk have been identified of showing spin precession.

4. Further recent tests with radio pulsars

In this work, we have so far concentrated on a few prominent, perhaps even spectacular recent examples of using pulsars for testing strong-field gravity. Much more can be studied, including fundamental concepts, such as the Universality of Free Fall (UFF) and the Strong Equivalence Principle (SEP), the possible variation of fundamental constants, or bounds on the graviton mass. We can also test specific alternatives to GR. Here, we refer to recent reviews (see Refs. 44, 45 for more in-depth discussions) and we point to other contributions of the MG16 meeting. Here, we will only highlight some recent examples.

4.1. *Universality of Free Fall (UFF)*

The UFF can be tested in the various regime that we discussed in context of Figure 1. In the solar system, we refer to the superb measurement using test masses aboard the MICROSCOPE satellite that was launched in April 2016 and operated until October 2018. The results indicate that any violation of the weak equivalence principle, Δ, is smaller than $\Delta < 10^{-15}$ (see Ref. 1).

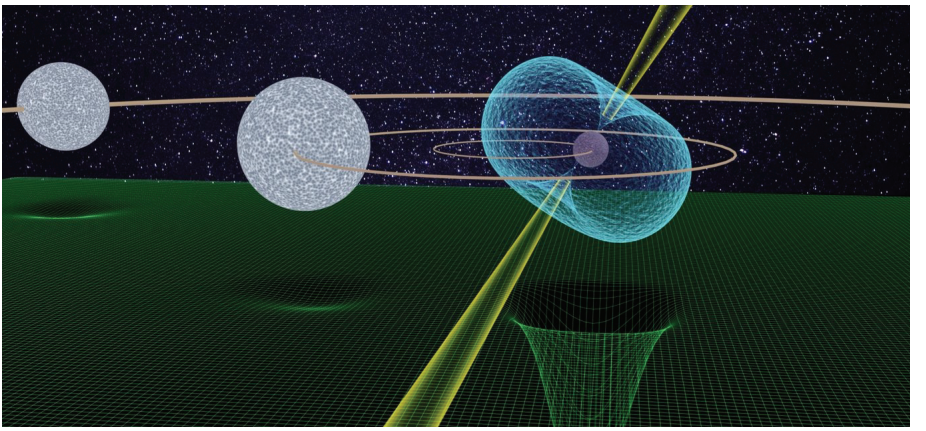

Fig. 10. Artistic impression of the Triple System, where a 2.7-ms pulsar, PSR J0337+1715, and a $0.20 M_\odot$ white dwarf are in an inner 1.63-day orbit, while being orbited themselves by a second $0.41 M_\odot$ white dwarf in 327 days. The figure is not to scale.

The Earth-Moon system allows to test the fall of two bodies with different gravitational self-energy, $\epsilon = E_{\rm grav}/mc^2$, where $E_{\rm grav}$ is the Newtonian gravitational binding energy, in the gravitational field of the Sun. For the Earth $\epsilon_E = -4.6 \times 10^{-10}$ and for the Moon, $\epsilon_M = -0.2 \times 10^{-10}$. The fall can be measured with Lunar Laser Ranging and limits on a deviation are currently at $\Delta < 2 \times 10^{-13}$.[46,47] Comparing this to the gravitational self-energy of the involved bodies, a limit on the violation of the SEP in the weak field of the solar system is $\Delta/\epsilon < 0.04\%$.

Pulsars allow us to test the SEP for strongly-self gravitating bodies, i.e. $\epsilon = -0.13$. The idea was already presented by Damour & Schäfer in 1991 (Ref. 48) who proposed to study the possible variation of the orbits of pulsar-white dwarf systems as they fall in the gravitational potential of the Milky Way. The discovery of a Triple System,[49] a pulsar with two White Dwarf (WD) companions, allows an important variation of this experiment, leading to a much more stringent test (see Figure 10).

The 2.7-ms pulsar, also known as PSR J0377+1715 is in a 1.63-day orbit with a WD of mass $0.2 M_\odot$. This inner binary system is orbited by a second, more massive WD ($0.41 M_\odot$) in a 327-day orbit. As pointed out already by Freire et al. (Ref. 50), in such a case, the pair of bodies with different gravitational self-energy falls in the gravitational potential of the outer WD, providing a much stronger field than that of the Milky Way. Archibald et al. (Ref. 51) presented the result of such an experiment and derived a limit of $\Delta < 2 \times 10^{-6}$. This may appear weaker than the weak-field limit from the solar system, but the SEP should apply for both weak- and strong-field conditions. Hence, when referring to a corresponding $\Delta/\epsilon < 0.002\%$, the importance of this measurement becomes clear.

Even more recently, Voisin et al. (Ref. 52) presented an important improvement on the experiment, using a completely independent data set. The improvements arise from a more uniformly sampled data set but also from an improved theoretical

treatment that incorporates the interesting parameter Δ directly into the analysis of the timing data set. The result is a limit of $\Delta = (+0.5 \pm 1.8) \times 10^{-6}$ at 95% confidence level. While the numerical improvement upon Ref. 51 is 30%, this result is statistics-limited and avoids limitation by systematics as previously encountered.

We complete this section by also referring to recent results and proposals for further experiments to test the UFF also towards dark matter. See Ref. 53 for more details.

4.2. *Alternative theories of gravity*

Despite the successes of GR when being confronted with experimental data, GR may not be our final answer in describing gravity on a macroscopic scale. Given a number of unsolved questions (e.g. dark matter, dark energy, inflation) or its incompatibility with quantum mechanics, is still possible that we encounter an experiment that contradicts GR's predictions. In this case, we would learn important and substantial lessons, and so it is important to explore all regimes presented in Figure 1, probing different aspects of the predictions of GR and alternative theories with different methods. For instance, observations with GW detectors are able to test the highly dynamical strong-field regime and radiative aspects of gravity, but they are not able to test aspects of light-propagation in strong fields. This may be eventually possible with images from super-massive black holes, but the curvature of spacetime is many orders of magnitude smaller than around stellar compact objects. This, on the other hand, and other aspects can be tested with binary pulsars.

The close agreement of the Double Pulsar experiment with the predictions of GR shown in Section 2.1 allows us to place tight constraints on various alternatives to GR. Kramer et al. (Ref. 15) used their recent results to study both "Damour–Esposito-Farése" (DEF) gravity and Bekenstein's tensor-vector-scalar theory (TeVeS).[54] The latter is a MONDian relativistic gravity theory that evades the need for dark matter in galaxies by a modification of GR. Even though this theory has been ruled out already with observations of GWs,[55] Ref. 15 points out that pulsar experiments are still useful to test the aspects of scalar field in the theory.

DEF is a two-parameter mono-scalar-tensor gravity,[56] containing GR as a limit with the two parameters $\alpha_0 = \beta_0 = 0$. As other alternative of GR, DEF violates the SEP, which should result in observable dipolar GWs and a location-dependent gravitational constant. We would measure such phenomena in the form of different functional dependencies of the PK parameters as described in Section 2 (see e.g. Ref. 57). Moreover, in certain regions of the parameter space, DEF gravity shows genuine non-perturbative strong-field effects that are only present in NSs and therefore are not testable in the weak-field regime of the solar system. Hence, one can convert our observational results into constraints for the parameters α_0–β_0. This is done by Ref. 15 as shown in Figure 11. It demonstrates that pulsar tests are complementary to each other as well as to other methods.

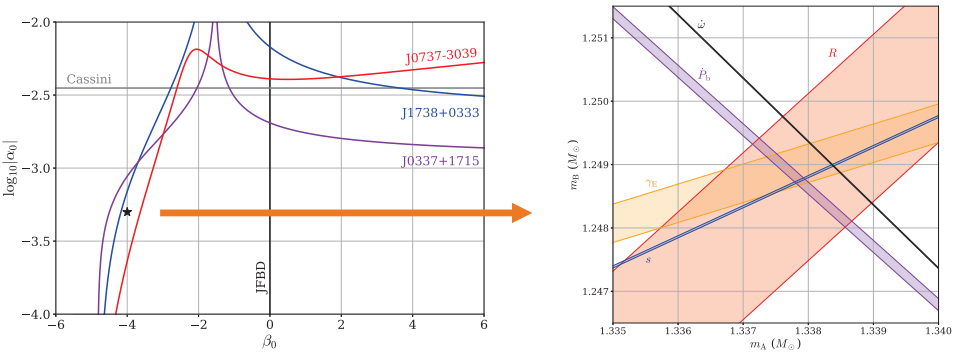

Fig. 11. (Left) Diagram displaying the α_0–β_0 parameter space of DEF gravity. Different experiments provide constraints shown as lines. Parameter space above a line is ruled out. In addition to constraints from the Cassini spacecraft, the figure includes constraints from limits on the existence of dipolar GW emission obtained from PSR J1738+0333, and constraints from the Triple System and the Double Pulsar as described earlier. GR is contained in this parameter space at $(\alpha_0 = 0, \beta_0 = 0)$. The Jordan-Fierz-Brans-Dicke (JFBD) theory is also contained along the vertical $(\beta_0 = 0)$-line. (Right) Every point in the left parameter space corresponds to a specific DEF theory and different realisations of the PK parameters. For a specific choice as an example, indicated by the star in the left figure, one obtains a mass-mass diagram that can be compared to Figure 7. Here, the PK lines fail to intersect in a single point and the specific theory should be rejected. This is already visible by the star's position in the left diagram, left and above the Double Pulsar line. This specific theory, however, would have passed other existing constraints as indicated. See Kramer et al. (2021) for details and references therein.

5. Conclusions

In this contribution, I have tried to summarise some recent key results in probing strong-field gravity using pulsars. In the past three years, the results have not only improved dramatically in precision, but also new effects could be studied. Pulsar continue to play an important role and complement other experiments which have only become possible in the recent years. This includes terrestrial GW detection as well as the imaging of black holes. What is unique about pulsars is the incredible precision that we can obtain in pulsar timing experiments. This is perhaps best demonstrated by the fact that we now have to consider the mass loss of a pulsar spinning down and the interior structure of neutron stars when we one to interpret our results.

Figure 12 attempts to bring the pulsar experiments into context with others. The chosen parameters plotted are a deliberate choice, as they clearly demonstrate that pulsars probe strong-field gravity, as pointed out by many authors in the past (e.g. Ref. 58). It also shows the size of the parameter space to be probed. Future telescopes, like the Square Kilometre Array (SKA), will contribute many more experiments and exciting constraints, as first results with MeerKAT clearly demonstrate.[43] The best is still to come.

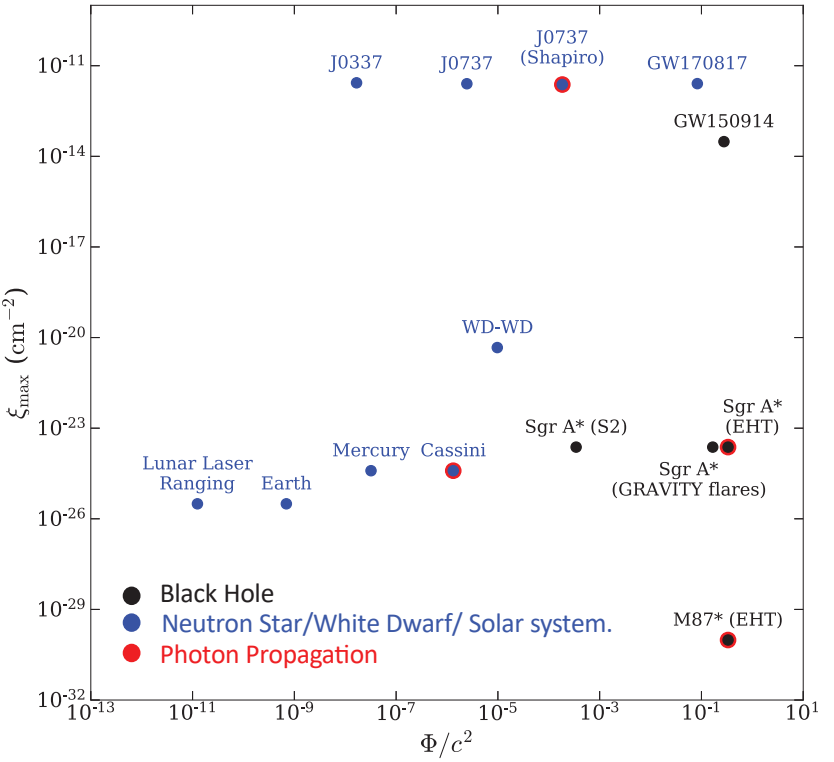

Fig. 12. Parameter space to compare different gravity experiments. While several possible combinations for 2-D diagrams are possible, none is complete in capturing all quantities relevant for gravity tests, and therefore each of them always gives an incomplete comparison. Adopting the plot from Kramer et al. (2021), we show the gravitational potential and the maximum spacetime curvature in a system, distinguishing between weakly and strongly self-gravitating masses amongst material bodies. Experiments that directly probe the coupling between gravitational and electromagnetic fields, i.e. the propagation of photons in a curved spacetime, are highlighted by red circles. We also mark experiments involving black holes as black dots. See Kramer et al. for a discussion of the choice of parameters and further details.

Acknowledgments

I am grateful to the organisers for inviting me to give the presentation. I thank my co-authors in the recent Double Pulsar work and in particular Norbert Wex for providing figures.

Dragging of inertial frames by matter and waves

Jiří Bičák
Tomáš Ledvinka
Institute of Theoretical Physics, Charles University
V Holešovičkách 2, Prague, Czech Republic

We review and analyze four specific general-relativistic problems in which gravitomagnetism plays the important role: the dragging of magnetic fields around rotating black holes, dragging inside a collapsing slowly rotating spherical shell of dust, compared with the dragging by rotating gravitational waves. We demonstrate how the quantum detection of inertial frame dragging can be accomplished by using the Unruh-DeWitt detectors. Finally, we shall briefly show how "instantaneous Machian gauges" can be useful in the cosmological perturbation theory.

Keywords: Einstein equations, Gravitomagnetism, Cosmology

1. Introduction

The relativistic effect of the dragging of inertial frames is associated with the profound criticism of the Newtonian concepts of absolute space and time by Mach. It was this criticism which appears to be one of the most influential for Einstein in the creation of general relativity. Ernst Mach (1838-1916) was born very close to Brno (like Kurt Goedel), today Czech Republic, formerly Austria-Hungary. He was professor at the Charles-Ferdinand University in Prague for 28 years and his influence on Prague physics indirectly also led to the stay of Albert Einstein in Prague.

Let us illustrate Mach's ideas by just one thought from his most influential work:

> [The] investigator ... must feel the need of ... knowledge of the immediate connections, say, of the masses of the universe. There will hover before him as an ideal insight into the principles of the whole matter, from which accelerated and inertial motions will result in the same way *(Science of mechanics)*.

Keeping the Mach tradition, on the 150th anniversary of the birth of Ernst Mach, the international conference was organized in September 1988 at the Charles University in Prague. The conference papers are published in the book [1], including several contributions by some leading scientists, philosophers and historians of science. The meeting was inspiring for Julian Barbour and Herber Pfister who, during the meeting, decided to organize the meeting on just Mach's principle. A comprehensive volume [2], based on the conference at Tübingen in July 1993, includes not

only many contributions by leading experts but also detailed texts recording many discussions.

Prague and Brno historically became attractive places for a number of influential scientists. Here we naturally recall the stay of Albert Einstein at the Karls-Ferdinand University from April 1911 until July 1912. His invitation to Prague was strongly supported by Mach's Prague pupils. Einstein wrote several pioneering papers showing the route to the final version of General Relativity, in particular in his answer to Max Abraham how a future theory of gravity should look like and, in the best known paper from Prague, he forecasted the light bending (we refer, e.g., to [3] for details). From the point of view of dragging, however, it is most interesting that it was in Prague where this phenomenon was first discussed, albeit based on Einstein's Prague preliminary version of general relativity. In his work [4] he considers a shell of matter and its influence on a mass point placed in its center as the shell starts to accelerate. In his words: *This suggests that the entire inertia of a mass point is an effect of the presence of all other masses, which is based on a kind of interaction with the latter. (This is exactly the same point of view that E. Mach advanced in his astute investigations on this subject.)*

Experiments

A nice experiment to measure rotational dragging was suggested by Braginsky, Polnarev and Thorne in 1984 [5]. The plane of a Foucault pendulum at the South Pole will be fixed with respect to "fixed stars" around which on average will not produce the dragging of the pendulum into the rotation. However, slowly rotating "very close" Earth does produce the effect of $\omega_{\rm drag} = 2J/R^3$, where J and R are angular momentum and radius of the Earth—see Fig. 1 left.

Most sophisticated experiment to confirm the dragging of inertial frames by the rotating Earth is, of course, Gravity Probe B.

The idea of placing a gyroscope on a free orbit around the Earth was conceived independently by L. J. Schiff and G. E. Pugh. In fact, the gyros (the "most spherical balls" produced by man) were four. There was also a telescope in the satellite with the gyros which was pointing towards the Guide Star—see Fig. 1. The launch occurred on April 20, 2004, and lasted 16 months. The first results appeared in April 2007 but the complete analysis was finished only in 2015 (see [6]). The measured frame dragging effect, -37.2 ± 7.2 mas y^{-1}, confirmed the general-relativistic prediction -39.2 ± 0.2 mas y^{-1}. The relatively large error was caused primarily by random patches of electric charge on rotors (gyros) and their housing.

A very nice experiment demonstrating the dragging effects on the nodal rates of 3 laser-ranged satellites using the Earth gravity field model produced by space mission GRACE was performed by the group of I. Ciufolini (see his plenary talk at this conference, contribution by D. Lucchesi in the Section PT5; see also the book on Gravitomagnetism by I. Ciufolini and J. A. Wheeler [7]).

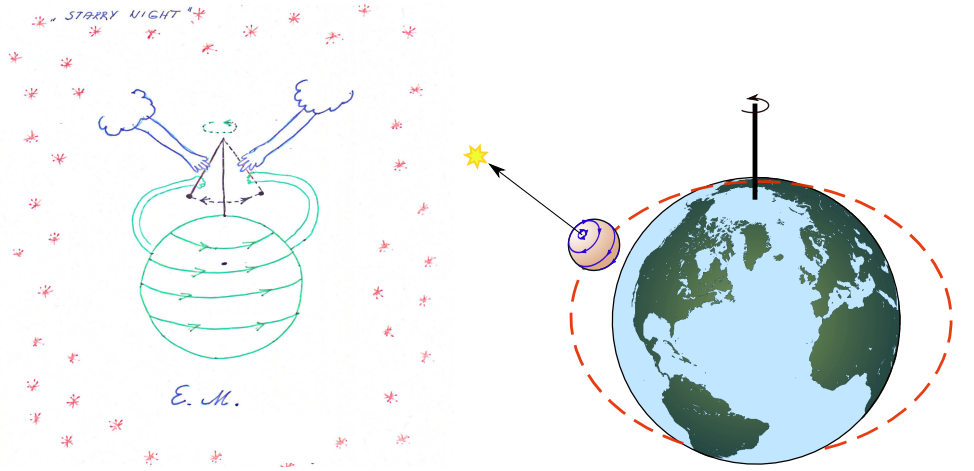

Fig. 1. *Left:* Dragging of the pendulum plane observed at the pole seen as a Machian competition between masses of distant stars and Earth. *Right:* A gyroscope on the polar orbit. Its axis changes direction both due to the geodesic precision ($\approx$ 6600mas y^{-1}) and due to frame dragging induced by Earth rotation ($\approx$ 39mas y^{-1}). This change with respect to a distant "guide" star was measured by the Gravity Probe B space experiment.

2. Magnetic fields, Meissner effect and dragging

Consider first the magnetic test field B_0 which is uniform at infinity and aligned with the hole rotation axis. Solution of Maxwell's equations on the background geometry of a rotating (Kerr) black hole with boundary condition of uniformity at infinity and finiteness at the horizon yields the field components; from these the lines of force are defined as lines tangent to the Lorentz force experienced by test magnetic/electric charges at rest with respect to locally non-rotating frames (preferred by the Kerr background field). The field lines are plotted in Fig. 2 for $a = 0.5M$ and in the extreme case when $a = M$. Notice that only weak expulsion occurs in the former case. There is a simple analytic formula for the flux across the hemisphere of the horizon, see [8–10]:

$$\Phi = B_0 \pi r_+^2 \left(1 - \frac{a^4}{r_+^4}\right), \tag{1}$$

where $r_+ = M + (M^2 - a^2)^{1/2}$. As a consequence of the coupling of magnetic field to frame-dragging effects of the Kerr geometry the electric field of a quadrupolar nature arises. Its field lines are shown in Fig. 3. Again the field lines are expelled: while even with $a = 0.95M$ it is still not very distinct, the expulsion becomes complete in the extreme case. One can demonstrate that total flux expansion takes place for all axisymmetric stationary fields around a rotating black hole [9, 10]. In Fig. 4 the field lines of a current loop in the equatorial plane are shown. The Meissner-type

effect arises also for charged (Reissner-Nordström) black holes as shown in Fig. 4 right.

Although extremely charged black holes ($e^2 = M^2$) are probably not important in astrophysics they may be significant in fundamental physics (as, for example, very special supersymmetric BPS states mass of which does not get any quantum corrections). In the charged case the electromagnetic perturbations are in general coupled to gravitational perturbations, the resulting formalism is involved. Nevertheless, one may construct explicit solutions, at least in stationary cases. From these the magnetic field lines follow as in the Kerr case. The magnetic field lines of a dipole located far away from the hole look like in a flat space, however, when the dipole is close to the horizon, the expulsion in the extreme case is evident (Fig. 4 right). Due to the coupling of perturbations closed field lines appear without any electric current inside; see [11] for details. There exist exact models (exact solutions of the Einstein-Maxwell equations) representing in general rotating, charged black holes immersed in an axisymmetric magnetic field. The expulsion takes place also within this exact framework - see [12–14]. Recently, the Meissner effect was also demonstrated for extremal black-hole solutions in higher dimensions in string theory and Kaluza-Klein theory. The question of the flux expulsion from the horizons of extreme black holes in more general frameworks is not yet understood properly. The authors of [15] "believe this to be a generic phenomenon for black holes in theories with more complicated field content, although a precise specification of the dynamical situations where this effect is present seems to be out of reach."

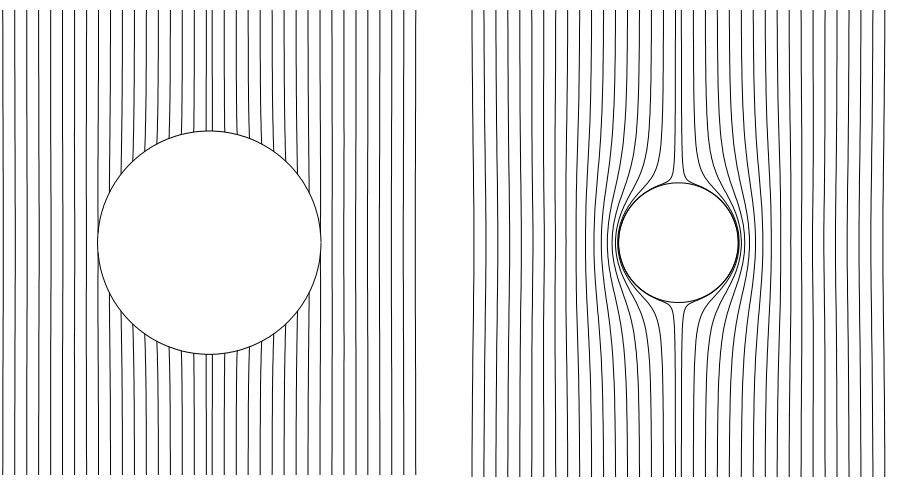

Fig. 2. Field lines of the test magnetic field uniform at infinity and aligned with the hole rotation axis. Two cases with a $= 0.5M$ (left) and $a = M$ (right) are shown.

The flux expulsion does not occur when the configuration is not axially symmetric. The electromagnetic field occurring when a Kerr black hole is placed in an

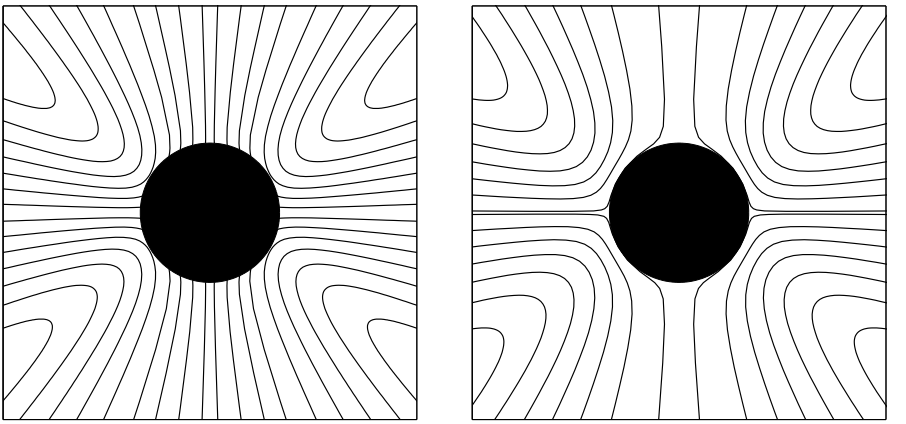

Fig. 3. Field lines of the electric field induced by the "rotating geometry" of Kerr black hole in asymptotically uniform test magnetic field; $a = 0.95M$ (left), and $a = M$ (right).

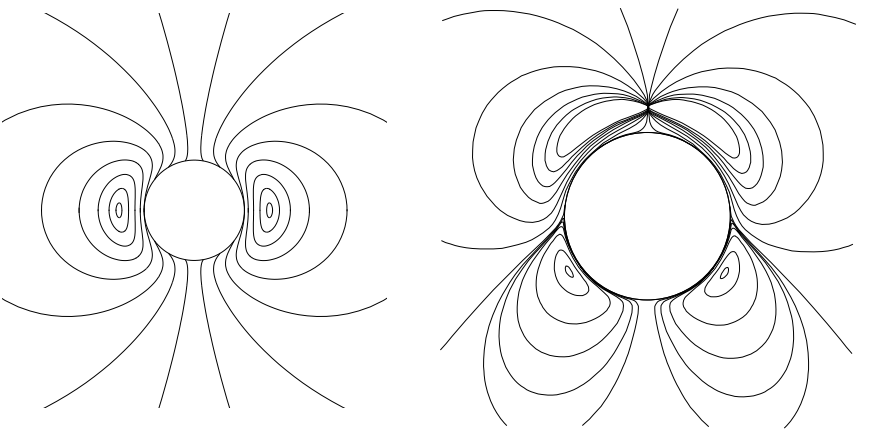

Fig. 4. *Left:* Field lines of the test magnetic field of a current loop in the equatorial plane of the Kerr spacetime with $a = 0.995M$. *Right:* Field lines of the test magnetic field of a magnetic dipole placed near the extreme Rissner-Nordström black hole.

originally uniform magnetic field without assuming the alignment of the direction of the magnetic field and the axis of symmetry of the black hole was first given in [16] (see also [17], [9]).

The properties of these "oblique" fields and their possible astrophysical relevance were already studied in the contribution [12] to the 5th Marcel Grossmann Meeting in Perth. They were then much developed in a number of important papers by V. Karas and his group appearing until today. Here we mention just few results and refer to the paper by V. Karas given in the Session PT5 of this MG16 meeting. One of the effects of the rotation on the fields which are asymptotically uniform and

perpendicular to the rotation axis is the dragging of field lines by rotation and, as a consequence, the appearance of critical points where the field vanishes as seen in Fig. 5.

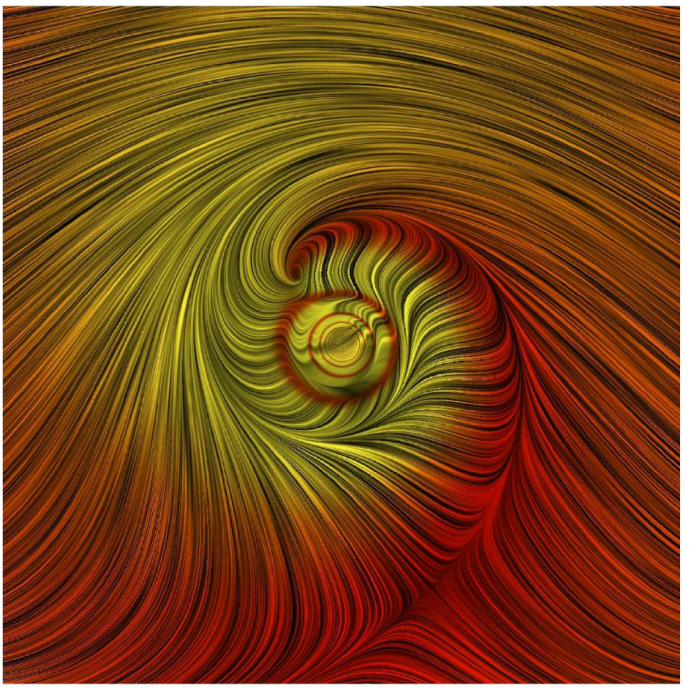

Fig. 5. Field lines in the equatorial plane of the Kerr black hole with color indicating the intensity of the field. Field lines which are asymptotically uniform and perpendicular to the rotation axis are dragged by rotation in vacuum (no conductive medium around). The horizon is in the center as a point. The critical point appears where the field vanishes (approx. at 11 hours). The figure is taken from [18].

In the most recent work, Karas *et al* realized that due to the presence of the plasma in the accretion flows and differential rotation even weak electromagnetic fields are crucial. Although magnetic fields within the accretion flow are turbulent in almost empty funnels around the rotation axis they can be organized on large scales and it is from here where they can accelerate the charged particles and produce collimated jets. Most recently, Karas and Kopáček conclude that inclined field (its oblique component) leads to more efficient acceleration and larger final Lorentz factors of escaping particles; see [19] and number of references therein. For an leading expert view on formation of jets and black-hole shadow in case of M87, see the contribution of R. Blandford to the Session PT5 of this MG16 meeting.

3. Dragging by a slowly rotating, collapsing spherical shell

A spherical shell in slow rotation and collapse (see Fig. 6) produces slightly perturbed Schwarzschild spacetime outside with the metric

$$ds^2 \doteq \left(1-\frac{2M}{r}\right)dt^2 - \left(1-\frac{2M}{r}\right)^{-1} dr^2 - r^2\,d\theta^2 - r^2\,(d\phi-\omega dt)^2\,. \qquad (2)$$

Here ω is the frame dragging potential given by $\omega = 2J/r^3$, J is fixed (small) total angular momentum of the shell. At the shell's surface $r = r_s$ is decreasing as shell collapses and $\omega_s = 2J/r_s^3$ is increasing. Notice (Fig. 6) that $\Omega = d\phi_s/dt$ is the angular velocity of the shell, $r_s^2\Omega^2$ is neglected.

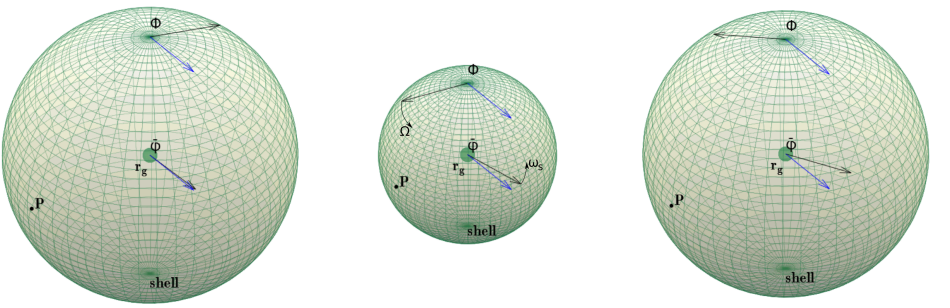

Fig. 6. Dragging of a gyroscope inside a slowly rotating, collapsing and rebouncing thin shell. Angular velocities of the vectors indicating the shell rotation Ω and the central inertial frame rotation ω_s are shown in the middle panel. See [21] for details. (Stills from the animation `https://utf.mff.cuni.cz/~ledvinka/psi/a1.mp4` by W. Barker.)

The spacetime inside the shell is flat in this approximation. Its metric $ds^2 = dt^2 - dr^2 - r^2\,d\theta^2 - r^2\sin^2\theta\,d\bar{\phi}^2$ can be joined across the shell to the metric outside. Because $d\bar{\phi} = d\phi - \omega_s\,dt$, the local *inertial* frames (LIFs) inside ($\bar{\phi}$ = const.) all rotate rigidly with the same angular velocity w.r.t. the observers at rest relative to infinity ("static observers" with ϕ = const). Thus $d\bar{\phi}/dt = 0$ implies the time-dependent angular velocity $d\phi/dt = \omega_s(t)$ of the rigid rotation.

As measured *in LIF's* own proper time the rate of rotation is

$$\frac{d\phi}{d\bar{t}} = \bar{\omega}_s = \omega_s \left.\frac{dt}{d\bar{t}}\right|_s . \qquad (3)$$

Static observers inside experience *Euler acceleration* (Coriolis $\sim \omega_s^2$, centrifugal $\sim \omega_s^2$) and the congruence of their *worldlines twists*. Rate of rotation $\bar{\Omega}_\tau$ of the shell itself measured in its proper comoving time τ is

$$\bar{\Omega}_\tau = \frac{3r_s}{4m_s}\omega_s = \frac{3J}{2m_s r_s^2}. \qquad (4)$$

Many details about this system can be found in Refs. [20–22].

4. Quantum detection of inertial frames dragging

Recently, we studied quantum Unruh-DeWitt detectors [23] and their suitability, at least in principle, for the detection of the dragging of inertial frames [24] and for the detection of a conicity of space [25]. We have shown, for the first time as far as we know, that the dragging of inertial frames (as well as conicity) can be observed by a quantum detector. We studied the response function of UdW detector placed in a slowly rotating shell which has flat spacetime inside and slowly rotating Kerr metric outside, as discussed in the previous Section. (Here we assume the shell to be stationary, not collapsing.)

The detector is a two-state system with energy gap Ω and the field-interaction Hamiltonian $\hat{H}(\tau) = \lambda\chi(\tau)\hat{\mu}(\tau) \otimes \hat{\Psi}(x(\tau))$, where $\chi(\tau)$ is switching function of the detector (ensuring that the interaction duration is $\Delta\tau = \pi/k$), $x(\tau)$ its worldline, $\hat{\mu}(\tau)$ its monopole momentum operator and λ is the coupling constant. We assume the detector-field system is in initial state $|0\rangle_D |0\rangle_\Phi$. Then the transition probability P to $|1\rangle_D$ is

$$P = \lambda^2 \mathcal{F} + O(\lambda^4). \tag{5}$$

The response function $\mathcal{F}$ of the detector turns out to be

$$\mathcal{F} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \chi(\tau_1)\chi(\tau_2) e^{-i\Omega(\tau_2-\tau_1)} W(x(\tau_1), x(\tau_2))\, d\tau_1\, d\tau_2, \tag{6}$$

where the Wightman function of the field is

$$W(x(\tau_1), x(\tau_2)) = {}_\Phi\langle 0| \hat{\phi}(x(\tau_2))\hat{\phi}(x(\tau_1)) |0\rangle_\Phi . \tag{7}$$

We show that the response function picks up the presence of rotation even though the spacetime inside the shell is flat and the detector is locally inertial. The detector can distinguish between the static situation when the shell is non-rotating and the stationary case when the shell rotates and the dragging of inertial frames, i.e. gravitomagnetic effects, arise. Moreover, it can do so when the detector is switched on for a finite time interval within which a light signal cannot travel to the shell and back to convey the presence of rotation.

The summary of the results for quantum detection of the dragging of inertial frames is taken from the publication [24]. (See also the contribution of W. Cong in the Session PT5 at MG 16.)

5. Dragging effects of gravitational waves

Rotating gravitational waves can also become a source of the dragging. The situation when the central frame is surrounded by rotating gravitational waves was for the first time modeled assuming the translational symmetry along z-axis in [26, 27]. Although this assumption implies unbounded energy of the gravitational waves and the spacetime is not asymptotically flat, the problem can be treated analytically as the master equation for the single function describing the gravitational wave has

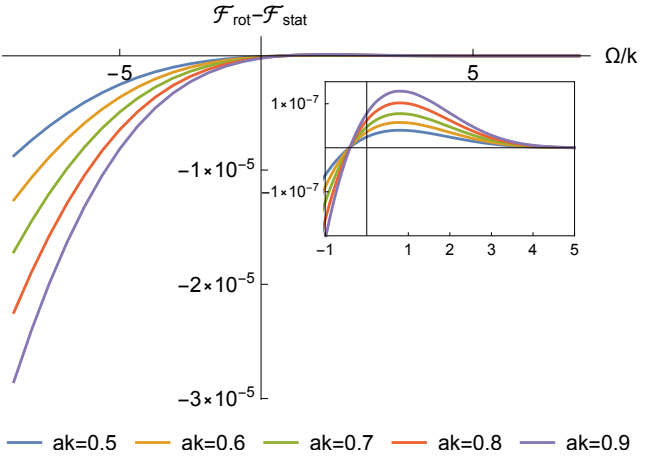

Fig. 7. Comparison with the detector in a static shell. Detector response function inside a slowly rotating shell is plotted for several values of the shell angular momentum $J = Ma$ appearing in the dimensionless parameter ak, where k is the frequency of detector switching function $\chi(\tau)$. The difference $\mathcal{F}_{rot} - \mathcal{F}_{stat}$ is plotted as a function of the energy gap Ω of the detector. Shell mass M and radius R radius satisfy $Mk = 1$, $Rk = 3$, detector is placed at $r_d = 0.5/k$ from the center.

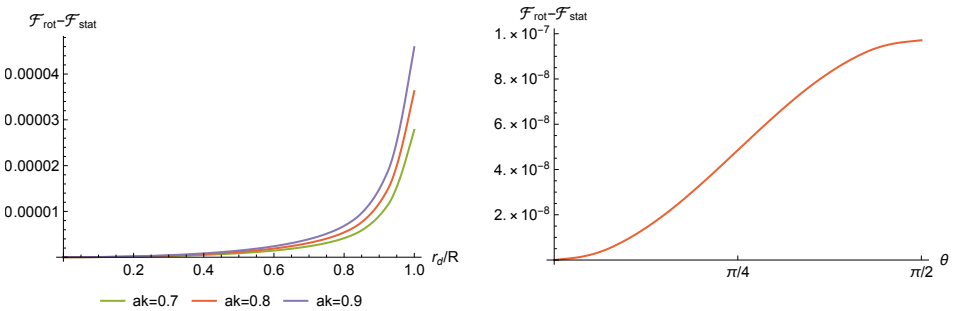

Fig. 8. Detected difference between rotating and static shell depends of the distance of the detector from the center (left) and on the spherical angular coordinate θ of the detector. Remaining parameters are described in Fig. 7.

the form of a flat-space wave equation $\Box\psi(t, \rho, \varphi) = 0$. Given a particular solution to this equation, other metric functions appearing in the line element

$$ds^2 = e^{2\gamma-2\psi}(dt^2 - d\rho^2) - W^2e^{-2\psi}(d\varphi + \omega\, dt)^2 - e^{2\psi}dz^2 \tag{8}$$

can be determined from the Einstein equations. In particular, averaging of their $t-\varphi$ component identifies $\langle\psi_{,t}\psi_{,\phi}\rangle$ as a source of the dragging of the inertial frames on the axis and for ψ in the form of a cylindrical shell the central frame rotation is then found in a closed form. The analogy with angular momentum transport in spiral galaxies is discussed in [27].

A similar problem permitting asymptotic flatness was then studied in [21, 28]. The gravitational waves are assumed to form a spherical shell described again by a single scalar function $\psi(t, \mathbf{x})$ satisfying flat-space wave equations $\Box\psi = 0$ which this time appears only as the first order approximation of the full Einstein equations. The spacetime metric (in which we now use signature $-+++$)

$$g_{\mu\nu} = \eta_{\mu\nu} + h^{(1)}_{\mu\nu} + h^{(2)}_{\mu\nu} + ... \tag{9}$$

is decomposed into a flat Minkowski metric $\eta_{\mu\nu} = \mathrm{diag}(-1, 1, r^2, r^2 \sin^2\theta)$ in spherical coordinates t, r, θ, φ, and the first and second-order perturbations $h^{(1)}_{\mu\nu}$ and $h^{(2)}_{\mu\nu}$. Then the first-order metric perturbations due to linearized gravitational waves appear the source of the second order perturbations

$$G^{(1)}_{\mu\nu}[h^{(2)}] = -G^{(2)}_{\mu\nu}[h^{(1)}, h^{(1)}], \tag{10}$$

where $G^{(2)}_{\mu\nu}[h^{(1)}, h^{(1)}]$ contains terms of the Einstein tensor $G_{\mu\nu}$ quadratic in the first-order perturbations.

Assuming the Regge-Wheeler gauge the function ψ then directly determines $h^{(1)}_{t\theta}, h^{(1)}_{t\varphi}, h^{(1)}_{r\theta}$, and $h^{(1)}_{r\varphi}$, with remaining first-order perturbations vanishing, and the effects of the linearized gravitational waves are then determined by the analysis of the second-order terms. To make space approximately flat for the central observer

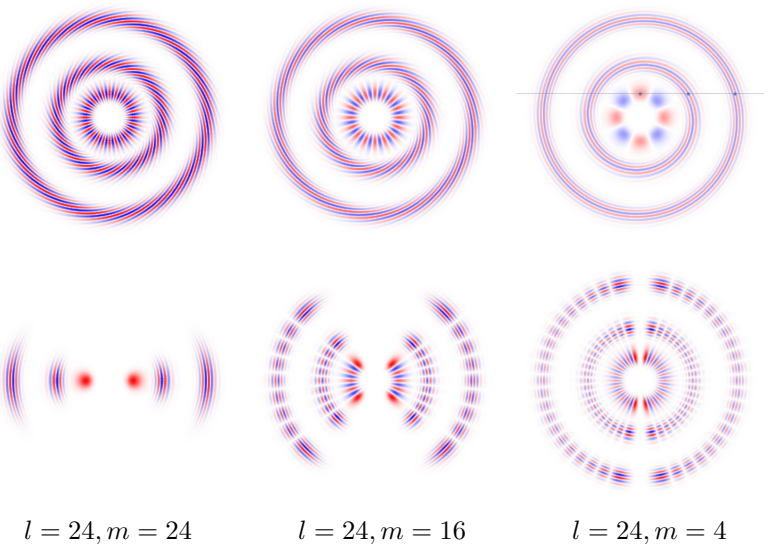

Fig. 9. Snapshots of the function ψ in the equatorial plane $\theta = \pi/2$ (top) and in the meridional plane $\varphi = 0, \pi$ (bottom) at three distinct times $t = 0, 2a, 4a$. The well-known behavior of spherical harmonics $Y_{lm} \sim \sin^{|m|}\theta$ means that for higher m the first order perturbations vanish not only near the center where we study the frame dragging but also along the z axis. The top right plot also shows the position of a null particle with $\mathbf{r} = a\hat{\mathbf{y}} + t\hat{\mathbf{x}}$ at given times to illustrate the localization of the wave at radii $r \approx \sqrt{a^2 + t^2}$. (We denote Cartesian unit vectors $\hat{\mathbf{x}}, \hat{\mathbf{y}}$, red/blue color indicates positive/negative ψ.)

and his inertial frame, $h^{(1)}_{\mu\nu}$ is assumed to vanish near the origin. Assuming a particular gauge, the quantity determining the central frame dragging can be determined from a quantity satisfying an elliptic equation, in a way similar to other situations. The central-frame rotation appears in the perturbation approach as a $l = 1, m = 0$ component in the expansion of $h^{(2)}_{\mu\nu}$ into mutually orthogonal spherical tensor harmonics. Then a projection of Eq. (10) into the relevant $m = 0$ tensor harmonic function resembles an averaging and yields

$$\frac{1}{2}\left[h_0^{(2)\prime\prime} - \frac{l(l+1)}{r^2}h_0^{(2)} - \dot{h}_1^{(2)\prime} - \frac{2}{r}\dot{h}_1^{(2)}\right] = \frac{1}{l(l+1)}\int_0^{2\pi}\int_0^{\pi} G^{(2)}_{t\varphi}[h^{(1)}, h^{(1)}]\partial_\theta Y_{l0}\; d\theta\; d\varphi,$$

where $h_0^{(2)}$ determines $h^{(2)}_{t\theta}, h^{(2)}_{t\varphi}$, and $h_1^{(2)}$ determines $h^{(2)}_{r\theta}, h^{(2)}_{r\varphi}$ components of the second-order metric perturbations. Dots and primes denote the time and radial derivatives. The rotation of the central frame $d\tilde{\varphi} = d\varphi - \omega_0 dt$ appears as $h^{(2)}_{t\varphi} = -\omega_0\, r^2\, \sin^2\theta$, so it is determined by the behavior of $h_0^{(2)}$ at $r = 0$. Using a global change of coordinate $\varphi \to \varphi + \delta\varphi^{(2)}(t, r)$, we can set

$$h_1^{(2)} = 0, \quad \text{i.e.,} \quad h^{(2)}_{r\varphi} = 0. \tag{11}$$

Near the center we then have the Minkowski metric in spherical coordinates with the dominating perturbation corresponding to the slow rigid rotating of the central frame with angular velocity $\omega_0(t)$. Fixing the gauge condition (11), $h^{(2)}_{1\,l=1,m=0} = 0$, prohibits any radial dependence of an additional coordinate transformation $\varphi \to \varphi + \delta\varphi^{(2)}(t, r)$ and the angle φ in the center and thus also the central frame rotation ω_0 is determined *unambiguously* with respect to spatial infinity. We find

$$\omega_0 = \frac{1}{4\pi}\iiint R^{(2)}_{t\varphi}[h^{(1)}, h^{(1)}]\;\frac{\sin\theta}{r} dr\, d\theta\, d\varphi. \tag{12}$$

To investigate further a particular closed-form solution ψ of the wave equation, it has been chosen in the form of a shell of null radiation converging toward the origin, bouncing at the minimal radius $r \approx a$, and then expanding back to infinity (see Fig. 9). This allowed us to evaluate the integral (12) and find the explicit (though lengthy) formula for ω_0. Assuming $l \gg 1$ it simplifies to

$$\omega_0(t) \doteq \frac{\omega_0^{\max}}{\left(1 + \frac{t^2}{a^2}\right)^{3/2}}. \tag{13}$$

In the same limit, we show in [21] that the frame dragging is determined by the angular momentum of the gravitational wave L_z and that the long exact formula can be approximated by $\omega_0^{\max} \doteq 2L_z/a^3$. The angular momentum of the linearized gravitational waves is defined using the effective stress energy tensor

$$L_z = -\int T^{\text{eff}}_{t\varphi}\; d^3x, \qquad T^{\text{eff}}_{t\varphi} = \frac{1}{8\pi}G^{(2)}_{t\varphi}[h^{(1)}, h^{(1)}]. \tag{14}$$

We can see that (12) and (14) differ by a factor r^3 inside the integral. This explains why the approximate relation (13) holds: because for $l \gg 1$ the function ψ is localized around a thin shell with radius $r(t) \doteq \sqrt{a^2 + t^2}$ (see Fig. 9), the factor r^3 can

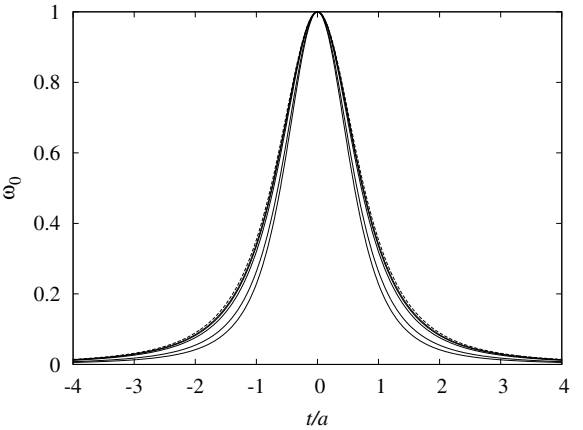

Fig. 10. The dependence of the normalized angular velocity of the central inertial frame $\omega_0(l,1;t)/\omega_0(l,1;t=0)$ on the parameter $l = 2, 3, 10, 20, 30$ (from inside to out). The dependence (13) is shown as a dashed line.

be put in front of the integral. The time dependence of $\omega_0(t)$ on the parameter l is shown in Fig. 10.

In an asymptotically flat spacetime we have two special flat-space worldlines categories — the one of the central observer and that of a cautious observer who slowly retreats to $r \gg a$ so that she never meets significant metric perturbations. The discrepancy between the orientation of the gyroscopes following these worldlines

$$\Delta\varphi_0 = \int_{-\infty}^{\infty} \omega_0(t)\, dt \tag{15}$$

can be seen as an illustration of the dependence of the parallel transport on the chosen worldline. In Fig. 11 we illustrate $\Delta\varphi_0$ as an obvious implication of the spacetime curvature due to the rotating gravitational waves. Thus, although the immediate value of ω_0 involves instantaneous effects, its integral (15) representing the total rotation of the central gyroscope is a well-defined observable quantity. In the approximation $l \gg 1$ we then obtain $\Delta\varphi_0 \doteq 2a\omega_0^{\max} \doteq 4L_z/a^2$. Such a simple relation is not available for dragging by a massive rotating shell, because its dynamics is not as unambiguous as that of gravitational radiation.

6. On the dragging of inertial frames and Mach's principle in cosmology

In our treatment of the dragging of inertial frames in a cosmological context we shall mostly confine ourselves to the linear (cosmological) perturbation theory, rather than to exact models. Our inspiration will be Mach's principle as generally formulated by Hermann Bondi in his classical book [29]: *...all motions, velocities, rotations and accelerations are relative; local inertial frames are determined through*

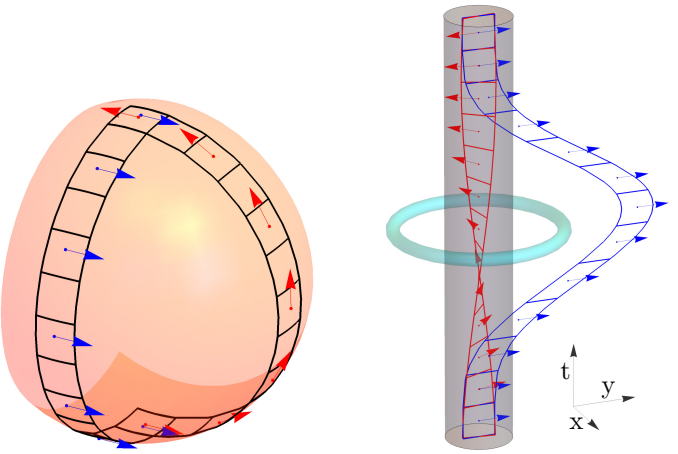

Fig. 11. *Left:* The fundamental dependence of parallel transport on the chosen path is usually demonstrated on a spherical surface naturally embedded in three-dimensional flat Euclidean space. Here we use neighborhoods of two meridians as an example of two approximately flat patches which yield mismatch when vector from the south pole is extended into both patches. *Right:* In our spacetime with rotating gravitational waves we also have two approximately flat patches. The spacetime is asymptotically flat which in the figure is symbolized by the blue "ladder" with arrows indicating "fixed" direction of a gyroscope. Because the gravitational waves do not reach the center, there is also approximately flat region near the center. Its worldtube is depicted as a gray cylinder. The gravitational waves are shown at the moment they are the strongest ($t = 0$) as a blue torus encircling the central observer. The rotation of the central inertial frame (and gyroscopes there) is illustrated by the twist of the red spacetime-coordinate "ladder" and the gyroscope orientation. The mismatch of gyroscope directions at the top demonstrates the meaning of Eq. (15) as the implication of a particular form of spacetime curvature accompanying the rotating gravitational wave.

distributions of energy and momentum in the Universe by some weighted averages of the apparent motions.

We started to realize such a "Machian program" in [30]. We first analysed frame-dragging effects due to slowly, rigidly rotating, but collapsing or expanding spheres in the (inhomogeneous) Lemaître-Tolman-Bondi universes, and we analysed the dragging effects of the vector perturbations of the FLRW universes described in a special gauge such that three (momentum) constraint equations enabled us to determine instantaneously metric perturbations h_{0k} $(k = 1, 2, 3)$ in terms of energy-momentum perturbations δT_{0k} and show how such averages are to be taken. In closed universes a linear combination of six Killing vectors (three rotations plus three quasitranslations) may be added to the h_{0k}. We also obtain the solutions of the three constraint equations when angular momenta corresponding to the three rotations and quasimomenta corresponding to the three quasitranslations of the sources (determined by δT_{0k}) are given. No absolute rotations exist in closed universe, only differences of rotation rates are determinable — in accord with Mach's ideas that 'all motions are relative'. (If the velocities of the bodies, described by perturbations of perfect fluid, are given, the metric perturbations are determined

uniquely.) The last result is related to the fundamental fact that six globally conserved quantities, corresponding to the six Killing vectors in a FLRW universe, must all vanish if considered for the whole closed universe.

It was, among others, an attempt to understand Mach's principle in cosmological perturbation theory, which inspired us to formulate conservation laws even for large perturbations with respect to curved backgrounds [31]. The resulting 'KBL superpotential' (using the designation by Julia and Silva in their profound analysis [32]), was found, after applying certain natural criteria, to be unambigous and most satisfactory in spacetimes with or without a cosmological constant, in any spacetime dimension. It also found applications in various studies of generation of cosmological perturbations (see [33] for references). For the recent generalization to the Horndeski theory, see [34].

In a more recent paper [33] we studied general linear perturbations of the FLRW universes from a 'Machian perspective'. This led us to investigate both rotations and accelerations of local inertial frames in perturbed universes. We first introduced congruences of cosmological observers' worldlines, defined their acceleration, rotation (twist, vorticity), shear and expansion in general, and then considered perturbed FLRW models ($g_{\mu\nu} = g^{\mathrm{FLRW}}_{\mu\nu} + h_{\mu\nu}$). We found that un-accelerated and non-rotating local inertial frames (LIFs) are determined by $h_{00,l}, h_{0l,m}, h_{0l,0}$.

We developed all the perturbed Einstein equations in a general gauge 'ab initio', without assuming harmonic decompositions. Introducing the standard conformal time in FLRW universes, putting tildas over all the perturbation quantities, introducing the traceless part of h^l_k and notation

$$\tilde{h}^l_{Tk} = \tilde{h}^l_k - \tfrac{1}{3}\delta^l_k \tilde{h}^n_n \,, \qquad \mathcal{T}_k = \nabla_l \tilde{h}^l_{Tk}, \qquad \mathcal{K} = \tfrac{3}{2}\dot{a}\tilde{h}_{00} \; + \tfrac{1}{2}a\dot{\tilde{h}}^n_n - \nabla_l \tilde{h}^l_0, \tag{16}$$

where ∇_l is the covariant derivative associated with the spatial FLRW background metric f_{kl}, a is the expansion factor, dot the derivative w.r.t. standard cosmological time t whereas the prime denotes the derivative with respect to conformal time $\eta, adt = d\eta$. Using $\nabla^2 = f^{kl}\nabla_{kl}$, $k = 0, \pm 1$ for the curvature index and $\mathcal{H} = aH$, H being the standard Hubble parameter, we find Einstein's equations for perturbations to obtain the form

$$a^2\kappa\delta\tilde{T}^0_0 = a^2\delta\tilde{G}^0_0 = \tfrac{1}{3}\nabla^2\tilde{h}^n_n + k\tilde{h}^n_n - 2\mathcal{H}\mathcal{K} - \tfrac{1}{2}\nabla_k\mathcal{T}^k, \tag{17}$$

$$a^2\kappa\delta\tilde{T}^0_k = a^2\delta\tilde{G}^0_k = \tfrac{1}{2}\nabla^2\tilde{h}_{k0} + k\tilde{h}_{k0} + \tfrac{1}{6}\nabla_{kl}\tilde{h}^l_0 + \tfrac{2}{3}\nabla_k\mathcal{K} - \tfrac{1}{2}\left(\mathcal{T}_k\right)', \tag{18}$$

$$a^2\kappa\left(\delta\tilde{T}^0_0 - \delta\tilde{T}^n_n\right) = a^2\left(\delta\tilde{G}^0_0 - \delta\tilde{G}^n_n\right) = \nabla^2\tilde{h}_{00} + 3a\left(\frac{1}{a}\mathcal{H}\right)'\tilde{h}_{00} + \frac{2}{a}\left(a\mathcal{K}\right)', \tag{19}$$

and

$$a^2\kappa\left(\delta\tilde{T}^l_k - \tfrac{1}{3}\delta^l_k\delta\tilde{T}^n_n\right) = a^2\delta\tilde{G}^l_{Tk} = \ldots \,. \tag{20}$$

We do not write down fully the last equation since it describes waves and is not important for the determination of LIFs.

To see how the LIFs can be determined by surrounding matter instantaneously on certain time-slices we use some specific gauges which we call the "Machian gauges". We give three examples of such gauges. For example, by putting $\mathcal{T}_k = 0$ and $\mathcal{K} = 0$, the first three equations become (hyper-) elliptic and the quantities determining LIFs can be found instantaneously when the (perturbations of) matter distribution are given. The gauge conditions $\mathcal{T}_k = 0$, fixing spatial coordinates, are associated with the "transverse-traceless" gauges in the linearized gravity and minimal-shear condition in numerical relativity. We assume these conditions to be valid in all three Machian gauges. In the first Machian gauge we choose the time slices to be so that $\mathcal{K} = 0$. This implies the "constant mean curvature slices", and it coincides with Bardeen's uniform-Hubble expansion gauge. In other two Machian gauges, together with the same gauge condition on spatial coordinates, we require "uniform-intrinsic scalar curvature condition" and the "minimal-shear hypersurface condition" (called the Poisson gauge by Bertschinger in 1995). In [33] these gauges are discussed in detail. In particular it is shown that they admit much less residual freedom than the synchronous gauge, frequently used in cosmology.

These Machian gauges have been considered in the group of D. Wiltshire, in particular, in [35], in the review [36] and, most recently, by his students M. Williams [37] and R. Gaur [38] in the context of the Post-Newtonian Cosmology.

We believe that dragging effects and Machian ideas will remain the source of inspiration.

Probes of the progenitors, engines and physics behind stellar collapse

SN are one of the most powerful explosions in the universe and astronomers have invoked the collapse of a stellar core down to a neutron star as a potential power source behind these cosmic blasts. The current paradigm behind core-collapse SN relies on convection in the region just above the newly formed neutron star. This engine was driven and confirmed by observations. We review this observational evidence, and the potential for further observational constraints in this paper.

Keywords: SNe; neutron star; black hole

PACS numbers: 97.60.Bw, 97.60.Jd, 97.60.Lf

1. Core-Collapse SNe (CCSNe)

The SN field was established Baade and Zwicky coined the term "Super-nova" (SN) to explain the most powerful class of novae.[1] Shortly thereafter, Zwicky also proposed what has become one of the standard energy sources behind these cosmic explosions: the collapse of the core of a massive star down to a neutron star.[2] Zwicky argued that this core-collapse SNe (CCSN) mechanism would tap the potential energy released when the core of a massive star collapsed down to a neutron star. The details of how this works has taken nearly 90 years to work out.

Over the past 8-9 decades, scientists have continued to refine the basic model behind CCSN. Stellar models focused on identifying which stars would produce cores that would collapse down to SNe. Stars are powered by nuclear fusion in their cores and the most massive stars can undergo a series of nuclear burning phases, where the ashes of the previous phase are fused in the next burning phase, until an iron core is produced. Iron is maximally compact, its fusion does not generate energy and the contraction of the iron core causes electron capture and the collapse of the core. This collapse only stops when the core forms a proto-neutron star, realizing the engine proposed by Zwicky.

1-dimensional simulations of stellar evolution have allowed astronomers to piece together the detailed evolution of these successive burning stages. This evolution is capture in a diagram developed by Kippenhahn.[3] Figure 1 shows the Kippenhahn diagram describing the evolution of a $22\,M_\odot$ star.[4] These Kippenhahn diagrams contain a wealth of information. The top curve denotes the mass of the star as a

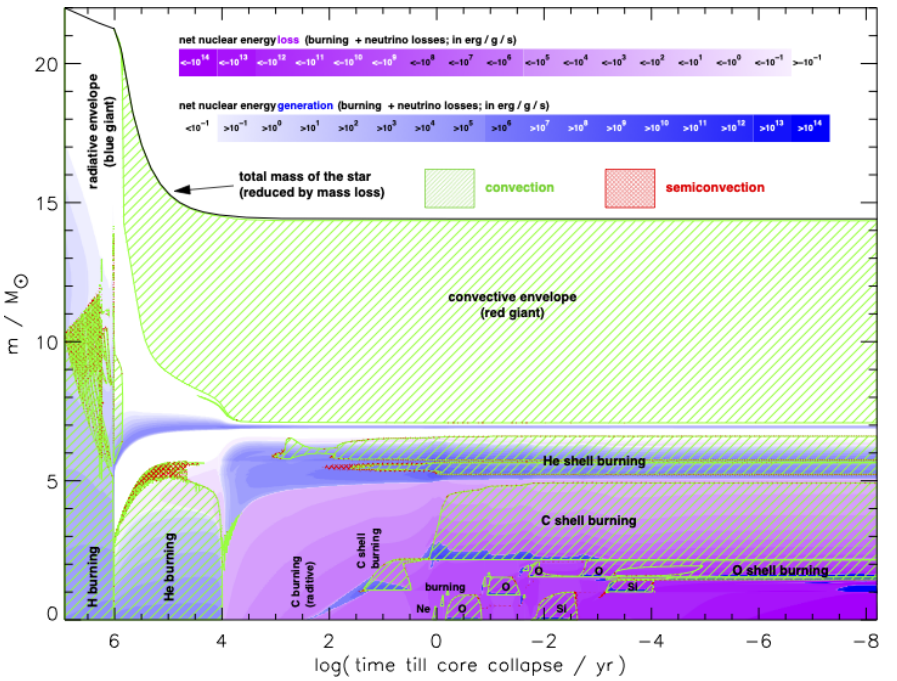

Fig. 1. Enclosed mass vs. time before collapse of a 22 $M_\odot$ star. This diagram encapsulates the entire life of the star. It color codes energy deposition from fusion and energy losses from neutrinos. Hash marks denote convection and the top line denotes mass loss from winds.

function of time. The lower-left corner shows the hydrogen burning core which lasts until a million years prior to collapse. The next phase is the helium core burning phase that lasts until 10,000 y prior to collapse. At the end of helium core burning, the core collapses and helium begins to fuse in a shell layer above this core. In the last 100 y, the star goes through a series of carbon, oxygen and silicon core and shell burning, building up an iron core. The timescales and the evolution of the core can all be learned from this diagram.

This iron core is supported by a combination of thermal and electron-degeneracy pressure. As the mass of this iron core continues to grow, the core contracts. Ultimately, electrons in the core capture onto protons, removing the support pressure and causing a runaway collapse. This collapse proceeds until the core reaches nuclear densities and neutron degeneracy pressure and nuclear forces halt the collapse. The collapse of the iron core to this proto-neutron star releases nearly 100 times the energy needed to drive the observed explosion. When the collapse halts, it can produce a strong bounce and preliminary 1-dimensional calculations of this collapse phase produced weak explosions.[5] These explosions did not match the observed energies and were missing critical pieces of physics, most importantly, the neutrino

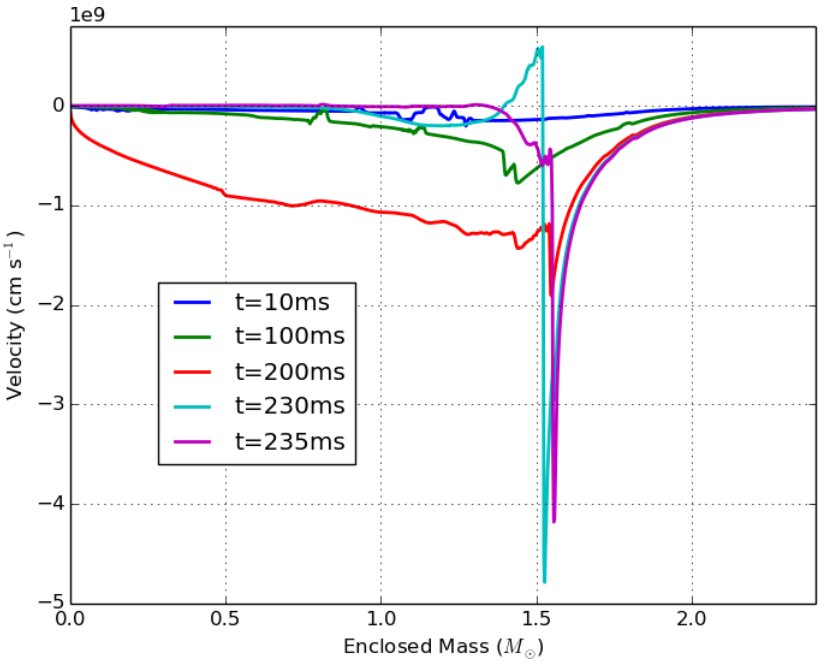

Fig. 2. Velocity vs. enclosed mass of the collapse, bounce and stall of a bounce shock for a 15 $M_\odot$ star at a series of times in the collapse. As the core begins to collapse, the infall accellerates until bounce. Shortly after the bounce, the bounce shock stalls. The different lines show this evolution.

physics. In the bounce, most of the potential energy converted into neutrinos and, as long as the neutrinos are trapped, the bounce shock propagates outward. But when the neutrinos in the outward-moving shock can escape, much of the bounce energy is lost, causing this shock to stall. Figure 2 shows the velocity evolution of a sample core collapse, bounce and bounce shock stall.

Although scientists realized that tapping the neutrinos leaking out of the core would be one way to revive the explosion, the diffusion of neutrinos was too slow to revive the shock. The first mention of convection in CCSN focused on using this convection to transport the neutrinos to the edge of the proto-neutron star, allowing the neutrinos to more quickly deposit their energy into the stalled shock.[6,7] Although this convection can play a role in our models, this is not the convection that has formed the basis for the current paradigm in SNe. The critical convection behind the convection-enhanced neutrino-driven SN engine is convection above the proto-neutron star, in the region between the edge of the proto-neutron star and the stalled shock. This paper focuses on this currently favored convection-enhanced paradigm, both the observational evidence leading to its development (Sec. 2) and the current and ongoing measurements confirming this paradigm (Sec. 3).

2. Observed Asymmetries and the Birth of the Convective Paradigm

Due to the difficulty in including all of the physics in SN models, most SN-engine simulations until the 1990s were 1-dimensional. But, with better observations of SNe and their remnants, astronomers began to demonstrate that these explosions were anything but spherically-symmetric.= In this section, we review the observations the led to the development of the convection-enhanced neutrino-driven SN explosion engine that is the current paradigm for normal SNe.

2.1. *Observed Asymmetries that Drove the Convective Paradigm*

Observations of SN remnants, both ejecta and remnant, have long argued for an asymmetries in the SN engine. Large asymmetries have been observed in many of the observed SN remnants. In spherically symmetric models, the ejecta from the SN is expected to follow the same elemental abundance layered distribution that was produced in the stellar evolution with the iron peak elements in the center with the elements getting lighter as we move out in the ejecta. The distribution in the Cassiopeia A SN remnant not only displays heavier elements further out than lighter elements but also a sizable amount of mixing,[8] suggesting an asymmetry in the explosion mechanism. Determining whether this mixing was due to asymmetries in the explosion or in the blastwave propagation through the surrounding medium,[9] along with limitations in the requirements to observe these abundances (shock-heating requirements, out-of-equilibrium atomic physics), limited the constraints these observations placed on the engine.

Another observational indication that the explosion mechanism in core collapse had large asymmetries is the observed distribution pulsar velocities with some pulsars moving faster than $1000\,\mathrm{km\,s^{-1}}$.[10] The high velocities observed in the pulsar velocity distribution suggests that these "kicks" are imparted onto the neutron stars during formation. One of the leading mechanisms behind these kicks is the asymmetric explosion of a SN engine. In this mechanism, the newly-formed compact remnant is kicked in the opposite direction of the ejecta conserving linear momentum. But a wide range of models have been proposed to explain these kicks (for a review, see[11]) and many don't require an asymmetric SN explosion. Like SN remnants, although suggestive, pulsar velocities were not definitive proof of supernova asymmetries.

Observations of SN 1987A provided this evidence and drove SN engine theorists to begin to actively gain new insight into the CCSN engine. First and foremost, SN 1987A provided essential confirmation of the basic core-collapse idea. Although theorists had argued that a CCSN could be produced by stars above $\sim 10\,\mathrm{M}_\odot$, no definitive proof existed until 1987, when a star in the Large Magellanic Cloud collapsed. Prior to its collapse, this star had been observed and its identification of this progenitor, Sanduleak -69 202, providing the first irrefutable evidence that

at least some SNe are produced through the death of massive stars.[12] In addition, a burst of neutrinos were detected from this nearby SN at a rate that can only be produced with a compact object (either formation or a merger).[13,14] These two observations definitively demonstrated that at least some SNe are produced by the core-collapse to a compact object of a massive star.

Although SN 1987A solidified the foundation of the CCSN engine, it also raised a number of a new issues: the star was a blue, not a red, supergiant as predicted by models (we now believe this to be due to binary effects), the gamma-rays from the decay of radioactive nickel appeared much sooner than expected and the line profiles from these gamma-rays and infra-red lines (of the iron) were both broader than expected as well as being redshifted (instead of blue-shifted). From infra-red to gamma-rays, SN 1987A was showing the limitations of our spherically symmetric model. Scientists immediately realized that by artificially mixing out nickel produced in the innermost ejecta of 1-dimensional models, they could explain the early rise time of gamma-ray signal.[15] However, this artificial mixing did not explain the redshifted lines. In addition, producing the extent of mixing needed to explain the observations was difficult to achieve with simple Rayleigh-Taylor mixing developing in a symmetric shock propagated through the stellar profile.[16,17]

These difficulties led scientists to turn their attention to the engine itself and, instead of focusing on convection in the proto-neutron star, they focused on the region between the edge of the neutron star and the stalled shock. The unstable entropy gradient produced as the shock stalled led to convection in this region.[18,19] After a few preliminary studies, the first 2-dimensional calculations found this convection could change the fizzle produced by a 1-dimensional model into a strong explosion.[20] These instabilities evolved into low-mode convection which could both facilitate the extensive mixing and explain the pulsar kicks.[21] Three-dimensional models followed soon after,[22] including 3-dimensional explosion models that demonstrated that very low-mode convection could also explain the redshifted lines features.[23,24] This initiated a broad set of scientific work studying the SN engine that we will discuss in the next section.

2.2. *Evolution of the SN Engine*

Before we discuss the details of the convective engine, let's review the basic steps behind this leading paradigm:[25]

(i) **Onset of Collapse:** The iron core of a massive star because so massive that it compresses to densities that cause electrons to capture onto protons, removing electron degeneracy pressure. This causes further compression and accelerates the electron capture, driving a runaway collapse (Fig 2).

(ii) **Bounce** This runaway collapse proceeds until the core reaches nuclear densities where nuclear forces and neutron degeneracy pressure halt the collapse, causing

the infalling core to bounce. The bounce shock moves out through the star (Fig 2).

(iii) **Stall of the Shock:** Most of the energy in the shock is stored in neutrinos. When the neutrinos are no longer trapped in the core, the shock loses energy and stalls at ∼100-200 km (Fig 2).

(iv) **Convective Engine:** The region between the compact core and the stalled shock is unstable to a range of instabilities, including Rayleigh-Taylor convection. This convection transports energy deposited at its base and transfers it outward to push against the infalling star. At the same time, it transports mass piling up at the stalled shock and allows it to convect to the core, releasing further potential energy and reducing the pressure that must be overcome at the stalled shock. These two effects, not modeled in 1-dimensional models, make it easier to drive an explosion (Fig 3).

(v) **Shock Launch:** When the pressure in the convective engine can overcome the ram pressure of the infalling star, an explosion is launched. The shock will be highly asymmetric (Rayleigh-Taylor tends to evolve to the largest mode possible in a convective region, Standing Accretion Shock Instabilities also produce low-mode convection). This aspherical shock will allow further accretion after its launch, allowing further energy deposition. But the neutrino-energy deposition will decrease as the density above the proto-neutron star decreases.

Here we focus most of our discussion on the convective engine. Figure 3 shows a 2-dimensional slice of a 3-dimensional simulation. This image shows both the high-entropy upflows and the low-entropy downflows. During the 15-20 s after the first 2-dimensional simulation of this engine, most studies focused on reproducing these results. Additional instabilities were studied, most notably the standing accretion shock instability (SASI).[26] The primary difference between these two mechanisms is the growth time of the instability and the latter interpretation of the convective motions is favored by models where the turbulence growth is slow. Simulations with more rapid convective growth argue for Rayleigh-Taylor instabilities.

The growth time is a key feature in the final result, both in the explosion energy and the remnant mass, so understanding this convection is critical. Unfortunately, a number of numerical artifacts make it difficult to model this convection. We can not resolve the convection and artificial viscosity (either explicitly state in smooth particle hydrodynamics or implicit in the numerical advection of grid-based codes). This growth time can be estimated analytically and we can test our calculations against this analysis. The growth time of this convection is on order of the inverse of the Brunt-Väisäla frequency:

$$T_{\rm growth} = \sqrt{-\omega_{\rm BV}^2} \tag{1}$$

where ω_{BV} is given by:p

$$\omega_{\rm BV}^2 = -g_{\rm eff}\left(\frac{1}{\rho}\frac{\partial \rho}{\partial r} - \frac{1}{\rho c_s^2}\frac{\partial P}{\partial r}\right) \tag{2}$$

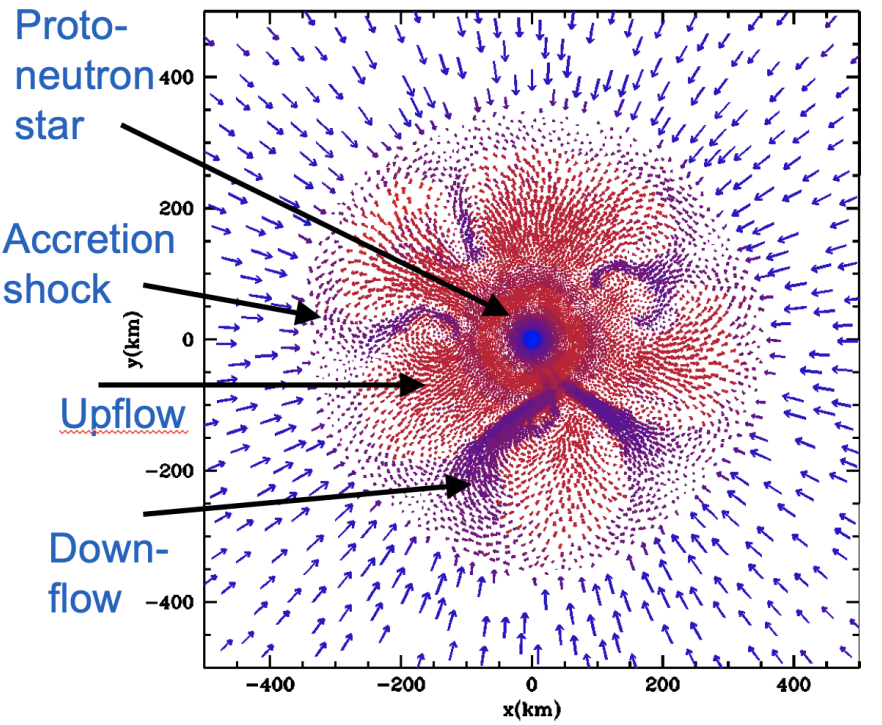

Fig. 3. Slice of a 3-dimensional convective engine. In this simulation, the convective region now extends to 300 km. The color-coding denotes entropy with red being high entropy and blue being low entropy. The vectors denote velocity magnitude (length) and direction. The proto-neutron star is in the inner 30 km. Material piles up at the top of the convective region near the stalled shock and the flows down in streams to the core.

where c_s is the sound speed, P is the pressure and $g_{\rm eff} = -\partial\Phi/\partial r + v_r \partial v_r/\partial r$ is the effective gravity with Φ is the gravitational potential and v_r is the radial velocity. For the region above the proto-neutron star, the growth time can be approximated by:

$$T_{\rm growth} \approx \sqrt{-\frac{GM_{\rm PNS}}{r_{\rm PNS}^2}\frac{\Delta S}{S\Delta r}} \tag{3}$$

where G is the gravitational constant, $M_{\rm PNS}$, $r_{\rm PNS}$ are mass and radius of the newly-formed, proto-neutron star, S is the entropy and ΔS is the change in entropy of a distance Δr in the region between the proto-neutron star and the stalled shock. With these conditions, we find the post-bounce convective growth-time to be on order of a few milliseconds.[25] All current calculations have growth times that are much longer than this prediction.

It could be that this simple analysis underestimates the growth time. We can further test the growth term by comparing our growth times to different prescriptions

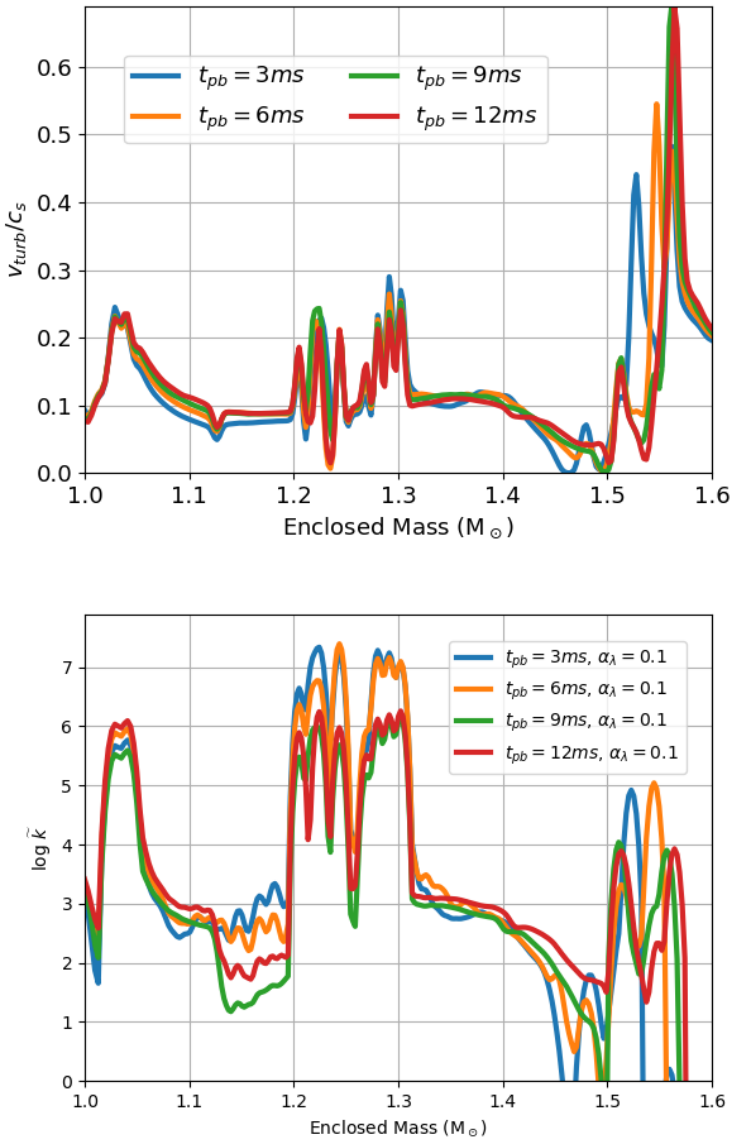

Fig. 4. Growth of turbulence, sound speed from mixing-length theory[27] and turbulent energy from a Reynolds Averaged Navier Stokes solution.[28] Strong turbulence develops in less than 10 ms.

(Fig 4) developed both in astrophysics (mixing-length theory[27]) and engineering (a Reynolds Averaged Navier Stokes solution[28]). Using 1-dimensional collapse models, these prescriptions also predict a very quick growth time for the instabilities: within a few ms, the Rayleigh-Taylor convection is strong with velocities/turbulent energies reaching a sizable fraction of the sound speed limit. Again, current models do not

reproduce these growth times. Until we match these growth times, our simulations will not be quantitatively accurate, but they can help us study many of the trends with respect to different physics in the SN engine. They can also be used to study qualitative features in the SN explosion.

Beyond insufficient resolution, what else can be missing in these convective models. One of the most important is the initial seeds used to drive the explosion. The initial 2- and 3-dimensional models used smooth particle hydrodynamics.[20,22] The initial setup conditions have an intrinsic stochasticity in the density and these initial studies argued that these perturbations were on par with the convective inhomogeneities of the progenitor star. Later studies focused on very extreme instabilities in an attempt to produce the observed neutron star kicks.[29,30] An interesting feature of this neutron-star kick mechanism is that, unlike most other kick mechanisms, it predicts that lower-mass progenitors will produce the strongest neutron star kicks. Observations can potentially confirm or refute this kick mechanism. More recent studies have modeled the stellar convection at the final stages of a star's life, following this burning through collapse to produce more consistent simulations of these convective seeds.[31] In all cases, these models found, as expected by analytic theories, that these seeds accelerated the growth of convection.

Active areas of research in the convective engine includes increased-resolution models to better understand the limitations of the numerical methods modeling this convection. But a number of more physics-informed models are also being developed to better understand convective in the collapsed core. These methods will lead to better implementation of subgrid models that can help capture effects like the turbulent pressure. Much more work must be done to understand convection and core-collapse engine theorists are bringing a wide array of numerical and analysis tools to improve our understanding of this engine.

3. Confirmation and Ongoing Constraints of the Convective Engine

Even with the limitations of the convective-enhanced neutrino-driven engine, we are able to make predictions from this model both to test it as a model and use observational features to help improve our understanding. Here we review current observational comparisons that have solidified this standard paradigm. We also discuss upcoming observations that will further test the engine, providing valuable insight into the explosion engine. Like 1987A, we expect upcoming observations to not only constrain this engine, but perhaps provide the evidence to pursue new insight into this developing engine.

3.1. *Explaining SN Energies*

Prior to the development of the convection-enhanced SN explosion mechanism, explaining why CCSNe tap only $\sim$1% of the total potential energy released in the

collapse of the core was one of the most baffling conundrums of the SN engine. But the convection-enhanced SN engine provided a natural explanation for this observation. The energy in the convective region continues to increase only until its energy is sufficient to overcome the ram pressure of the infalling material. The accretion rate of this infalling material and the time it takes the engine to overcome its ram pressure dictates the explosion energy. Figure 5 shows the energy required to overcome the ram pressure as a function of time in the collapse for a series of different progenitor stars. In all cases, this energy lies between a few tenths to a few times 10^{51}erg[a].

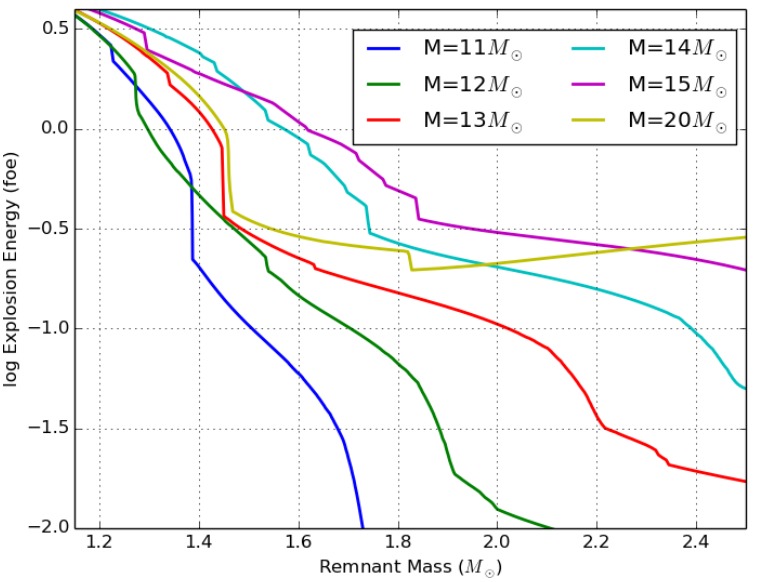

Fig. 5. Explosion energy vs. enclosed mass for different stellar models.

The power of this natural explanation for the explosion energy is often underappreciated in the astronomy community. Let's compare it to the leading alternative engine for SNe, the magnetar-engine scenario. In this scenario, strong magnetic fields tap the rotation energy of the SN to power the explosion. The rotational energy is given by:

$$E_{\rm magnetar} = 2/5 M_{\rm PNS} R_{\rm PNS}^2 \Omega_{\rm PNS}^2 \tag{4}$$

where $M_{\rm PNS}$, $R_{\rm PNS}$, and $\Omega_{\rm PNS}$ are the mass, radius and rotation rate of the proto-magnetar. When the explosion is launched (which must be in the first $\sim$ second after collapse so that the core does not accrete too much to collapse to a black hole), $R_{\rm PNS}$ is roughly 30 km. If the proto-neutron star contracts to form a 10 km

[a]Ten to the Fifty One Erg was termed a "foe" by Hans Bethe. This unit is also known as a Bethe.

neutron star spinning at 100 ms, we'd expect an average SN energy of 5×10^{47} erg instead of the observed $0.1 - 3 \times 10^{51}$ erg. Only the rare, fastest spinning stars would produce strong SNe.

3.2. *Predicting SN Progenitors*

One of the great successes of the convective-engine paradigm is its prediction of which stars produce strong SN explosions versus which collapse to form black holes. Under the convective paradigm, whether or not the convective engine can produce an explosion depends upon whether the energy of the convective engine can grow fast enough to overcome the ram pressure of the infalling material. A successful explosion is a race between the energy deposition timescale and the collapse timescale from accretion. If we ignore stellar winds, massive stars will have larger cores with higher accretion rates. This means that the timescale to collapse decreases and there is less time to develop convection and drive an explosion. In addition, the energy needed to overcome the higher accretion ram pressure is higher. Unless the engine becomes more efficient, these stars will not explode. Assuming minimal winds, the convective engine predicted that stars more massive than $\sim 23\, M_\odot$ would either fail to explode or produce weak explosions.[32]

Shortly thereafter, observations of SN lightcurves argued that most SN had ejecta masses above 15-20 $M_\odot$.[33] The magnetar model could produce explosions with such high ejecta masses, suggesting it might be the better standard SN engine. In this case, however, the analysis of the SN light-curves was wrong. As the sample of observed progenitors increased, it became clear that the vast majority of SN are produced from stars less massive that $20\, M_\odot$,[34] confirming the first prediction (vs. post-diction) of the convective engine and providing another strike for the magnetar model.

3.3. *Compact Remnant Distribution*

For the convective-engine paradigm, the mass of the compact remnant formed in CCSN can be described through a series of phases each of which depend on different properties of the explosion. The compact remnant initially forms during the collapse bounce phase. Typically, the mass of this bounce core is low (roughly 1.1 $M_\odot$[35]). As the convective engine develops, the core continues to accrete mass. Both the progenitor mass (that determines the infalling mass accretion rate with time) and the time it takes for this engine to develop dictates the mass of the core at the launch of the explosion. Finally, the explosion energy determines how much material ultimately falls back onto the compact core. All of these effects are important in determining the final compact remnant mass.

Observations of the compact remnant mass distribution provide insight into these explosion properties. Initially, observations argued for a remnant mass distribution that peaked strongly at two separate masses: a peak at $\sim$1.4 $M_\odot$ and another

peak at $\sim M_{\odot}$.[36] These highly-peaked mass distributions are difficult to reproduce within convective-engine paradigm, especially when including the fallback of material after the launch of the launch.[37] Fallback occurs because the SN blastwave must drive the entire star to explode. As it decelerates, some of the ejecta can decelerate sufficiently that this material can not escape the gravitational potential of the star. This fallback has been studied both analytically and through a series of simulations,[38,39] demonstrating that fallback accretion decreases following a power-law time evolution: $\dot{M}_{\rm fallback} \propto^{-5/3}$. The amount of integrated fallback depends on the explosion energy and the progenitor structure (and hence, its mass).

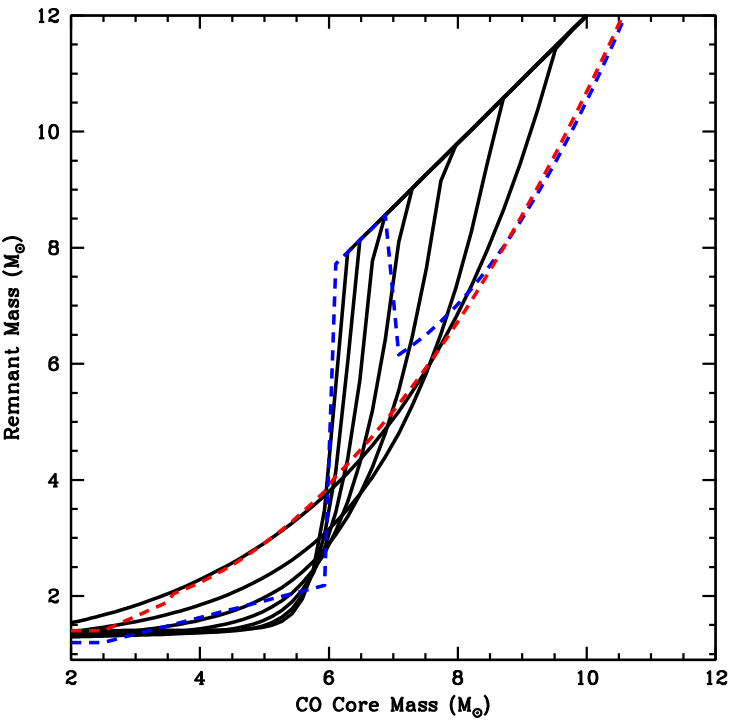

Fig. 6. Remnant mass as a function of CO core mass for rapid/slow convective models[35] along with a parameterized growth time model. The steeper the rise in remnant mass (caused by faster convective growth time), the deeper the mas gap produced.

One of the key observational constraints from the compact remnant mass distribution is the gap between neutron stars and black holes. Observations of neutron stars and black holes (binary pulsars and X-ray binaries) argued for an absence of neutron stars in the compact mass region lying between 2.5 and $4\,M_{\odot}$. Whether this was an observational bias or due to low-number statistics has been a matter of debate for many years. If the gap exists, it places strong constraints on the growth time of the convection.[35] Figure 6 shows the compact remnant mass as a function

of the CO core mass while varying the convective growth time (and, hence, the injection time of the energy). Producing a pristine mass gap requires very rapid and strong explosions to avoid falllback filling in this gap. It is possible that fallback will drive further outflows that then limit further fallback such that, even though fallback occurs, the amount of mass accreted is limited.[40] Until recently, the mass gap favored rapid explosions, affecting both our understanding of the SN engine and predictions for a wide range of SN properties. However, gravitational wave observations suggest that the mass gap region is not as pristine as originally believed[41] and, because of this, the constraints on the convective growth time are less stringent (we will discuss this further in section 3.6).

With all of the current observations, we must consider the observational biases. One of the potential observational biases of the mass gap is that the observed compact mass distribution is limited to systems in close binaries. Any comparison of the predictions of the remnant mass distribution to the observed mass distribution must include calculations of these binaries and are limited by the associated uncertainties of binary population synthesis.[42–44]

3.4. *SN Ejecta Remnants*

The ejecta from CCSNe form another form of remnant as the ejecta in the SN blastwave propagates through the interstellar medium. As we discussed in Section 2.1, the morphology of these ejecta remnants provided the first hints that the SN engine must be aspherical. Although these remnants are highly aspherical, it is often difficult to extract properties of the explosive engine from other effects in the propagation of a SN remnant. As also we discussed in section 2.1, the effects of the propagation through the circumstellar medium and the modeling of the atomic physics in these non-local thermodynamic equilibrium conditions can make it difficult to tie the properties of the remnant to the explosion itself. Nonetheless, remnants can prove powerful probes of the SN explosion and its engine.

First, let's better understand the difficulties through the example of analyses of the Cassiopeia A SN remnant. As the blastwave propagates through the circumstellar medium, it decelerates, causing a reverse shock to progress inward (in mass coordinates) through the remnant, lighting up the material and allowing astronomers to probe properties of the explosion.[45,46] But the morphology of the shock can be shaped by the circumstellar medium[9] and the masses and properties inferred (masses, abundance rations) depend on assumptions in the atomic physics, i.e.[47] Cassiopeia A demonstrates the pitfalls of such an analysis. Images and analysis of the shock-heated material in Cassiopeia A suggests a jet-like explosion, suggesting a magnetar and disk model.[8] To verify this conclusion, astronomers developed another probe of this morphology by, instead of observing shocked material, observing material through the decay of radioactive material produced in the explosion. In particular, the NuStar satellite mapped out the ^{44}Ti production from the SN

producing this remnant. ^{44}Ti is ideally suited as a probe of the central engine. It is produced in the innermost ejecta where ^{56}Ni is produced. It has a long enough half-life to be observed in SN remnants (unlike ^{56}Ni whose half-life is too short) and, because it is unstable (unlike iron), we know the observed ^{44}Ti was produced in the explosion. This innermost material may not yet be affected by the surrounding medium, especially if the reverse shock has yet to reach it. What the ^{44}Ti observations of the Cassiopeia A SN remnant showed was a clumpy distribution mimicking the convective motions in the SN engine.[48,49] This is the most direct observation to date proving the convection-enhance neutrino-driven SN engine. At least for this SN remnant, the engine is not matched by the magnetar model. Although limited to velocity imaging, the ^{44}Ti observations of SN 1987A suggest the same convective engine.[50]

Although these NuStar observations of remnants through the decay photons from radioactive elements provide a direct probe, the number of remnants that can be observed in such a manner is limited. Even with next generation gamma-ray detectors like COSI mission,[51] increasing the number of remnants with resolved images of the ^{44}Ti will be difficult. However, there exists a wealth of data of shock-heated material and combined with infra-red observations (and increasingly sophisticated models of the atomic physics), SN remnants will become an increasingly powerful probe of the SN engine. SN remnants measure key elements in the explosion that probe both the progenitor and the explosion energy. To demonstrate this, figure 7 shows the abundance fraction versus enclosed ejecta mass for two 1-dimensional SN explosions of a $15\,M_\odot$ star.[52] The abundances in this plot span the typically-observed abundances in SN remnants. The different observed abundances probe different aspects of the SN and different regions in the progenitor star. For example, Fe is produced in the innermost ejecta and is very sensitive to the explosion energy. Si, S, Ca, and Ar are produced just above the iron ejecta also probe the explosion energy. O, Mg, and Ne yields are produced even further out and are better probes of the progenitor because their production is much less sensitive to the explosion energy.

3.5. *Nucleosynthetic Yields*

Nucleosynthetic yields provide an excellent probe of the SN engine, especially of the elements produced near the engine (e.g. iron peak and heavier isotopes). As we discussed in Section 3.4, SN remnants provide a measure of the nucleosynthetic yields and their morphology. These remnant measurements probe the progenitor, explosion energy, and morphology of the explosion. ^{44}Ti observations are not only more direct probes (because the physics behind its analysis is more straightforward). The sensitivity of the ^{44}Ti production on the electron fraction of the inner ejecta[53] also means that it can probe the conditions in the convective region (and the properties of the neutrinos, including neutrino oscillations) in this region.

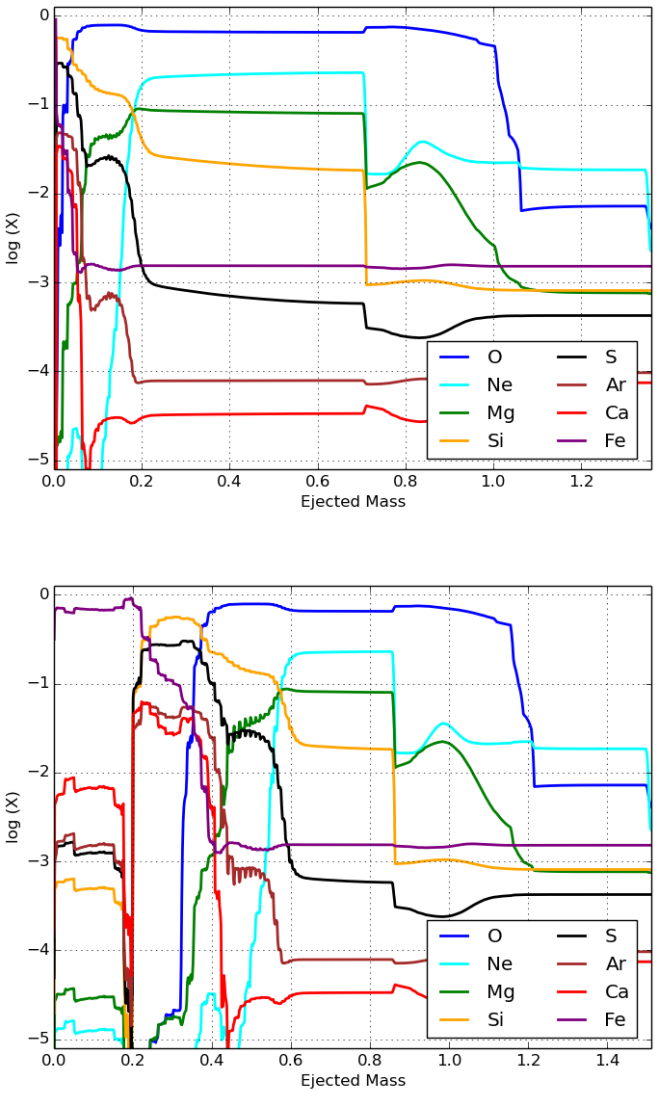

Fig. 7. Nucleosynthetic yiels from an 0.82 (top) and 1.86 (bottom) foe (10^{51} erg) explosion of a a 15 $M_\odot$ star. O, Mg, Ne are produced in stellar evolution and the supernova shock primarily destroys these abundances. Si, S, Ar, Ca are produced at the base of the C/O layer and their production depends somewhat on the SN explosion energy. Iron is produced in the core from shock-driven Si burning. It is very sensitive to the explosion energy, both to drive the nuclear fusion and to avoid falling back onto the proto-neutron star.

But remnants aren't the only way we can measure nucleosynthetic yields. Based on isotopic ratios, scientists have identified a set of pre-solar dust grains produced by SNe. With the detailed isotopic ratios and relative element abundances, scientists can begin to probe the detailed yields from SNe.[54–56] In addition, galactic chemical

evolution, which measures the evolution of the abunadances as a function of metallicity, can be used to both determine which transients form different elements and the variation in their production rates.[57, 58]

3.6. *Neutrinos and Gravitational Waves*

The neutrino detection of SN 1987A provided conclusive evidence that at least some SNe are produced in the formation of a compact remnant. Neutrinos remain one of the most direct probes of the SN engine. With a detailed neutrino spectrum, scientists can not only probe the nature of the proto-neutron star (and the nuclear matter equation of state) and the neutrino physics (including neutrino oscillations). Unfortunately, neutrinos are difficult to detect and, to date, SN 1987A remains the only SN detected in neutrinos. With hyperKamiokande, scientists expect to observer SNe out to 1 Mpc.[59] This can increase the neutrino detection rate, but for the detailed spectra to do most of the neutrino SN science will still require a Galactic SN.

Gravitational waves provide another[53] probe different physics of the inner engine: the rotation and the convection. To measure convection, we need a nearby SN, well within the Milky Way.[60] But, fast rotating collapses can be seen further out (in extreme cases, out to 1 Mpc).[61] With next generation detectors, a Galactic SN would produce a strong enough signal to measure the growth and extent of the SN mixing and the expected rate of fast-spinning collapses is sufficiently high that we will begin to place constraints on the angular momentum in stars (determining the importance of rotation in the SN engine). Next generation detectors will increase the number of mass-constraints on compact objects 100-fold, providing an extremely accurate mass distribution of compact objects (in close binary systems). With these masses, we can constrain the mixing in the SN engine (see Section 3.3).

3.7. *SN Light Curves and Early-Time Emission*

We have already discussed issues with using SN light-curves. One of the primary difficulties in studying the engines and progenitors of SNe from the SN light-curve lies in the fact that most of the emission occurs long after the SN blastwave has broken out of the star and interactions with the surrounding medium blur the features (and in particular the extent of the asymmetries) in the explosion and its progenitor star. Observing the emission from the SN blastwave as it breaks out of the star provides a much more direct probe of the explosion (asymmetries) and progenitor (convection, radii, and mass loss).[62–64] Figure 8 shows the early emission from a SN as it breaks out of the photosphere of a Wolf-Rayet star. This emission is driven by shocks produced as the SN blastwave propagates first through the convective envelope, then down the transition region from stellar edge to wind and then through the clumpy wind. By characterizing this emission, astronomers will probe the properties of the star, in particular, the convection in the stellar

envelope (convection is a key uncertainty of massive star evolution) and stellar mass-loss (which alters the structure of the star and can change its final fate). This emission also prov ides a probe of the SN asymmetries. Ultrasat[65] and SIBEX[66,67] satellite missions are being developed to obtain a large number of this early-time SN emission.

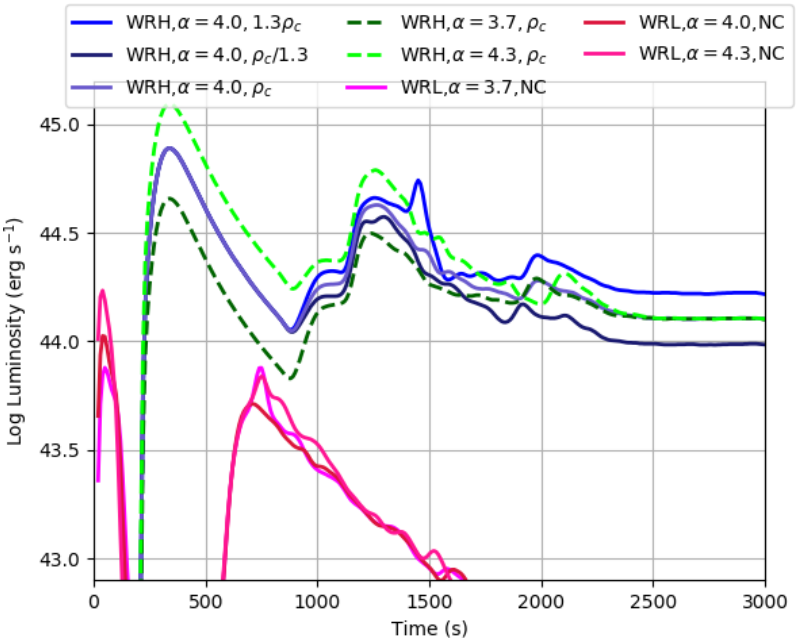

Fig. 8. Shock breakout emission (bolometric) from a high mass (WRH) and low mass (WRL) Wolf-Rayet progenitor star varying properties of the wind (with and without clumps) and the density slope of the transition region ($\rho = \rho_0 r^{-\alpha}$). Signal without clumps (NC) are compared to those with a wind clump density that varies by 30%. This emission is predominantly in the X-ray and UV bands.

4. Conclusion

In this paper, we reviewed the broad set of observations that led to, confirmed, and have constrained the convective-enhanced neutrino-driven SN engine paradigm. We have also outlined the the future observations that will place further constraints. For our understanding of the SN engine, the future is bright.

The observation of high-energy neutrinos from the cosmos: Lessons learned for multimessenger astronomy

Francis Halzen

Department of Physics, University of Wisconsin–Madison, Madison, WI 53705, US

The IceCube neutrino telescope discovered PeV-energy neutrinos originating beyond our Galaxy with an energy flux that is comparable to that of GeV-energy gamma rays and EeV-energy cosmic rays. These neutrinos provide the only unobstructed view of the cosmic accelerators that power the highest energy radiation reaching us from the universe. We will review the results from IceCube's first decade of operations, emphasizing the measurement of the diffuse multiflavored neutrino flux from the universe and the identification of the supermassive black hole TXS 0506+056 as a source of cosmic neutrinos and, therefore, cosmic rays. We will speculate on the lessons learned for multimessenger astronomy, among them that extragalactic neutrino sources may be a relatively small subset of the cosmic accelerators observed in high-energy gamma rays and that these may be gamma-ray-obscured at the times that they emit neutrinos.

Keywords: Neutrinos; cosmic rays; multimessenger astronomy.

PACS numbers: 95.55.Vj; Neutrino; muon; pion; and other elementary particle detectors; cosmic ray detectors

1. Neutrino Astronomy: A Brief Introduction

The shortest wavelength radiation reaching us from the universe is not radiation at all; it consists of cosmic rays—protons and high-energy nuclei. Some reach us with extreme energies exceeding 10^8 TeV from a universe beyond our Galaxy that is obscured to gamma rays and from which only neutrinos reach us as astronomical messengers.[1] Their origin is still unknown but the identification of a supermassive black hole powering a cosmic-ray accelerator[2,3] represents a breakthrough towards a promising path for resolving the century-old puzzle of the origin of cosmic rays: multimessenger astronomy.

The rationale for searching for cosmic-ray sources by observing neutrinos is straightforward: in relativistic particle flows near neutron stars or black holes, some of the gravitational energy released in the accretion of matter is transformed into the acceleration of protons or heavier nuclei, which subsequently interact with ambient radiation or matter to produce pions and other secondary particles that decay into neutrinos. For instance, when protons interact with intense radiation fields near the source via the photoproduction processes

$$p + \gamma \to \pi^0 + p \quad \text{and} \quad p + \gamma \to \pi^+ + n\,, \tag{1}$$

both neutrinos and gamma rays are produced with roughly equal rates; while neutral pions decay into two gamma rays, $\pi^0 \to \gamma + \gamma$, the charged pions decay into three high-energy neutrinos (ν) and antineutrinos ($\bar{\nu}$) via the decay chain $\pi^+ \to \mu^+ + \nu_\mu$ followed by $\mu^+ \to e^+ + \bar{\nu}_\mu + \nu_e$. The fact that cosmic neutrinos are inevitably accompanied by high-energy photons transforms neutrino astronomy into multimessenger astronomy.

A main challenge of multimessenger astronomy is to separate these photons, which we will refer to as *pionic* photons, from photons radiated by electrons that are accelerated along with the cosmic ray protons. Another challenge is to identify the electromagnetic energy associated with the pionic photons because they do not reach our telescopes with their initial energy. They suffer losses in interactions with the extragalactic background light (EBL), predominantly with microwave photons, via the process $\gamma + \gamma_{cmb} \to e^+ + e^-$. Importantly, they may also lose energy in the source. As is the case when constructing a neutrino beam in a particle physics laboratory, neutrinos require a target that transforms the energy of the proton beam into neutrinos. Powerful neutrino sources within reach of IceCube's sensitivity require a dense target that is likely to be opaque to pionic gamma rays. Additionally losing energy in the source, these may reach Earth with MeV energies or below. We will review the accumulating indications that cosmic neutrinos originate in gamma-obscured sources with their associated multimessenger signals emerging below the detection thresholds of high-energy gamma-ray satellites and ground-based TeV gamma-ray telescopes.[4,5]

2. High-Energy Cosmic Neutrinos

Close to the National Science Foundation's research station located at the geographical South Pole, the IceCube project[6] transformed one cubic kilometer of natural Antarctic ice into a Cherenkov detector. The deep ice of the Antarctic glacier constitutes the detector, forming both support structure and Cherenkov medium. Below a depth of 1,450 meters, a cubic kilometer of glacial ice has been instrumented with 86 cables called "strings," each of which is equipped with 60 optical sensors; see Fig. 1. Each digital optical module (DOM) consists of a glass sphere containing a photomultiplier and the electronics board that captures and digitizes the light signals locally using an onboard computer; see Fig. 2. The digitized signals are given a global time stamp accurate to 2 ns and are subsequently transmitted to the surface. Processors at the surface continuously collect the time-stamped signals from the optical modules, each of which functions independently. The digital messages are sent to a string processor and a global event trigger. They are sorted into the Cherenkov radiation patterns that are emitted by muon tracks produced by muon neutrinos interacting in the ice, or by secondary particle showers initiated by electron and tau neutrinos. These reveal the flavor, energy, and direction of the incident neutrino.[7]

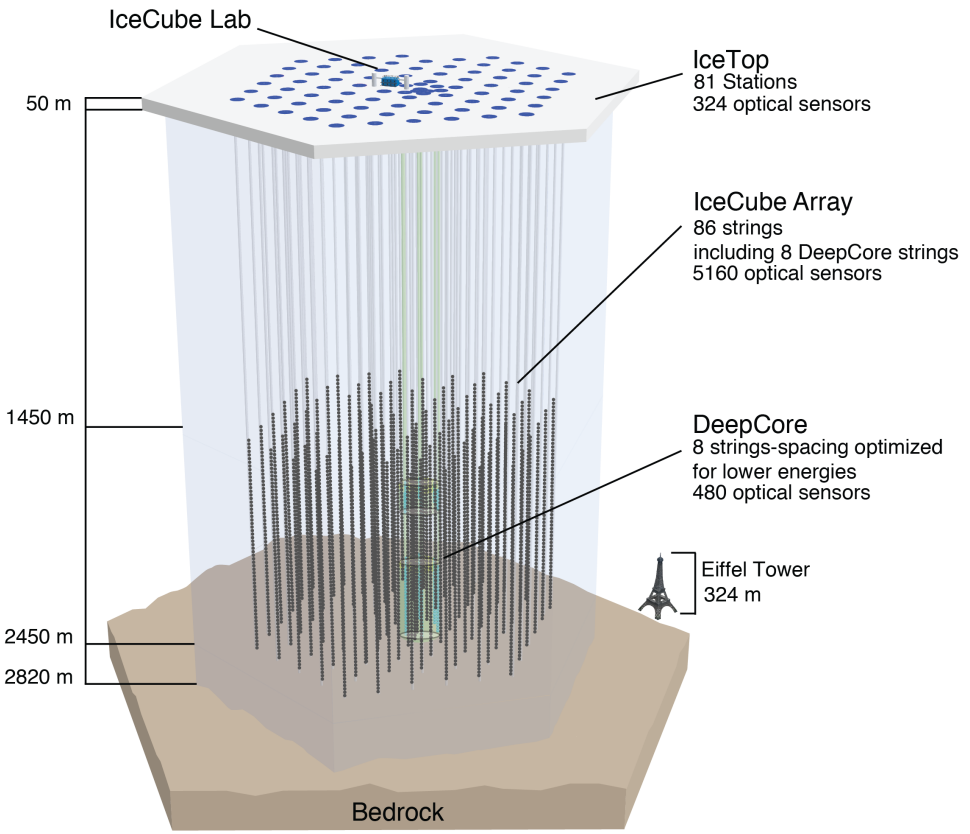

Fig. 1. Architecture of the IceCube observatory.

Constructed between 2004 and 2010, IceCube has now taken 10 years of data with the completed detector.

The arrival direction of a secondary muon track, or of an electromagnetic shower initiated by an electron or tau neutrino, is reconstructed from the arrival times of the Cherenkov photons at the optical sensors, while the number of photons is a proxy for the energy deposited by secondary particles in the detector. Although the detector only records the energy of the secondary muon inside the detector, from Standard Model physics we can infer the energy spectrum of the parent neutrino.

Tracks resulting from muon neutrino interactions can be pointed back to their sources with a $\leq 0.4^\circ$ angular resolution for the highest energy events. In contrast, the reconstruction of cascade directions, in principle possible to within a few degrees, is still in the development stage in IceCube, achieving 8° resolution.[8,9] On the other hand, determining the shower energy from the observed light pool is straightforward, and a resolution of better than 15% can be achieved. For illustration, we contrast

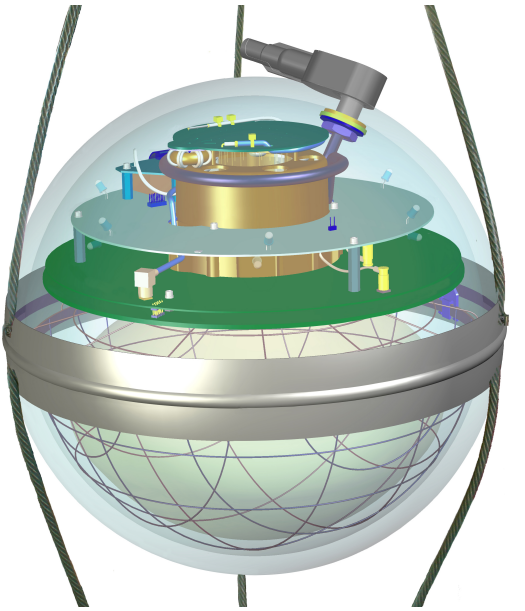

Fig. 2. Digital optical module showing the down-facing 10-inch photomultiplier and the associated electronics that digitize the light signals.

in Fig. 3 the Cherenkov patterns initiated by an electron (or tau) neutrino of 1 PeV energy (top) and a neutrino-induced muon losing 2.6 PeV energy while traversing the detector (bottom).

IceCube identifies cosmic neutrinos in a large background of muons and neutrinos produced by cosmic rays interacting in the atmosphere. Two principal methods are used to separate neutrinos of cosmic origin from the background of atmospheric muons and neutrinos. The first method reconstructs muon tracks reaching the detector from directions below the horizon, the second identifies neutrinos of all flavors that interact inside the instrumented volume of the detector; examples of events are shown in Fig. 3. We will describe these methods in turn.

2.1. *Muon Neutrinos Through the Earth*

Detecting particles from directions below the horizon has the immediate advantage of eliminating the overwhelming background of cosmic-ray muons that reach the detector from above. The tracks are separated from the background of atmospheric muons using the Earth as a filter. IceCube thus collects samples of muon neutrinos with high purity, typically well above 99%, at a rate of more than 100,000 per year. The neutrino energies cover more than six orders of magnitude, from ~ 5 GeV in the highly instrumented inner core, labeled DeepCore in Fig. 1, to extreme energies beyond 10 PeV. IceCube thus measured the atmospheric neutrino flux over more than five orders of magnitude in energy with a result that is consistent with theoretical

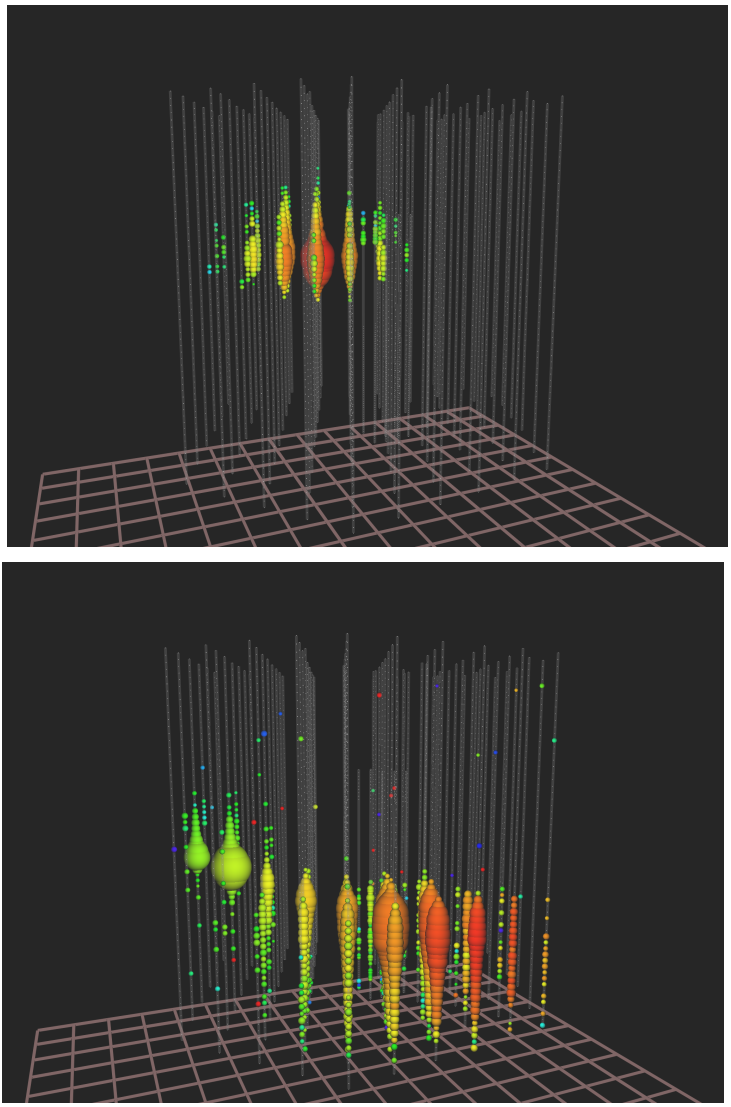

Fig. 3. **Top Panel:** Light pool produced in IceCube by a shower initiated by an electron or tau neutrino of 1.14 PeV, which represents a lower limit on the energy of the neutrino that initiated the shower. White dots represent sensors with no signal. For the colored dots, the color indicates arrival time, from red (early) to purple (late) following the rainbow, and size reflects the number of photons detected. **Bottom Panel:** A muon track coming up through the Earth, traverses the detector at an angle of 11° below the horizon. The deposited energy, i.e., the energy equivalent of the total Cherenkov light of all charged secondary particles inside the detector, is 2.6 PeV.

calculations. Muon neutrinos can be detected even when interacting outside the detector because of the kilometer range of the secondary muons. More importantly, IceCube has observed an excess of neutrino events at energies beyond 100 TeV[10–12]

that cannot be accounted for by the atmospheric flux at the 5.6σ level. A recent measurement of the energy flux covering 9.5 years of data was performed yielding a sample of 650,000 neutrinos with 99.7% purity; see Fig. 4. The excess cosmic neutrino flux (red) over the atmospheric background (purple) is well described by a power law with a spectral index of -2.37 ± 0.09 and a normalization at 100 TeV neutrino energy of $(1.36^{+0.24}_{-0.25}) \times 10^{-18}\,\mathrm{GeV}^{-1}\mathrm{cm}^{-2}\mathrm{sr}^{-1}\mathrm{s}^{-1}$.[13] The residual atmospheric muon background is small (yellow). For more details, see Ref. 14.

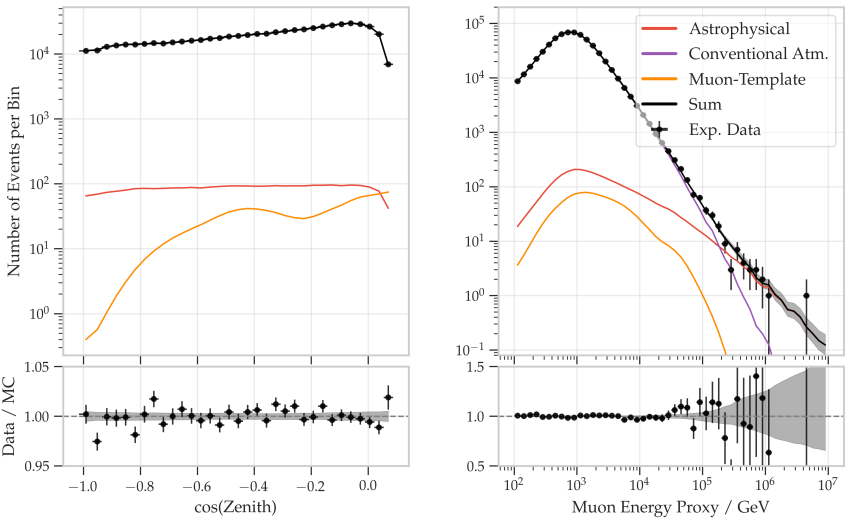

Fig. 4. The distributions of muon tracks arriving from the Northern Hemisphere, i.e., with declination greater than $-5°$, for the period 2010-18,[13] are shown as a function of reconstructed zenith (left) and muon energy (right). The full data set consists of about 650,000 neutrino events with a purity of 99.7%. Best fits to the low-energy atmospheric and high-energy astrophysical components of the neutrino flux are superimposed. Statistical errors are shown as crosses, the grey bands in the ratio plots show an estimate of the systematic error obtained by varying all fit-parameters within their uncertainties.

The measured arrival directions of the astrophysical muon tracks are isotropically distributed over the sky. Surprisingly, there is no evidence for a correlation to nearby sources in the Galactic plane; IceCube observes a diffuse flux of extragalactic sources. Only after collecting 10 years of data[15] did the first evidence emerge at the 3σ level that the neutrino sky is not isotropic. The anisotropy results from four sources—TXS 0506+056 among them (more about that source later)—that emerge as point sources of neutrinos with a p-value of less than 0.01 (pretrial); see Fig. 5. The strongest of these sources is the nearby active galaxy NGC 1068, also known as Messier 77, which, independently, also emerges as the most significant source in a list of about a hundred candidates that had been preselected by the collaboration as targets of interest.

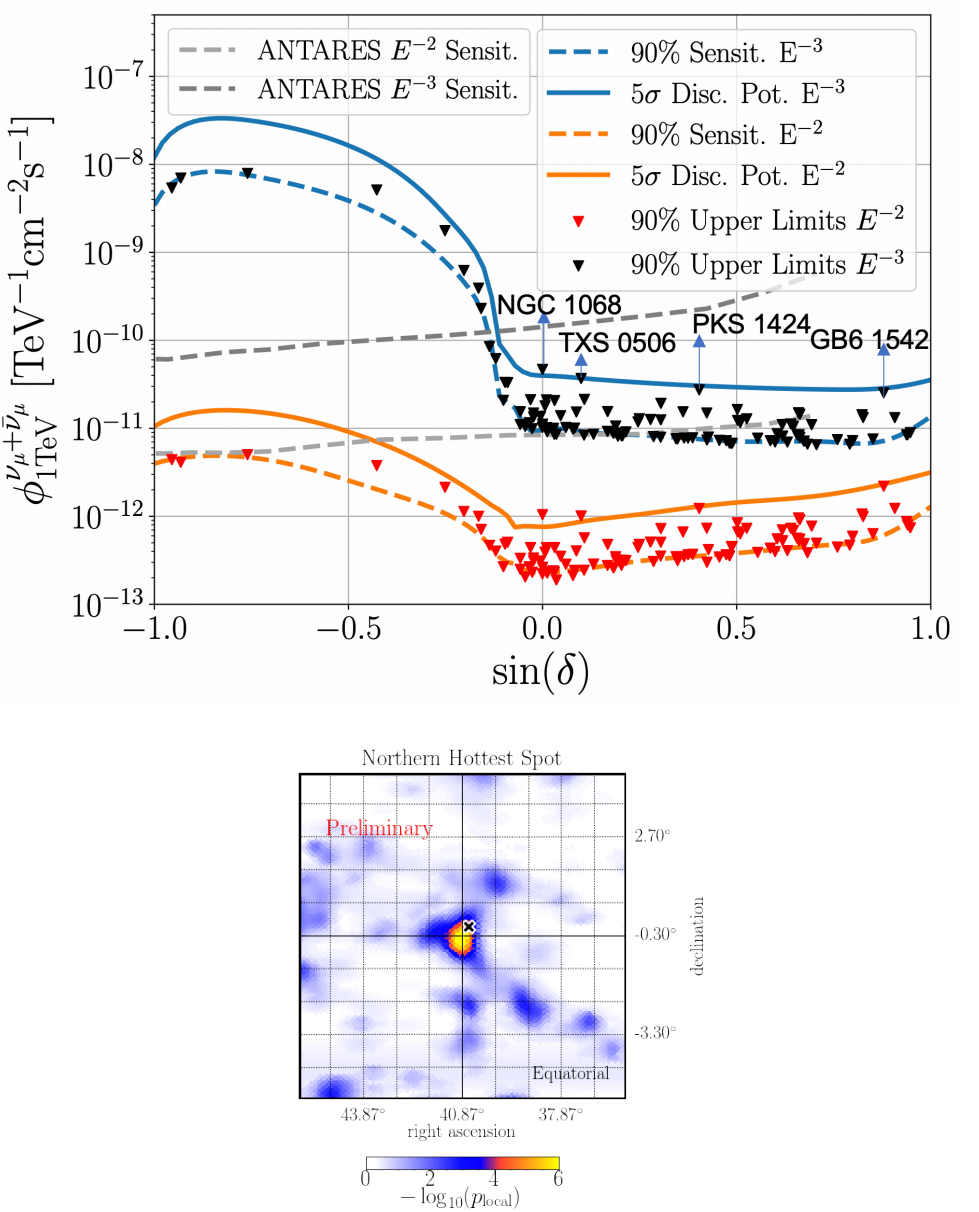

Fig. 5. **Top Panel:** Upper limits on the flux from candidate point sources of neutrinos in 10 years of IceCube data assuming two spectral indices of the flux.[15] Also shown as triangles are limits on a preselected list of about one hundred candidate sources. Four sources exceed the 4σ level (pretrial) and collectively result in a 3σ anisotropy of the sky map. **Bottom Panel:** Association of the hottest source in the sky map as well as in the list of preselected candidate sources with the active galaxy NGC 1068.

2.2. *Neutrinos Interacting Inside the Instrumented Volume*

The second method for separating cosmic from atmospheric neutrinos exclusively identifies high-energy neutrinos interacting inside the instrumented volume of the detector, so-called starting events. After only two years of operation, IceCube used this method to make the initial discovery of an extragalactic flux of cosmic neutrinos[1] with an energy flux, $E^2 dN/dE$, in the local universe that is, surprisingly, similar to that in gamma rays.[16,17] Using this method, one divides the instrumented volume of ice into an outer veto shield and a $\sim$ 500-megaton inner fiducial volume. The advantage of focusing on neutrinos interacting inside the instrumented volume of ice is that the detector functions as a total absorption calorimeter,[8] allowing for a good energy measurement that separates cosmic from lower-energy atmospheric neutrinos. In contrast to the first method, neutrinos from all directions in the sky and of all flavors can be identified, including both muon tracks and secondary showers produced by charged-current interactions of electron and tau neutrinos and neutral current interactions of neutrinos of all flavors. A sample event with a light pool of roughly one hundred thousand photoelectrons extending over more than 500 meters is shown in the top panel of Fig. 3.

The starting event samples revealed the first evidence for neutrinos of cosmic origin.[1,18] Events with PeV energies and with no trace of coincident muons that reveal either the decay products of a parent meson or an accompanying atmospheric shower are highly unlikely to be of atmospheric origin. The present seven-year data set contains a total of 60 neutrino events with deposited energies ranging from 60 TeV to 10 PeV that are likely to be of cosmic origin. The deposited energy and zenith dependence of the high-energy starting events[12,19] is compared to the atmospheric background in Fig. 6. A purely atmospheric explanation of the observation is excluded at 8σ.

The flux of cosmic neutrinos has by now also been characterized with a range of other methods. Their results agree, pointing at extragalactic sources whose flux has equilibrated in the three neutrino flavors after propagation over cosmic distances,[21] with $\nu_e : \nu_\mu : \nu_\tau \sim 1 : 1 : 1$. Fig. 7 shows the measurement of the cosmic neutrino flux of a recent analysis that specializes to showers only. These have been isolated from the atmospheric background down to energies below 10 TeV.[22] The energy spectrum of $E^{-2.5}$ agrees with the measurement using upgoing muons with a spectral index of $E^{-2.4}$ above an energy of $\sim$ 100 TeV.[12] In general, analyses reaching lower energies exhibit larger spectral indices with the updated 7.5 years starting-event sample,[19] yielding a spectral index value of -2.87 ± 0.2 for the 68.3% confidence interval.

2.3. *Cosmic Tau Neutrinos*

We should comment at this point that there is yet another method to conclusively identify neutrinos that are of cosmic origin: the observation of high-energy tau neutrinos. Tau neutrinos are produced in the atmosphere by the oscillations of muon neutrinos into tau neutrinos, but only for neutrino energies well below 100 GeV.

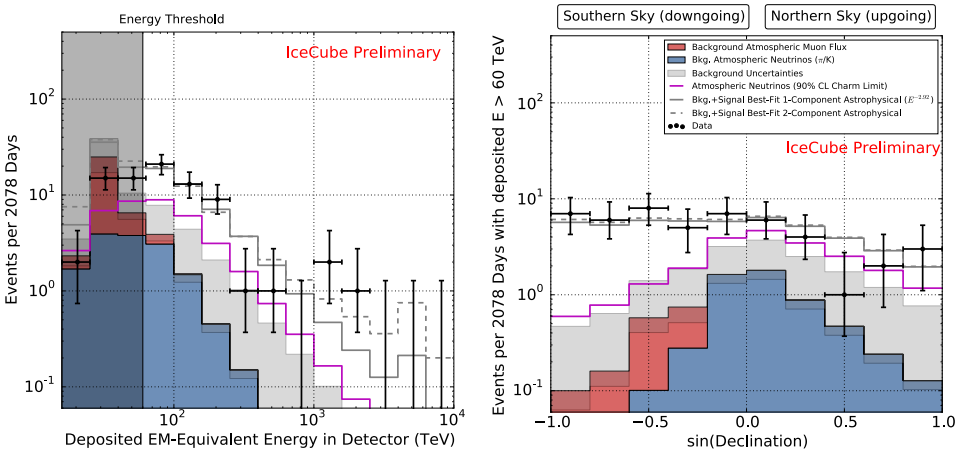

Fig. 6. **Left Panel:** Deposited energies, by neutrinos interacting inside IceCube, observed in six years of data.[12] The grey region shows uncertainties on the sum of all backgrounds. The atmospheric muon flux (blue) and its uncertainty is computed from simulation to overcome statistical limitations in our background measurement and scaled to match the total measured background rate. The atmospheric neutrino flux is derived from previous measurements of both the π, K, and charm components of the atmospheric spectrum.[20] Also shown are two fits to the spectrum, assuming a simple power-law (solid gray) and a broken power-law (dashed gray). **Right Panel:** The same data and models, but now showing the distribution of events with deposited energy above 60 TeV in declination. At the South Pole, the declination angle δ is equivalent to the distribution in zenith angle θ related by the identity, $\delta = \theta - \pi/2$. It is clearly visible that the data is flat in the Southern Hemisphere, as expected from the contribution of an isotropic astrophysical flux.

Above that energy a tau neutrino must be of cosmic origin, produced in cosmic accelerators with a neutrino flux with a tau fraction of approximately one third. Tau neutrinos produce two spatially separated showers in the detector, one from the interaction of the tau neutrino and the second from the decay of the secondary tau produced.[23] The mean decay length of the tau lepton is $\lambda_\tau = (E_\tau/m)\, c\tau \approx 50\ \mathrm{m} \times (E_\tau/\mathrm{PeV})$, where m, τ, and E_τ are the mass, lifetime, and energy of the tau, respectively. Two such candidate events have been identified.[24] An event with a decay length of 17 m and a probability of 98% of being produced by a tau neutrino is shown in Fig. 8. The energies of the two showers are 9 TeV and 80 TeV.

Yet another independent confirmation of the observation of neutrinos of cosmic origin appeared in the form of the Glashow resonance event shown in Fig. 9. The event was identified in a dedicated search for partially contained showers of very high energy.[25] The reconstructed energy of the shower is 6.3 PeV, which matches the laboratory energy for the production of a weak intermediate W^- in the resonant interaction of an electron antineutrino with an atomic electron: $\bar{\nu}_e + e^- \to W^- \to q + \bar{q}$. Given its high energy, the initial neutrino is cosmic in origin; it represents an independent discovery of cosmic neutrinos at the level of 5σ. Assuming the Standard Model cross section, we expect 1.55 events in the data sample searched, assuming an antineutrino:neutrino ratio of 1:1 characteristic of a cosmic source producing

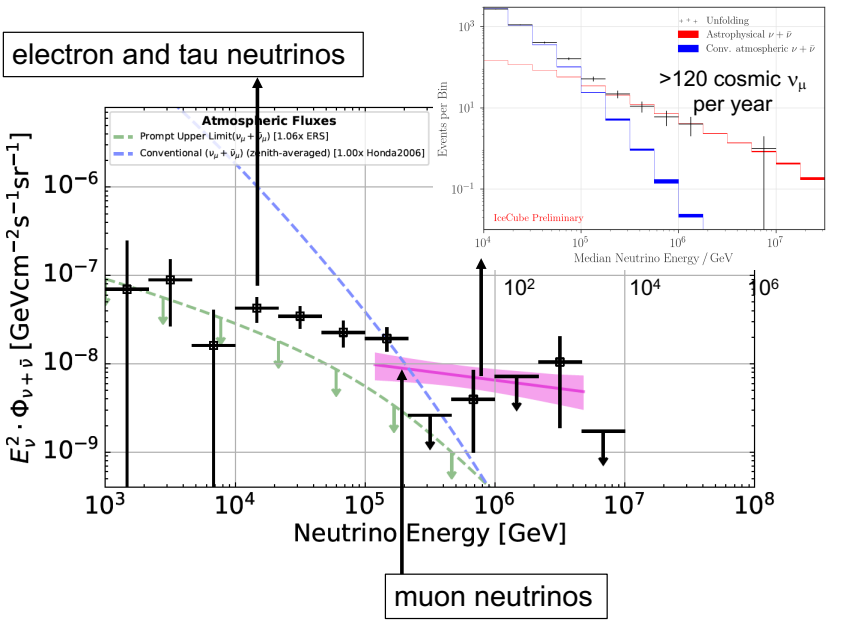

Fig. 7. The flux of cosmic muon neutrinos[12] inferred from the eight-year upgoing-muon track analysis (red solid line) with 1σ uncertainty range (shaded range; from fit shown in upper-right inset) is compared with the flux of showers initiated by electron and tau neutrinos.[22] The measurements are consistent assuming that each neutrino flavor contributes an identical flux to the diffuse spectrum.

an equal number of pions of all three electric charges. Taking into account the detector's energy resolution, the probability that the event is produced off resonance by deep inelastic scattering is only 0.01, assuming a spectrum with a spectral index of $\gamma = -2.5$. Furthermore, the presence of both muons and an electromagnetic shower is consistent with the hadronic decay of a W^- produced on the Glashow resonance.[25]

The observation of a Glashow resonance event indicates the presence of electron antineutrinos in the cosmic neutrino flux. Its unique signature provides a method to disentangle neutrinos from antineutrinos; their ratio distinguishes accelerators that produce neutrinos via pp and $p\gamma$ interactions and is also sensitive to their magnetic field.[25]

Finally, data from the ANTARES experiment are consistent with the observation of a flux of cosmic origin although with limited statistical significance.[26]

3. Multimessenger Astronomy

The most important message emerging from the IceCube measurements may not be apparent yet: the prominent role of neutrinos relative to photons in the extreme

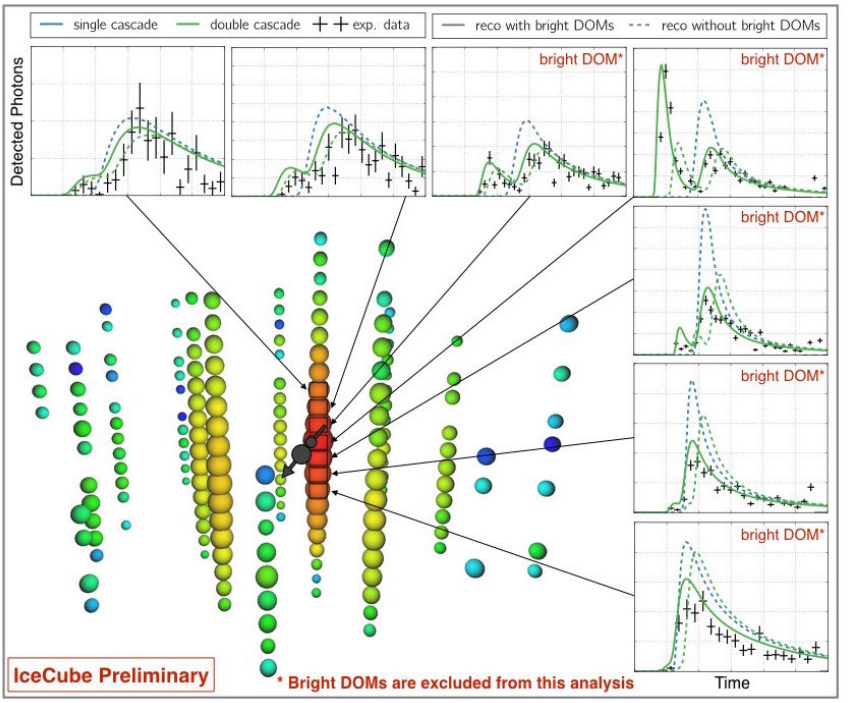

Fig. 8. Event view of a tau neutrino.[24] The Cherenkov photons associated with the production and subsequent decay of the tau neutrino are identified by the double-peaked photon count as a function of time for the bright DOMs, for instance, the one shown in the top-right corner. The best fit (solid line) corresponds to a 17 m decay length and is far superior to fits assuming a single electromagnetic or hadronic shower (dashed lines).

universe. Photons are inevitably produced in association with neutrinos when accelerated cosmic rays produce both neutral and charged pions in interactions with target material in the vicinity of the accelerator. While neutral pions decay into two gamma rays, $\pi^0 \to \gamma + \gamma$, the charged pions decay into three high-energy neutrinos (ν) and antineutrinos ($\bar{\nu}$) via the decay chain $\pi^+ \to \mu^+ + \nu_\mu$ followed by $\mu^+ \to e^+ + \bar{\nu}_\mu + \nu_e$ and the charged-conjugate process. On average, the four final state leptons equally share the energy of the charged pion. With these approximations, gamma rays and neutrinos carry on average 1/2 and 1/4 of the energy of the parent pion.

Modeling of gamma ray observations generally indicated that the flux in pionic photons would be relatively small compared to a dominant flux of photons radiated by electrons in electromagnetic processes, synchrotron radiation, and inverse Compton scattering. These were generally assumed to dominate the energy production of sources in the Galaxy and beyond. IceCube observations show that this is not the case. To illustrate this point, we show in Fig. 10 the energy fluxes, $E^2 dN/dE$, of neutrinos and gamma rays in the universe. Clearly, the energy flux of cosmic

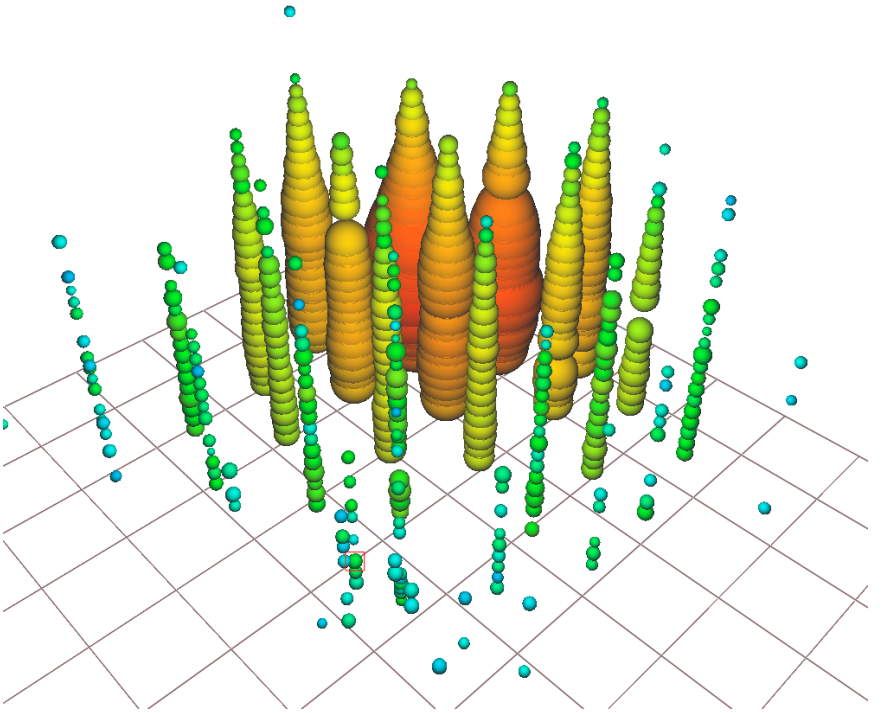

Fig. 9. Particle shower created by the Glashow resonance.[25] Its energy is reconstructed at the resonant energy for the production of a weak intermediate boson W^- in the interaction of an antielectron neutrino with an atomic electron in the ice. The properties of the secondary muons produced in the particle shower are consistent with the hadronic decay of a W^- boson.

neutrinos is comparable to the one for the highest energy gamma rays observed by the NASA Fermi satellite.[16] This already indicates a more prominent role of hadronic processes than routinely anticipated. We will look at this match of the neutrino and gamma-ray energies in more detail.

The neutrino production rate Q_{ν_α} (with typical units $\mathrm{GeV}^{-1}\mathrm{s}^{-1}$ and with the subscript α labeling the neutrino flavor) can be related to the one for charged pions Q_π by

$$\sum_\alpha E_\nu Q_{\nu_\alpha}(E_\nu) \simeq 3\,[E_\pi Q_{\pi^\pm}(E_\pi)]_{E_\pi \simeq 4E_\nu} \ , \tag{2}$$

while, similarly, the production rate of pionic gamma rays is related to the one for neutral pions by

$$E_\gamma Q_\gamma(E_\gamma) \simeq 2\,[E_\pi Q_{\pi^0}(E_\pi)]_{E_\pi \simeq 2E_\gamma} \ . \tag{3}$$

Pion production in the interactions of cosmic rays with photon fields proceeds resonantly via the processes $p + \gamma \to \Delta^+ \to \pi^0 + p$ and $p + \gamma \to \Delta^+ \to \pi^+ + n$.

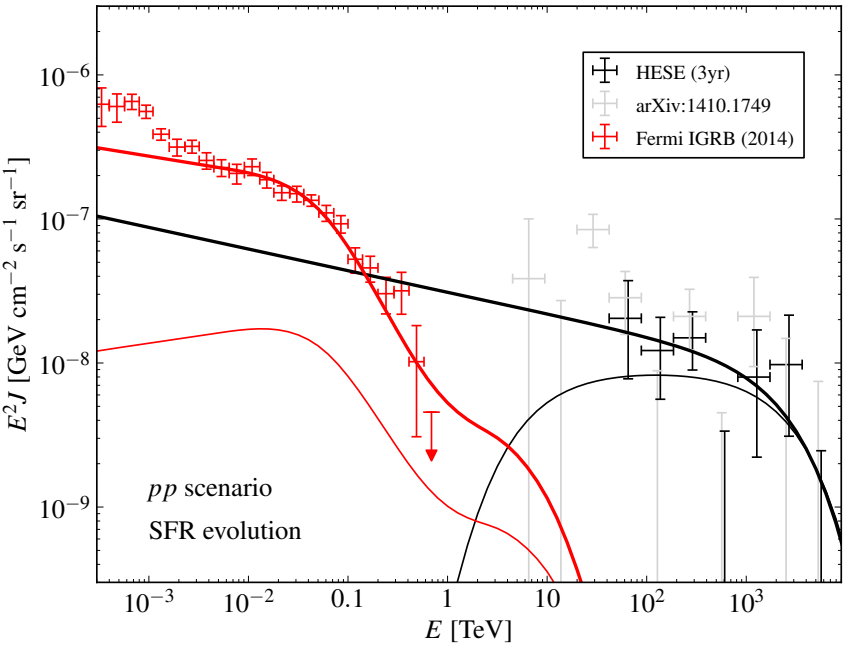

Fig. 10. A calculation illustrating that the photon flux that accompanies the neutrino flux (thick black line) measured by IceCube matches the gamma-ray flux (thick red line) observed by Fermi. We assume a $E^{-1.5}$ energy spectrum, star-formation redshift evolution and, importantly, gamma-ray transparent sources, i.e., pionic photons lose energy in the EBL but not in their sources. The black data points are early IceCube measurements.[27,28] The result suggests that the decay products of neutral and charged pions from pp interactions may be significant components of the nonthermal radiation in the extreme universe.[29] (Introducing the cutoff on the high-energy flux, shown in the figure, does not affect the result.) The calculation is compared to an identical calculation adopting a spectral shape characteristic for the production of cosmic neutrinos on a gamma-ray target in the source (thin lines). While the pionic gamma-ray energy flux is now suppressed relative to the Fermi observations, the neutrino energy spectrum underestimates the IceCube observations and the conclusion that the sources are likely obscured is recovered after correct normalization to the most up to date measurements.[29]

These channels produce charged and neutral pions with probabilities 2/3 and 1/3, respectively. However, the additional contribution of nonresonant pion production changes this ratio to approximately 1/2 and 1/2. In contrast, cosmic rays interacting with matter produce equal numbers of pions of all three charges: $p + p \to n_\pi\,[\,\pi^0 + \pi^+ + \pi^-] + X$, where n_π is the pion multiplicity. We thus obtain a charge ratio $K_\pi = n_{\pi^\pm}/n_{\pi^0} \simeq 2$ and 1 for pp and $p\gamma$ interactions, respectively.

Eqs. 2 and 3 can now be combined to obtain a direct relation between the gamma-ray and neutrino production rates:

$$\frac{1}{3}\sum_\alpha E_\nu^2 Q_{\nu_\alpha}(E_\nu) \simeq \frac{K_\pi}{4}\left[E_\gamma^2 Q_\gamma(E_\gamma)\right]_{E_\gamma = 2E_\nu}\,, \tag{4}$$

where the factor 1/4 accounts for the fact that two gamma rays are produced in the neutral pion decay with twice the energy of the accompanying neutrino, $\langle E_\nu \rangle / \langle E_\gamma \rangle \simeq 1/2$. Note that the relative production rate of gamma rays and neutrinos only depends on the ratio of charged-to-neutral pions produced without any reference to the cosmic-ray beam that initiates their production in the target. This powerful relation follows from the fact that pion production conserves isospin and nothing else.

Before applying this relation to data, one must recall that the universe is transparent to extragalactic neutrinos but not to the accompanying gamma rays. These will interact with microwave photons and other components of the extragalactic background light (EBL) to initiate an electromagnetic cascade that reaches Earth in the form of multiple photons of lower energy. The electromagnetic shower subdivides the initial PeV photon energy into multiple photons with GeV to TeV energies by the time it reaches Earth.[30,31] If the source itself is opaque to gamma rays, the high-energy gamma rays will lose energy even before reaching the EBL to possibly emerge at Earth below the threshold of Fermi, at MeV energies and below.

In order to underscore the power of the multimessenger connection between photons and neutrinos, we first calculate the gamma-ray flux accompanying the diffuse cosmic neutrino flux observed by IceCube, which we describe by a power law with spectral index of -2.15, consistent with the neutrino data above an energy of 100 TeV. The result is shown in Fig. 10 assuming gamma-ray transparent sources and equal multiplicities of all three pion charges, i.e., $K_\pi = 2$. The cascaded gamma-ray energy flux resulting from the pionic photons accompanying the neutrino flux matches the energy flux of extragalactic gamma rays measured by Fermi.

Clearly, in this illustration, the slope and overall normalization of the neutrino spectrum have been adjusted to not exceed the isotropic extragalactic gamma-ray background observed by the Fermi satellite. We conclude that the high-energy cosmic neutrino flux above 100 TeV shown in Fig. 10 saturates the Fermi measurement for the highest photon energies; higher normalization and larger spectral index of the neutrino flux will result in a gamma-ray flux that exceeds the Fermi observations. Fitting the IceCube data with a $E^{-2.5}$ spectral index, closer to the present observations, results in larger neutrino energy fluxes at energies below 100 TeV for both neutrinos and their accompanying photons. After cascading in the EBL, the latter exceeds the Fermi observations. There is no conflict here; in this case, we conclude that the assumption that the sources themselves are transparent to photons is untenable. The resolution is as mentioned above, that the photons lose energy in the source even before entering the EBL and, as a result, reach Earth with energies that are below the detection threshold of the Fermi satellite, at MeV energy or below.

Alternatively, the target for producing the neutrinos may be photons. This changes the value of K_π and, more importantly, the shape of the energy spectrum; for a detailed discussion, see, for instance, Ref. 32. Yielding an energy spectrum that peaks near PeV energies, as shown in Fig. 10, the contribution to the Fermi flux is suppressed at lower energies relative to the power law assumed in Fig. 10. However,

as was the case for *pp* interactions, fits that do not exceed the Fermi data tend not to accommodate the cosmic neutrino spectrum below 100 TeV. This is illustrated in Fig. 10 where we obtain a neutrino spectrum well below the Fermi observations at the price of not fitting the overall normalization of the neutrino data. If sources of the TeV-PeV neutrinos are transparent to gamma rays with respect to two-photon annihilation, tensions with the isotropic diffuse gamma-ray background measured by Fermi seem unavoidable, independently of the production mechanism.[29]

The conclusion is inescapable that the energy fluxes of neutrinos and gamma rays in the extreme universe are qualitatively the same. Furthermore, the IceCube observations point at contributions to the diffuse flux from gamma-obscured sources.

We therefore anticipate that multimessenger studies of gamma-ray and neutrino data will be a powerful tool to identify and study the cosmic ray accelerators that produce cosmic neutrinos. Accordingly, IceCube has developed methods, most promising among them the real-time multiwavelength observations with astronomical telescopes, to identify the sources and build on the discovery of cosmic neutrinos to launch a new era in astronomy.[33,34]

An important lesson for multiwavelength astronomy is that strong high-energy gamma-ray emitters may not be the best candidate neutrino sources. For instance, IceCube does not observe neutrinos from gamma-ray bursts, but this result covers a sample of bursts that are strong gamma-ray emitters.[35] A handful of bursts have been identified that are obscured in gamma rays and may instead provide the key to detecting a neutrino signal. The strongest sources in the 10-year IceCube sky map, the galaxies NGC 1068 and TXS 0506+O56, are gamma-ray-obscured sources at least at the time that they emitted neutrinos. We will discuss this next.

Interestingly, the common energy density of photons and neutrinos is also comparable to that of the ultra-high-energy extragalactic cosmic rays.[36]

4. Identifying Neutrino Sources: The Supermassive Black Hole TXS 0506+056

Phenomenological studies[37,38] and recent data analyses[39–41] have converged on the fact that Fermi's extragalactic gamma-ray flux shown in Fig. 10 is dominated by blazars, AGN with jets pointing at Earth. It is tempting to conclude, based on the matching energy fluxes of photons and neutrinos discussed in the previous section, that the unidentified neutrino sources contributing to the diffuse neutrino flux have already been observed as strong gamma-ray emitters. This is not the case. A dedicated IceCube study[42] correlating the arrival directions of cosmic neutrinos with Fermi blazars shows no evidence of neutrino emission from these sources. The limit leaves room for a contribution of Fermi blazars to the diffuse cosmic neutrino flux below the 10% level. Surprisingly, the multimessenger campaign launched by the neutrino alert IC-170922A[2] identified the first source of cosmic neutrinos as a Fermi "blazar." We will discuss how the multiwavelength data shed light on the apparent contradiction.

Since 2016, the IceCube multimessenger program has grown from issuing Galactic supernova alerts[43] and matching neutrinos with early LIGO/Virgo gravitational wave candidates to a steadily expanding set of automatic filters that select in real time rare, very high energy neutrino events that are likely to be cosmic in origin.[44] Within less than one minute of stopping in the instrumented Antarctic ice, the arrival directions of the neutrinos are reconstructed and automatically sent to the Gamma-ray Coordinate Network for potential follow-up by astronomical telescopes.

4.1. *Observation of a Cosmic Neutrino Source: TXS 0506+056*

On September 22, 2017, the tenth such alert, IceCube-170922A,[45] reported a well-reconstructed muon that deposited 180 TeV inside the detector, corresponding to a most probable energy of the parent neutrino of 290 TeV. Its arrival direction was aligned with the coordinates of a known Fermi blazar, TXS 0506+056, to within 0.06°. The source was "flaring" with a gamma-ray flux that had increased by a factor of seven in recent months. A variety of estimates converged on a probability on the order of 10^{-3} that the coincidence was accidental. The identification of the neutrino with the source reached the level of evidence, but not more. What clinched the association was a series of subsequent observations, culminating with the optical observation of the source switching from an "off" to an "on" state two hours after the emission of IC-170922A, conclusively associating the neutrino with TXS 0506+056.[46] The sequence of observations can be summarized as follows:

- The redshift of the host galaxy, a known blazar, was measured to be $z \simeq 0.34$.[47] It is important to realize that nearby blazars like the Markarian sources are at a distance that is ten times closer, and therefore TXS 0506+056, with a similar flux despite the greater distance, is one of the most luminous sources in the universe. This suggests that it belongs to a special class of sources that accelerate proton beams in dense environments, revealed by the neutrino. That the source is special eliminates any conflict between its observation and the lack of correlation between the arrival directions of IceCube neutrinos and the bulk of the blazars observed by Fermi.[42] Such limits implicitly assume that all sources in an astronomical category are identical, and this is a strong, unstated assumption as underscored by this observation.
- Originally detected by NASA's Swift[48] and Fermi[49] satellites, the alert was followed up by ground-based air Cherenkov telescopes.[50] MAGIC detected the emission of gamma rays with energies exceeding 100 GeV starting several days after the observation of the neutrino.[51] Given its distance, this establishes the source as a relatively rare TeV blazar.
- Informed where to look, IceCube searched its archival neutrino data up to and including October 2017 for evidence of neutrino emission at the location of TXS 0506+056.[3] When searching the sky for point sources of

neutrinos, two analyses have been routinely performed: one that searches for steady emission of neutrinos and one that searches for flares over a variety of timescales. Evidence was found for 19 high-energy neutrino events on a background of fewer than 6 in a burst lasting 110 days. This burst dominates the integrated flux from the source over the last 9.5 years of archival IceCube data, leaving the 2017 flare as a second subdominant feature. We note that this analysis applied a published prescription to data; the chance that this observation is a fluctuation is small.

- Radio interferometric images[52,53] of the source revealed a jet that loses its tight collimation beyond 5 milliarcseconds running into material or intense radiation fields that are likely to be the target for producing the neutrinos. The nature of the target is still a matter of debate. Speculations include the merger with another galaxy that may supply plenty of material to interact with the jet of the dominant galaxy. Alternatively, the jet may interact with the dense molecular clouds of a star-forming region or simply with supermassive stars in the central region of the host galaxy.[52,53] Also, in a so-called structured jet, the accelerated protons may catch up and collide with a slower moving and denser region of jetted photons. Additionally, the VLBA data reveal that the neutrino burst occurs at the peak of enhanced radio emission at 15 GHz, which started five years ago; see Fig. 11. The radio flare may be a signature of a galaxy merger; correlations of radio bursts with the process of merging supermassive black holes have been anticipated.[54]
- The MASTER robotic optical telescope network has been monitoring the source since 2005 and detected its strongest time variation in the last 15 years to occur two hours after the emission of IC170922, with a second variation following the 2014-15 burst.[46] The blazar switches from the "off" to the "on" state two hours after the emission of the neutrino. After an episode of monitoring the uniformity of their observations of the source in the first quarter of 2020, they argue that the time variation detected on September 22, 2017 conclusively associates the source with the neutrino.[46]

Additionally, it is important to note the fact that the high-energy photon and neutrino spectra covering the 2014 burst are consistent with a hard E^{-2} spectrum, which is expected for a cosmic accelerator. In fact, the gamma-ray spectrum shows a hint of flattening beyond E^{-2} during the 110-day period of the 2014 burst.[55,56]

In summary, both the multiwavelength campaign[2] and the observation of an earlier burst of the same source in archival neutrino data provide statistically independent[3] evidence for the association of neutrinos with TXS 0506+056 at the 3 and 3.7σ level, respectively. The significances contributed by the optical and TeV associations on timescales of hours and days are not taken into account, and it is not straightforward to do so because of their a posteriori nature. We conclude, however, that the association of neutrinos with the source summarized above is compelling.

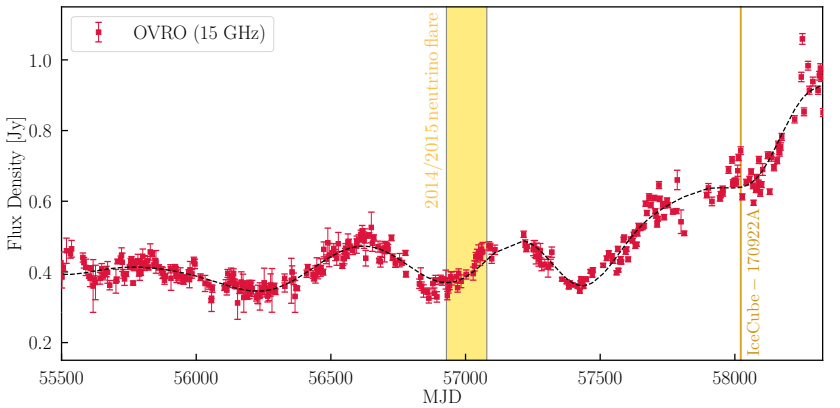

Fig. 11. TXS 0506+056 radio light curve from Owen Valley Radio Observatory (OVRO) at 15 GHz (red). The dashed line illustrates the pattern of the radio flux density. The 2014/15 110-day neutrino flare (yellow band) and the IceCube-170922A episodes are shown.

Other IceCube alerts have triggered intriguing observations. Following up on a July 31, 2016, neutrino alert, the AGILE collaboration, which operates an orbiting X-ray and gamma-ray telescope, reported a day-long blazar flare in the direction of the neutrino one day before the neutrino detection.[57] A tentative but very intriguing association of an IceCube alert[58] has been made with a tidal disruption event, an anticipated source of high-energy neutrino emission. Even before IceCube issued automatic alerts, in April 2016, the TANAMI collaboration argued for the association of the highest energy IceCube event at the time, dubbed "Big Bird," with the flaring blazar PKS B1424-418.[59] Interestingly, the event was produced at a minimum of the Fermi flux,[5] indicating a gamma-ray-obscured source. AMANDA, IceCube's predecessor, observed[60] three neutrinos in coincidence with a rare flare of the blazar 1ES 1959+650 detected by the Whipple telescope in 2002.[61] However, none of these identifications reach the significance of the observations triggered by IC-170922A.

4.2. *The Blueprint of the TXS 0506+056 Beam Dump?*

Blazars are accelerators with their jets pointing at Earth. The gamma-ray community has developed a routine procedure for modeling their spectrum with two components: a lower energy component produced by synchrotron radiation by the electron beam and a high-energy component resulting from the inverse Compton scattering of (possibly the same) photons by accelerated electrons; for a recent discussion, see Ref. 62. Such a source cannot accommodate the TXS observations for two reasons: an electron beam does not produce pions that decay into neutrinos, and, even with the presence of protons in the beam, a target is required to produce the parent pions. It is also evident that a source that emits high-energy gamma rays is transparent to $\gamma\gamma$ absorption and unlikely to host the target material to

produce neutrinos. The opacity for $\gamma\gamma$ interactions to absorb photons is typically two orders of magnitude larger than the one for $p\gamma$ interactions to produce pions and neutrinos.[63]

With the opacity to photons about two orders of magnitude larger, the target producing the neutrinos is unlikely to be transparent to TeV photons, only to photons with tens of GeV energy, and that is indeed what is observed by Fermi at the time of the 2014 flare. There is also evidence that, temporarily, TXS 0506+056 was a gamma-ray-obscured source at the time the IC-170922A neutrino was emitted. The optical observations show a dramatic transition of the blazar from the "off" to the "on" state two hours after the emission of the neutrino, resulting additionally in the doubling of its total optical luminosity.[46] Also at the time of IC-170922 the ground-based atmospheric gamma-ray telescopes observed rapid variations in the flux around the time of the neutrino emission,[2] with the gamma-ray emission observed by MAGIC only emerging after several days.[51]

A more direct indication that strong neutrino emitters are gamma-ray-obscured is indicated by a more recent alert, IC-190730A, sent by IceCube on July 30, 2019. A well-reconstructed 300-TeV muon neutrino was observed in spatial coincidence with the blazar PKS 1502+106.[64] With a reconstructed energy just exceeding that of IC-170922A, it is the highest energy neutrino alert so far. OVRO radio observations[65] show that the neutrino is coincident with the peak flux density of a flare at 15 GHz that started five years prior,[66] matching the similar long-term radio outburst of TXS 0506+056 at the time of IC-170922A; see Fig. 11. Even more intriguing is the fact that the gamma-ray flux observed by Fermi shows a clear minimum at the time that the neutrino is emitted; see Fig. 12. We infer that at this time the jet meets the target that produces the neutrino. Inevitably, the accompanying high-energy gamma rays will be absorbed and the bulk of their electromagnetic energy will cascade down to energies below the Fermi threshold, i.e., MeV or below. Accumulating evidence indicates that cosmic neutrinos are produced by temporarily gamma-suppressed blazars or some other category of AGN.

The coincidence of the two highest energy alerts to date with extended periods of radio emission has led to the speculation that all,[67] or at least some,[68] cosmic neutrinos originate in radio-bright galaxies. The significance of the correlation and its physical origin, if any,[69] are debated.

We suggest that neutrino sources are special, with properties unlikely to match any astronomical classification; astronomical observations catalog accelerators, not neutrino sources. If the neutrino flux observed from TXS 0506+056 over the last decade were typical of all blazars, these would overproduce the total diffuse flux observed by IceCube by well over an order of magnitude.[63] The diffuse neutrino flux limits the density of such sources in the universe to $\sim 5 \times 10^{-10}\,\mathrm{per\,Mpc^3}$, i.e., about 5% of all blazars, and more likely an even smaller fraction of all AGN.[4] Attempts by IceCube and others to find a correlation between the directions of high-energy neutrinos and *all* Fermi blazars must inevitably be unsuccessful, as was the case in Ref. 42.

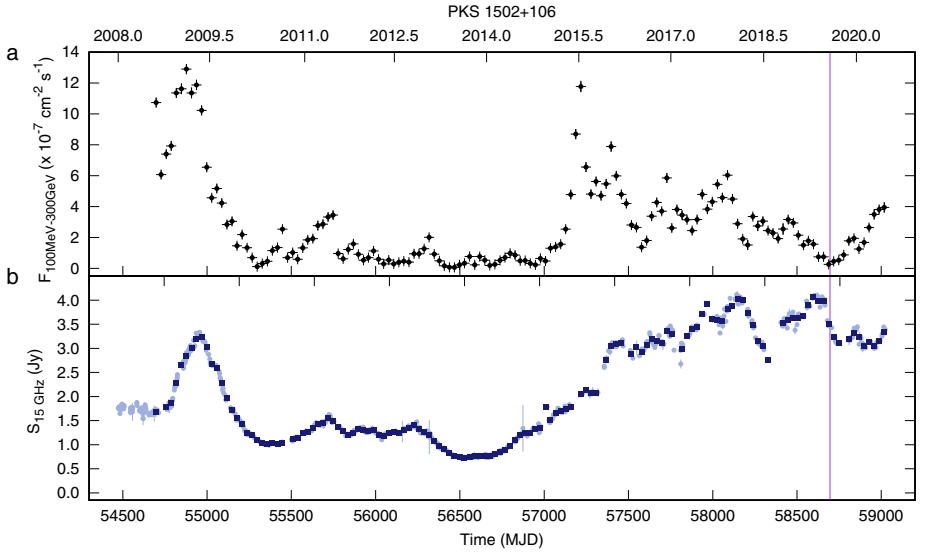

Fig. 12. Temporal variation of the γ-ray and radio brightness of PKS 1502+106.[5] **Top Panel:** Fermi-LAT likelihood light curve integrated between 100 MeV and 300 GeV (marked by black dots with error bars). **Bottom Panel:** OVRO flux density curve of PKS 1502+106 plotted with light blue dots, which is superimposed by the radio flux density curve binned to the Fermi-LAT light curve (marked with dark blue squares). The detection time of the neutrino IC-190730A is labeled by a vertical purple line.

The nature of this special class of sources has not been settled. One straightforward explanation could be that a subclass of AGN, selected by redshift evolution, are powerful proton accelerators producing neutrinos in the past and no longer active today. This assumption accommodates the relatively large redshift of TXS 0506+056, which would be the closest among a set of sources that only accelerated cosmic rays at early redshifts.[70]

Alternatively, in merging galaxies there is plenty of material for accelerated cosmic rays to interact with the jet of the dominant galaxy. Merger activity in active galaxies in not uncommon. The fresh material provides optically thick environments and allows for rapid variation of the Lorentz factors. A cursory review of the literature on the production of neutrinos in galaxy mergers is sufficient to conclude that they can indeed accommodate the observations of both the individual sources discussed above and the total flux of cosmic neutrinos.[71–73] Besides mergers, some form of structured jet where the accelerated protons collide with a slower moving and denser region of jetted photons is a possibility. The jet could also interact with dense molecular clouds of a star-forming region or simply with supermassive stars in the central region of the host galaxy.[52,53]

The observation that the energy flux in neutrinos and very high energy cosmic rays are similar supports the fact that cosmic rays must be highly efficient at

producing neutrinos, requiring a large target density that renders them opaque to high-energy gamma rays. A consistent picture emerges with the source opacity $\tau_{p\gamma}$ exceeding a value of 0.8,[4,63] resulting in a gamma-ray cascade where photons lose energy in the source before cascading to yet lower energies in the extragalactic background light. Some of their energy emerges below the Fermi threshold by the time they reach Earth. This is consistent with the discussion in the previous section that the multimessenger relation between neutrinos and gamma rays points at obscured sources.

We previously mentioned the evidence emerging from 10 years of IceCube data that the arrival directions of cosmic neutrinos are no longer isotropic.[74] The anisotropy results from four sources—TXS 0506+056 among them—that show evidence for clustering above the 4σ level (pretrial). The strongest of these sources is the nearby active galaxy NGC 1068. There is evidence for shocks near the core and for molecular clouds with column density reaching $\sim 10^{25}\,\mathrm{cm}^{-2}$.[75] Similar to TSX 0506+056, a merger onto the black hole is observed—either with a satellite galaxy or, more likely, with a star-forming region[76] accounting for the molecular clouds. This major accretion event may be the origin of the increased neutrino emission.

Although it is obviously challenging to provide a final conclusion on the origin of neutrinos and cosmic rays, we should not lose sight of the fact that high-energy neutrino astronomy exists and that IceCube has demonstrated it has the tools to reveal the extreme universe with more data, or, more realistically, with a larger detector.

5. From Discovery to Astronomy: Larger Telescopes with Better Angular Resolution

Neutrino astronomy has reached a stage that reminds us of the time when Trevor Weekes's 11-meter ground-based Cherenkov telescope had established one convincing TeV source: the Crab. Even today we do not know how the Crab produces gamma rays that track the pulsations of the pulsar at TeV energy. We have to take the lead on TeV astronomy: building more and better telescopes.

Following the pioneering work of DUMAND,[77] several neutrino telescope projects were initiated in the Mediterranean Sea and in Lake Baikal in the 1990s.[78–81] In 2008, the construction of the ANTARES detector off the coast of France was completed. It demonstrated the feasibility of neutrino detection in the deep sea and has provided a wealth of technical experience and design solutions for deep-sea components. An international collaboration has started construction of a multi-cubic-kilometer neutrino telescope in the Mediterranean Sea, KM3NeT.[82] KM3NeT in its second phase[82] will consist of two units for astrophysical neutrino observations, each consisting of 115 strings carrying more than 2,000 optical modules. Since April 2021, six are operational and taking data.[83]

A parallel effort is underway in Lake Baikal with the construction of the deep underwater neutrino telescope Baikal-GVD (Gigaton Volume Detector).[84] The first

GVD cluster was upgraded in the spring of 2016 to its final size: 288 optical modules, a geometry of 120 meters in diameter and 525 meters high, and an instrumented volume of 6 Mton. Each of the eight strings consists of three sections with 12 optical modules. At this time, 7 of the 14 clusters have been deployed, reaching a sensitivity close to the diffuse cosmic neutrino flux observed by IceCube.

IceCube itself is deploying seven new strings at the bottom of the detector array that have been designed as an incremental extension of the DeepCore detector and as a test bed for the technologies of a next-generation detector. The new instrumentation will dramatically boost IceCube's performance at the lowest energies, increasing the samples of atmospheric neutrinos by a factor of ten. New calibration devices will advance our understanding of the response of the light sensors in both current and new strings, resulting in improved reconstructions of cascade events, better identification of tau neutrinos, and an enhanced pointing resolution of muon neutrinos that could approach the 0.1 degree level for the highest energy events of cosmic origin. The improved calibration of the existing sensors will also enable a reanalysis of more than ten years of archival data and significantly increase the discovery potential for neutrino sources before the construction of a second-generation instrument.

Further progress requires a larger instrument. Therefore, as a next step, IceCube proposes to instrument $10\,\mathrm{km}^3$ of glacial ice at the South Pole, capitalizing on the large absorption length of light in ice to thereby increase IceCube's sensitive volume by an order of magnitude.[85] This large gain is made possible by the unique optical properties of the Antarctic glacier revealed by the construction of IceCube. Exploiting the extremely long photon absorption lengths in the deep Antarctic ice, the spacing between strings of light sensors will be increased from 125 to close to 250 meters without significant loss of performance of the instrument at TeV energies and above. The instrumented volume can therefore grow by one order of magnitude while keeping the instrumentation and its budget at the level of the current IceCube detector. The new facility will increase the rates of cosmic events from hundreds to thousands over several years. The superior angular resolution of the longer muon tracks will allow for the discovery of cosmic neutrino sources, currently seen at the $\sim 3\sigma$ level in the 10-year sky map; see Fig. 5.

Acknowledgements

Discussion with collaborators inside and outside the IceCube Collaboration, too many to be listed, have greatly shaped this presentation. Thanks. I would like to single out Markus Ahlers, Qinrui Liu and Ali Kheirandish for contributing to aspects of this manuscript. This research was supported in part by the U.S. National Science Foundation under grants PLR-1600823 and PHY-1913607 and by the University of Wisconsin Research Committee with funds granted by the Wisconsin Alumni Research Foundation.

The first results of PandaX-4T

Jianglai Liu*

School of Physics & Astronomy and Tsung-Dao Lee Institute, Shanghai Jiao Tong University, Shanghai, 200240, China

E-mail: jianglai.liu@sjtu.edu.cn

**On behalf of the PandaX Collaboration*

Dark matter, an invisible substance which constitutes 85% of the matter in the observable universe, is one of the greatest puzzles in physics and astronomy today. Dark matter can be made of a new type of fundamental particle, not yet observed due to its feeble interactions with visible matter. In this talk, we present the first results of PandaX-4T, a 4-ton-scale liquid xenon dark matter observatory, searching for these dark matter particles from deep underground. We will briefly summarize the performance of PandaX-4T, introduces details in the data analysis, and present the latest search results on dark matter-nucleon interactions.

Keywords: Dark Matter; WIMPs; Liquid xenon; PandaX-4T.

1. Introduction

The detection of the weakly-interacting-massive-particles (WIMPs) has been outlined by Goodman and Witten in 1985.[1] Yet, in the direct detection of dark matter, we have not seen convincing signals. At the large mass region (approximately 100 GeV/c^2 and above), the front runners are xenon-based experiments.[2–4] The sensitivities of these experiments, roughly speaking, correspond to a few events per tonne per year.

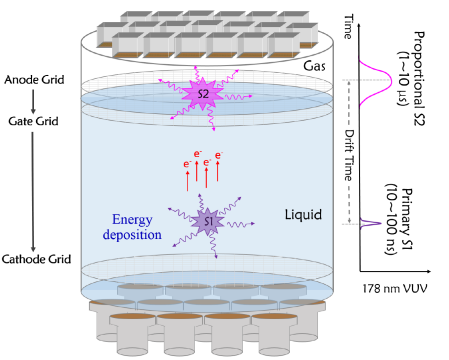

Fig. 1. Working principle of a two-phase TPC.

All of these xenon experiments are based on a tank of liquid xenon cooled at negative one hundred degrees. The detector is the so-called Time Projection

Chamber (TPC), capable of measuring both the energy deposition and its location, utilizing the detection of prompt scintillation photons ($S1$) and delayed electroluminescence signals due to ionized electrons ($S2$). See Fig. 1. The interaction of dark matter and xenon nucleus produces nuclear recoils (NR), and the background gamma rays produce electron recoils (ER). The ratio of $S1$ and $S2$ is a natural discriminant for ER background.

The three dark matter experiments with xenon TPC are LUX-ZEPLIN (LZ), XENONnT and PandaX-4T. LZ is located at the 4850 feet level of the Sanford Underground Research Facility in Lead, SD, containing seven active tonnes of liquid xenon. At the Laboratori Nazionali del Gran Sasso (LNGS) of INFN in Italy, the XENONnT detector is an upgrade to XENON1T, with an active mass of six tonnes. Both LZ and XENONnT are under active preparation. The experiment I am going to focus here, PandaX-4T, with 3.7 tonnes of active mass, is located in China Jinping Underground Laboratory (CJPL), southwest of China, 2400 meters underneath a rock mountain.

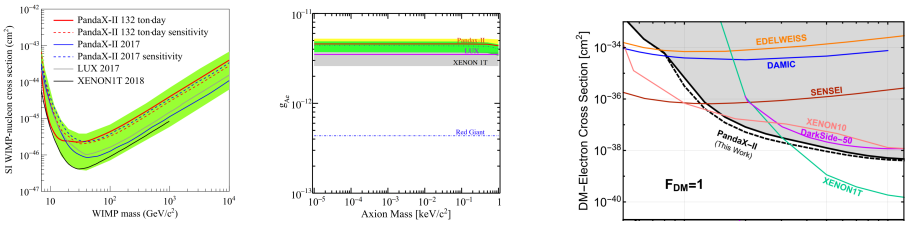
CJPL is the deepest underground laboratory in the world. CJPL-I has a small space and only holds two experiments, PandaX and CDEX (China Dark matter Experiment), to detect dark matter with different methods. CJPL-II has a much expanded lab space, with eight experimental halls, each with a dimension of 65 m long and 14×14 m^2 cross section. Currently, there are three experimental halls in occupation, PandaX, CDEX and JUNA (Jingping Underground lab for Nuclear Astrophysics).

2. The PandaX Experiment

The PandaX collaboration is formed in 2009. Up to now, we have undergone two completed phases. The first phase, PandaX-I, had 120 kg of xenon target. The second, PandaX-II, has 580 kg of xenon target. In particularly, PandaX-II has produced several leading results on the direct detection of dark matter. Since the August of 2019, the new generation of the experiment, PandaX-4T, was officially moved into CJPL-II.

2.1. *Results of PandaX-II*

In 2019, we finished the full exposure of 130 ton·day of PandaX-II. As shown in Fig. 2(a), the data set was increased by a factor of 2.5 in sensitivity for WIMPs,[5] in comparison with the results in 2017.[8] But the upper limit is worsened due to background fluctuation. For ER signals, we are looking directly for the solar axion signal and the anonymous neutrino magnetic moment from the solar neutrinos. In light of the recent XENON1T excess, in this region, the data are contaminated by the tritium background, with limited sensitivity to confirm or refute XENON1T (Fig. 2(b)).[6] Fig. 2(c) gives a new search using an extremely low threshold data by giving up $S1$ and only taking $S2$. This pushes the energy threshold down to 80 eV.



(a) (b) (c)

Fig. 2. (a) The 90% confidence level upper limits vs. WIMP mass for the spin-independent WIMP-nucleon elastic scattering cross sections from the full exposure data of PandaX-II, overlaid with that from PandaX-II 2017, LUX 2017, and XENON1T 2018;[5] (b) A search of solar axion-electron coupling constant g_{Ae} in PandaX-II, in comparison with other experiments;[6] (c) 90% C.L. upper limits (solid: the constant model, dashed: NEST 2.0) on WIMP-electron scattering cross section from PandaX-II data for a point-like interaction.[7]

Therefore, we can look for the direct scatterings of WIMPs and electrons. Because of the low threshold, we have the best sensitivity around 25 MeV/c^2 in WIMP mass for a point-like interaction, which was unexplored previously.[7]

2.2. *Overview of PandaX-4T*

For the newly deployed PandaX-4T experiment, a 900 m^3 water tank is acting as the shielding of the central detector. The detector resides in a platform at the middle of this tank. At the center of the detector, there is a TPC with a 1.2 m height and 1.2 m diameter, holding 3.7 tonnes liquid xenon. On the top and bottom, it is covered by roughly 400 channels of 3-in PMTs.

The preparation of PandaX-4T started in April, 2018, after the permission from the CJPL management. The installation of the entire apparatus was completed on May, 2020. The commissioning run extended from Nov. 28, 2020 to Apr. 16, 2021, of which the data will be reported here.

Most of our instrumentation severing the detector is located in a 10000-class clean room. All the TPC assemblies were carried out in a 1000-class clean room. To avoid the contamination of radon, the air going into the 1000-class clean room were purified by a radon removal system.

3. Performance of PandaX-4T Commissioning

3.1. *Cryogenics*

The cryogenics is very stable during the commissioning. In fact, the heat load of the system is only 50 W, much smaller than the maximum cooling power 580 W by design. We have two circulation loops trying to clean out the electronegative outgassing from the detector with a rate of 40 kg/h. Through out the stable running period, the pressure and the temperature are stable within 0.5% and 0.1 K, respectively.

3.2. *Electronics and DAQ*

We utilize a triggerless electronics system. Every channel is read out separately by a faster digitizer whenever the signal is above 1/3 photonelectron (PE), with a sampling rate of 250 MS/s. The average single photon efficiency is around 95%, and the maximum bandwidth of the DAQ is 450 MB/s.

3.3. *TPC operation conditions*

As illustrated in Fig. 1, between the anode and the gate is a 10 mm amplification region for the ionized electrons. Between the gate and the cathode is the drifting region, with a maximum drift distance of 1.2 m. Below the cathode, we have a 10 cm shielding region to suppress the background from bottom PMTs. During the operations, the HVs on the electrodes were set at a few different values to avoid excessive discharges.

3.4. *Data taking history*

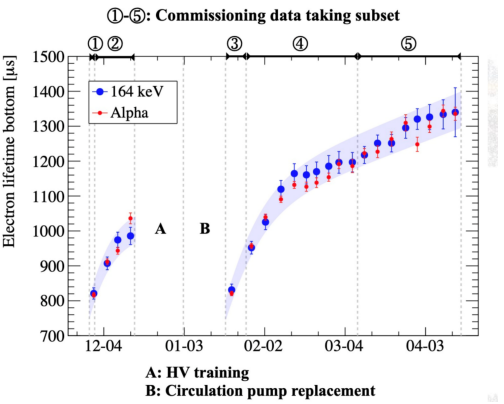


Fig. 3. Electron lifetime for different commissioning data taking subset.

Electronegative impurities tend to attach ionized electrons, leading to an exponential attenuation of the $S2$ signals vs. drift time. The purity of the liquid is characterized by the mean attenuation time, i.e. the electron lifetime. Using internal gamma or alpha peaks, the extracted electron lifetime also gives the vertical correction for $S2$. In total, we have a stable data running period of 95 days, and as shown in Fig. 3, the electron life time is kept around 1000 μs. In comparison, the maximum drift time in the TPC is about 840 μs.

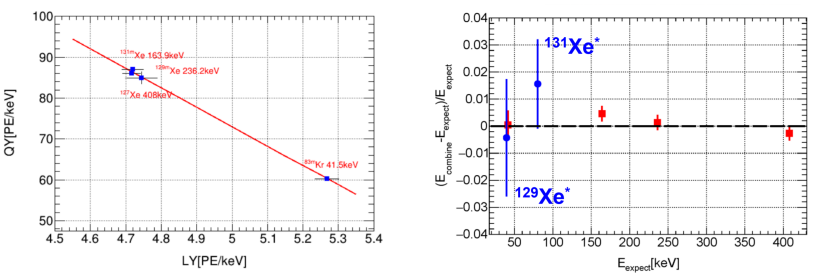
3.5. *Calibration*

Calibration is one of the most important aspects. PandaX-4T adopted three main methods. One is the gas source injection, where we can load in radioactive ^{83m}Kr and ^{220}Rn into the detector. They are short-lived, but uniformly distributed in the detector. Second is the external calibration loops, where a source can go into these loops at three different height of the TPC. Lastly, we have a Deuteron-Deuteron (D-D) fusion generator for neutrons. It produces semi-monoenergetic neutrons, which are then beamed directly into the detector.

- Uniformity correction with ^{83m}Kr. When ^{83m}Kr radioactive sources are loaded into the detector, they uniformly distribute in the detector with a characteristic 41.5 keV energy, based on which the uniformity of $S1$ and $S2$ can be calibrated. For $S2_b$, the RMS variation in the fiducial volume is 12% and for $S1$, the RMS variation 20%. The measured energy resolution is 6.8%.
  For the energy reconstruction, event-by-event we use a linear combination of $S1$ and $S2$ according to Eq. 1.

$$\mathrm{E} = 13.7\mathrm{eV} \times \left(\frac{\mathrm{S1}}{\mathrm{PDE}} + \frac{\mathrm{S2_b}}{\mathrm{EEE} \times \mathrm{SEG}} \right), \tag{1}$$

  in which PDE, EEE and SEG are corresponding to the photon detection efficiency, electron extraction efficiency and single electron gain, respectively.



(a) (b)

Fig. 4. (a) Charge yield vs. light yield in PE/keV and the linear fit. (b) Fractional differences between the reconstructed and expected energy. Blue squares represent uniformly distributed electron recoil peaks, ^{131m}Xe(164 keV), ^{129m}Xe(236 keV),^{127}Xe(408 keV) and ^{83m}Kr(41.5 keV). Blue points in (b) represent de-excitation gammas from ^{129}Xe*(39.6 keV) and ^{131}Xe*(80.2 keV) after neutron activation, with the NR components subtracted from $S1$ and $S2$, which are not used in the linear fit.

SEG can be obtained using the smallest $S2$ signals identified in the data. The uniform distribution to the detector is only 13% for the RMS variation. The top and bottom ratio for these low energy is also very stable. Then with various ER peaks in the data, we can fit for PDE and EEE using Eq. 1, as shown in Fig. 4(a). Just for the check, the reconstruction energy, after applying these two

fitted parameters, shows on Fig. 4(b). The red points have been used in the fit. We use two more independent data points produced by illuminating xenon with neutrons and looking at de-excitation gamma rays. They are also at the zero line, but with a large uncertainty because the de-excitation energy contains some of the nuclear energy component.

- Nuclear recoil calibration with D-D neutrons.

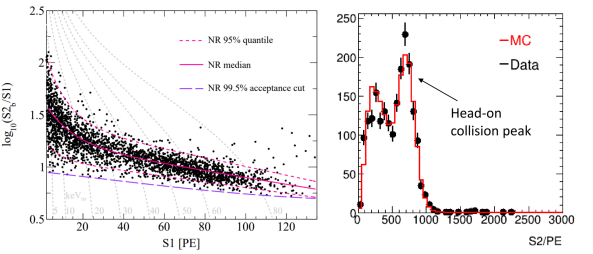


Fig. 5. D-D neutron calibration. The left picture shows $\log_{10} S2/S1$ over $S1$; The right plot gives the one-dimensional projection of $S2$, which is in agreement with MC expectation.

The other aspect of the calibration is to determine the low energy response of the detector, particularly relevant to the dark matter search. If dark matter interacts with xenon, and produces a low energy nuclear recoil, the best calibration should come from the neutrons. Fig. 5 summarizes the neutron recoil calibration with the D-D neutron band. D-D neutron band can generate a monoenergetic neutron around 2.2 MeV. The data set is used in combination with the AmBe data set, another neutron source, to tune the parameters, such as the light yield, charge yield, as well as fluctuations in the signal model.

4. ER calibration with ^{220}Rn

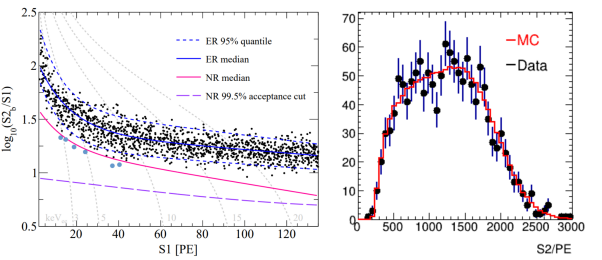

Fig. 6. ^{220}Rn calibration. In the left plot, purple solid line is the medium of neutron calibration. The right plot gives the one-dimensional projection of $S2$, which is in agreement with the MC data.

ER calibration is critical for us to understand the majority of the background. The ER response is calibrated by injecting ^{220}Rn into the detector, which only have 55 s life time. One of the decay progeny ^{212}Pb is a beta emitter, producing a flat energy spectrum at low energy. We characterize the rejection power by simply counting how many events are leaked underneath the nuclear recoil medium line. As shown in Fig. 6, the full rejection power is 0.43%, with roughly 50% uncertainty.

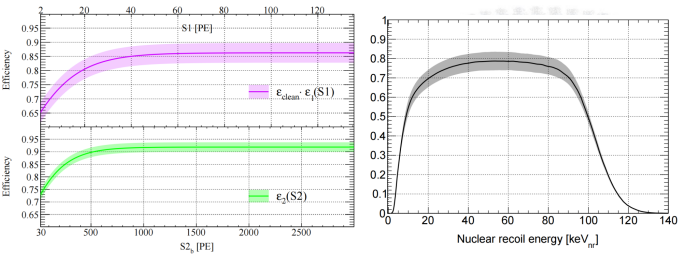

Fig. 7. Selection efficiency. The left picture shows the data quality cut efficiency for $S1$ an $S2_b$; The right plot gives the efficiency vs. nuclear recoil energy.

Using the same electron or nuclear recoil low energy data set, we can determine the efficiency for both $S1$ and $S2$. As illustrated in Fig. 7, at the plateau region, we have an efficiency of around 78%@40 keV.

4.1. *Backgrounds*

The major background components considered in the dark matter analysis are the following:

The first is the material background from the detector. If we bin our detector into several regions, the top, the bottom, the outer and the center, the background component is different. Comparing the expectation from the data, the overall agreement is around 14%. After converting all these high energy events into the low energy in the dark matter region, it is a minor background with 33 events expected.

^{222}Rn background, distributed uniformly into a detector, is important. They can come out of the surface of an emanation material. However, ^{222}Rn can be identified easily through their decay progeny. There are alphas that one can identify, as well as α-β coincidence signals. We find that the rate of radon is about 5 μBq/kg. This number is improved by six times from PandaX-II. The extracted background is estimated to be 347$\pm$190 events.

^{85}Kr, another noble gas, is used to be a major problem for the earlier generation of PandaX. Using a delayed coincidence technique, the krypton level is measured to be 0.33 ppt, improved about twenty times from PandaX-II. The residual ^{85}Kr background is estimated to 53$\pm$34 events.

^{127}Xe normally do not exist in the xenon. It is produced when xenon is exposed too longer on the surface. Through the characterized gamma and X-rays in the electron-capture process, we can track them in the detector. The half live of ^{127}Xe is only 36 days, and will decay soon. The background in the dark matter region is the 5 keV K-shell X-rays. Actually, we can tag these X-rays through the 33 keV L-shell X-rays. The expected events of ^{127}Xe background is estimated to be 9±2.

Tritium background is unfortunately identified in our data. They are likely originated from a calibration at the end of PandaX-II, where we loaded tritium into the detector, trying to calibrate the detector and see how well we can remove them. Unfortunately, the removal is probably inefficient, leaving some residuals in PandaX-4T. In our fit, we left this contaminant to be floated, resulting into about 5×10^{-24} mol/mol concentration, a value that one cannot see with direct assay measurement.

Surface background is related to radon. Radon progeny can attach to the surface of the detector. These events can be clearly identified from the data by looking for αs with abnormally small $S2$. Because they are closed to the PTFE reflector, we can get both the position distribution and the $S2$ distributions to estimate how much of these backgrounds could leak underneath the dark matter search window. The expected background for these wall surface is estimated to be 0.6±0.2.

Neutron background generates directly nuclear recoil. For these neutron background, once they enter the detector, they could multi-scatter, and eventually get capture onto xenon, producing high energy capture signals. Both processes are bench-marked by neutron source calibration. In the end, the neutron background is estimated to be 1.3±0.6.

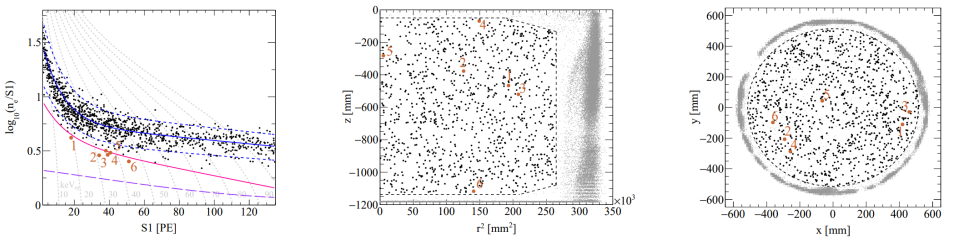
Accidental background is formed by random coincidence between uncorrelated $S1$ and $S2$. Therefore, cuts imposing the diffusion relations observed in data are effective in removing them. The expected accidental background was suppressed by two times in comparison with PandaX-II. It is estimated to be 2.4±0.5.

Fiducial volume determination utilizes the expected background from detector materials, as well as a combination of the radon background and the tritium background that is measured *in-situ*, to maximize a figure-of-merit related to the search sensitivity. The fiducial mass is settled at 2.67 tonnes.

5. Results

Fig. 8 shows the dark matter candidates within the fiducial volume and dark matter selection window. There are 1058 candidates in total. Six events are identified below the NR median curve. Candidates are uniformly distributed in the fiducial volume, which is expected if backgrounds are dominated by the tritium and radon. A fit to the data is consistent with background-only hypothesis, with a goodness-of-fit p-value of 0.7.

Based on the fit, we therefore set the bound on the spin-independent WIMP-nucleon scattering, summarized in Fig. 9. With a 0.63 tonne·year, we have a



(a) $\log_{10}(n_e/S1)$ vs. $S1$ (b) z vs. r^2 (c) y vs. x

Fig. 8. Distributions of the final dark matter candidates in $\log_{10}(n_e/S1)$ vs. $S1$ (a), z vs. r^2 (b), and y vs. x (c). n_e is the number of electrons derived from $S2$ so that different run sets under different gate conditions can be plotted on the same graph. In (a), the solid blue and red lines are the ER and NR medians, respectively, and the dashed blue lines are the corresponding 95% quantiles of ER events. The dashed violet line represents the 99.5% NR acceptance cut. The nuclear recoil energy in keV_{nr} are indicated with the grey dashed lines. The six ER events located below the NR median line are highlighted in brown. In (b) and (c), the dashed lines are projections of the fiducial volume, and black (light grey) dots represent events inside (outside).

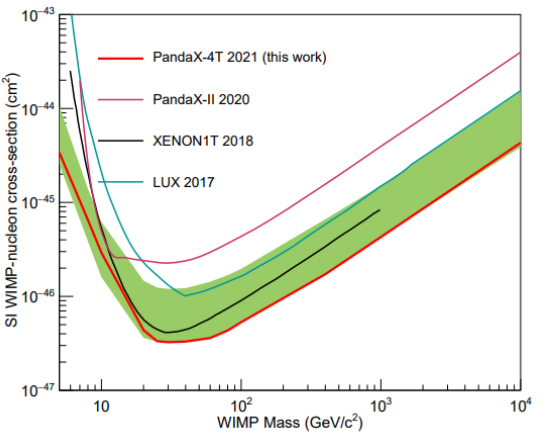


Fig. 9. The 90% C.L. upper limit vs. m_χ for the SI WIMP-nucleon elastic cross section from PandaX-4T commissioning data (red), overlaid with that from LUX 2017,[4] XENON1T 2018[3] and PandaX-II 2020.[5] The green band represents the $\pm 1\sigma$ sensitivity band.

sensitivity which is improved from the previous PandaX-II final analysis by 2.8 times at 40 GeV/c^2. Comparing the results (red line) with XENON1T, we are slightly edged, for example, at 40 GeV/c^2 where our exclusion limit is 1.3 times stronger. With this data, we can also dive into previously unexplored territory, such as approaching the low energy neutrino floor, and getting deeper into the SUSY parameter space.

6. Conclusion and Outlook

As mentioned, we have completed the first commissioning run of PandaX-4T with a 0.63 tonne·year exposure. PandaX-4T has produced the strongest WIMP-nucleon interaction constraint.[2] This demonstrates the physics potential of a highly sensitive multi-ton liquid xenon detector. PandaX-4T is currently performing an offline tritium removal campaign, aiming to reduce the electron recoil background by at least two-fold. In parallel, the collaboration is developing the plan for the next generation xenon experiment at CJPL.

and the XRISM team

The X-Ray Imaging and Spectroscopy Mission (XRISM) is a JAXA/NASA X-ray observatory with collaboration from ESA and several institutes and academic institutions worldwide. It is proposed to fulfill the promise of high-resolution X-ray spectroscopy with imaging once realized but unexpectedly terminated by a mishap of ASTRO-H/Hitomi. XRISM carries two sets of X-ray Mirror Assemblies and is equipped on the focal plane with a 6×6 pixelized X-ray micro-calorimeter array and an aligned X-ray CCD camera. With the combination of high-resolution spectroscopy imaging and the broader field of view, XIRSM is expected to pioneer a new horizon of the Universe in X-ray astrophysics. Aiming to launch the satellite in the Japanese Fiscal Year 2022, we fabricate the instruments and test for the satellite integration starting at the beginning of 2022. The paper reports the development status, reviewing the science objectives and the operation plan.

Keywords: X-ray astronomy; observation satellite; spectroscopy; imaging

1. Overview of XRISM

The X-ray imaging and spectroscopy mission — XRISM[1, 2] is a recovery mission of ASTRO-H Hitomi[3] launched on February 17, 2016. After the launch and following the commissioning of the onboard instruments, Hitomi started observation. However, due to a series of mishaps in the attitude control system, Hitomi was forced to stop operation on March 26. The observation period was only one month, but the results clearly show the X-ray microcalorimeter epoch-making capability. The observation was terminated before opening the gate valve. The valve was equipped to protect the sensor assembly from the atmosphere on the ground, but the gate valve limited the bandpass below ~ 2 keV. Even with the limitation in the low energy band, the unprecedented energy resolution enables us to measure the plasma turbulence velocity and detect weak lines of rare metals with a few ks exposure. The obtained spectrum is a highlight obtained from the Perseus cluster of galaxies.[4]

The central concept of XRISM is to maximize the X-ray micro-calorimeter science since it is an entirely new scientific field. We chose a conservative combination

with the CCD camera to strengthen the science. Table 1 summarizes of required specifications of the instruments of XRISM.

Table 1. XRISM mission instruments specifications

Parameters	Resolve	Xtend
Feild of view	$\geq 2.9' \times 2.9'$	$\geq 22' \times 22'$
Angular resolution†	$\leq 1.7'$	$\leq 1.7'$
Effective area at 6 keV	≥ 210 cm^2	≥ 300 cm^2
Imaging pixel format	6×6	1280×1280
Energy range	$0.3 - 12$ keV	$0.4 - 13$ keV
Energy resolution‡	≤ 7 eV (goal 5 eV)	≤ 250 eV*

†: The half power diameter
‡: The full width half maximum at 6 keV
*: At the end of mission life.

1.1. *Resolve*

The critical device of XRISM — the X-ray microcalorimeter realizes the high-resolution spectroscopy with imaging by the X-ray Mirror Assembly (XMA). The XMA is a Wolter-I X-ray mirror of their reflectors' figure in conical approximation. The reflectors of the mirror are made of heat formed aluminum sbstrate followed by epoxy replication on gold-sputtered smooth Pyrex clindrical mandrels. The XMA is developed and fabricated by NASA/Goddard Space Flight Center (GSFC). The imaging spectroscopy telescope of XRISM is named "Resolve."[5] The device measures phonons induced by a penetrated X-ray photon. The X-ray photon heats the mercury tellurized absorber by a few mK, and the temperature rise is measured by the attached silicon thermometer in the accuracy of μK. All the pixelized detectors are cooled down to 50 mK to reduce both heat capacity and thermal noise. The equipped adiabatic de-magnetized refrigerator (ADR) and liquid helium realize the extremely low temperature at the sensor in the vacuum dewar, whose thermal shields are cooled by Joule-Tomson coolers and two-stage Stirring coolers. The detector system is placed on the focal plane of an X-ray mirror assembly, and the 6×6 pixels realize a moderate imaging capability and unprecedented energy resolution. The Resolve telescope is emphasized with the high energy resolution of 7 eV FWHM at 6 keV. The energy resolution allows us to measure the velocity dispersion of the iron line in the accuracy of 100 km s^{-1}.

The detector assembly and the ADR cooling system are developed by NASA/GSFC, while JAXA and Sumitomo Heavy Industry (SHI) develop and provide the vacuum dewar and the mechanical cooling systems.

1.2. *Xtend*

The wide-field X-ray CCD imager with the identical XMA constitutes the "Xtend" telescope, which covers the same energy band of Resolve with a 200 μm thick back-illuminated CCDs.[6] The X-ray CCD, operated at the temperature of -110°C utilizing the one-stage Stirling cooler, covers almost the same energy band from oxygen lines to highly ionized irons. The device was developed for the Hitomi/SXI and employed by XRISM with a slight modification. The CCD is produced by Hamamatsu Photonics, is calibrated by the Xtend team of XRISM, and is installed in a camera body electronics by Mitsubishi Heavy Industry (MHI).

The spacecraft of 2.3 tons is 7.9 m long, 9.2 m wide, and the baseplate diameter is about 3 m. It is designed to work for three years with cryogen of Resolve. After three years, we can conduct cryogen-free operation with installed mechanical coolers.

2. Science Cases

The high energy resolution and weak line detection capability of Resolve exceed the previous observatories above 0.8 keV. The Xtend is excellent in grasp capability, which is the product of effective area and the solid angle of field of view. With the combination of a narrow field of view, Resolve, Xtend is useful for producing reliable scientific outputs with the brand new X-ray micro-calorimeter system. The science cases with X-ray microcalorimeter are summarized in ASTRO-H White Papers.[7–23]

2.1. *Structure formation of cluster of galaxies*

The precision of cluster cosmology depends on the accuracy of the mass measurements. One of the most important ways of measuring cluster masses is based on hydrostatic equilibrium — the assumption that the thermal pressure alone supports the hot gas against the cluster's gravity. However, numerical simulations show that the macroscopic motions of the intra-cluster medium (ICM) may provide significant non-thermal pressure support, up to 25 – 30% at the radius at which the cluster mass density is 200 times the critical density of the universe (r_{200}).

Hitomi observed the Perseus core, which is dominated by the central massive galaxy NGC 1275, to reveal the macroscopic motion of the ICM (Fig. 1. By measuring the line doppler broadening, the Hitomi succeeded in showing that the turbulent velocity dispersion is 164 ± 10 km s^{-1} as mentioned.[4] This kinetic pressure is less than 10% of the thermal pressure on a scale of 60 kpc. XRISM will continue Hitomi's legacy by measuring velocities of gas motions and the non-thermal pressure contribution with an accuracy of a few percent in many relaxed, bright galaxy clusters. Velocity measurements up to r_{2500}, for even a small sample of nearby relaxed clusters, will significantly improve the constraints on dark energy and other cosmological parameters.[17]

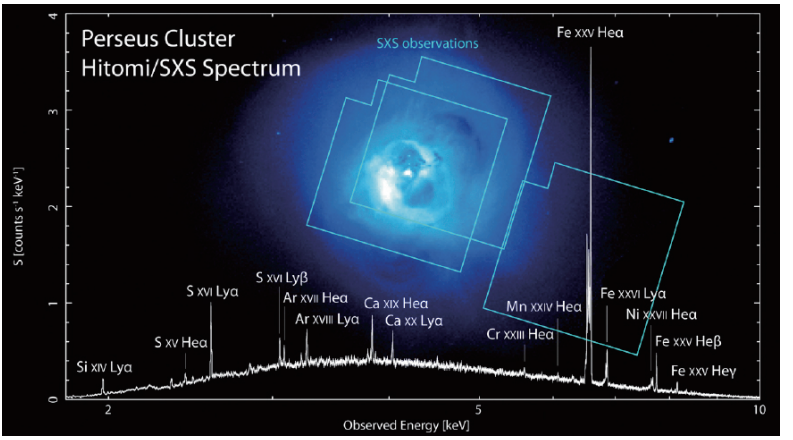

Fig. 1. Chandra image[24] and the Hitomi SXS spectrum from Perceus cluster of galaxies.[4,25] The blue boxes in the image indicates the field of view of Hitmoi SXS. Hitomi observed the centeral region and obtained the high resolution spectrum. Evaluating the Fe-K lines width, the Hitomi collaboration[4] reveals the turbulent velocity dispersion of 164 ± 10 km s^{-1}.[a]

2.2. *Transportation of energy and matters*

XRISM will conduct spatially and spectrally investigation on the Active Galactic Nucleus (AGN) feedback.[19] Figure 2 left panel shows Chandra X-ray image of the core region of the Virgo cluster of galaxies dominated by the central galaxy M 87, which highlights the complexity of structures in the gas. We focus that the 1 keV gas indicates uplifted gas produced by the AGN feedback. These structures will be resolved by the Resolve utilizing the imaging spectroscopy capability. Each white box (6×6) shows the field of view of Resolve, and by mapping, XRISM will observe both the uplifted gas structure and surrounding ICM. Figure 2 right shows a simulated Resolve spectrum of one of the regions with the expected outflows in M 87 assuming a 100 ks exposure. The spectrum resolves the contributions from the different thermal components to the Fe-L line complex and allows us to distinguish uplifted cool gas from the ambient hot ICM.

The chemical evolution of the universe reflects the history of billions of supernovae. Resolve will detect weak lines from rare elements in the ICM, such as Na, Al, Cr, and Mn. Al and Na are sensitive tracers of the metallicity of the underlying stellar population. Also, Cr and Mn can be used to probe the characteristics of SN Ia progenitors, resulting in information about the chemical enrichment history of the ICM and the universe.

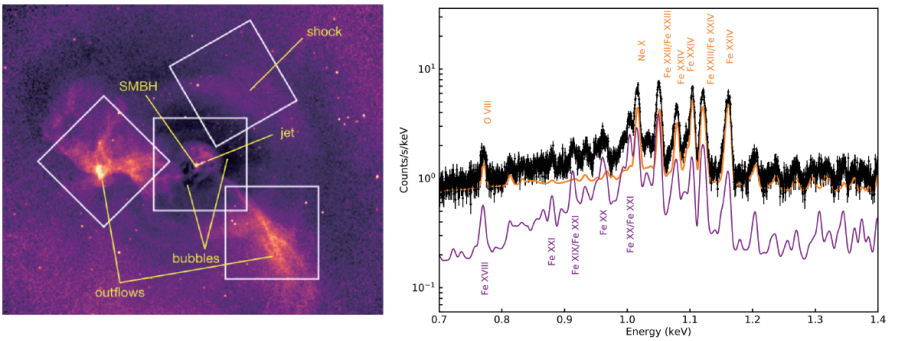

Fig. 2. Spatially and spectrally resolving AGN feedback with XRISM. Reprinted by courtesy of the authors from Figure 5 of "Science of XRISM"[30] which is updated from an ASTRO-H White Paper.[17] **Left:** Chandra X-ray image of the core region of the Virgo cluster, including the central galaxy M 87, divided by a spherically symmetric model of surface brightness. The image highlights the complexity of structures in the gas produced by the AGN feedback.[28,29] Each white box ($2.9' \times 2.9'$) shows the field of view of Resolve. The two regions point at the cool and bright structures, such as the shock and the center of M 87. **Right:** a 100 ks simulated Resolve spectrum of one of the regions with outflows (left box) in M 87. The spectrum shows the contributions from the different thermal components to the Fe-L line complex.

2.3. *Relativistic objects*

XRISM will revolutionize our understanding of accreting SMBHs, starting from how cold gas flows in from the interstellar medium (ISM) of the galaxy down to the inner accretion flow where matter is affected by the strong gravity of the black hole.[18]

Relativistic Doppler broadening and gravitational redshifts in the accretion disks surrounding black holes have been investigated for decades.[26] In particular, the ASCA observation of MCG–6-30-15 opened our observational view of a broad Fe K line in AGN X-ray spectra.[27] The implication of the broad line is immense, as it may provide a way of measuring an elusive fundamental parameter of a black hole — spin. As such, the broad Fe-K line has ignited debate and continued interest.

Rapid time variability shown in the following observations, including the X-ray reverberation mapping or quasar microlensing, improved our understandings. They indicate that the broad Fe K line is produced by reprocessing the inner accretion disk within $\sim 10R_g$. However, the details of the inner disk radius and kinematics of the flow are still highly debated.

By disentangling the expected contributions from other spectral features — narrow emission from the outer disk and torus or absorption through ionized outflows along our line of sight —, XRISM probes properties of the inner accretion flow to estimate the black hole spin. Thus, we will clearly understand how much material is making it to the black hole and how much material is removed through massive outflows.

Figure 3 left chart shows Fe-K line prole of MCG–6-30-15 as seen in 300 ks by XMM-Newton pn (blue) and Chandra HETGS (green), along with a Resolve simulation in red. The red XRISM spectrum alone shows clear spectral features in this Fe-K energy band. The middle chart shows The ratio of the XMM pn spectrum to a power-law model t between 2 and 4 keV, and 7.5 and 10 keV. The pn spectrum can be well described either by pure relativistic reflection with an inclination of 5 deg (blue) or by relativistic reflection with an inclination of 75 deg with additional emission and absorption, including an ultrafast outflow of $v_{\rm out} = 0.13\ c$ (red). The right panel shows that XRISM will easily distinguish between these two scenarios since it resolves the narrow emission and absorption features.

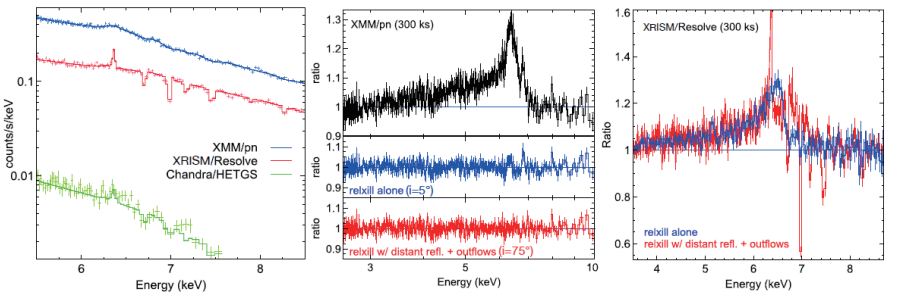

Fig. 3. Reprinted by courtesy of the authors from Figure 6 of "Science of XRISM." **Left**: Fe-K line pro le of MCG–6-30-15 as seen in 300 ks by XMM-Newton pn (blue) and Chandra HETGS (green), along with a Resolve simulation in red. **Middle:** The ratio of the XMM pn spectrum to a power-law model fit between 2–4 keV and 7.5 – 10 keV. The pn spectrum can be equally well described by pure relativistic reflection with an inclination of 5 deg (shown in blue) or by relativistic reflection with an inclination of 75 deg with additional emission and absorption, including an ultrafast outflow of $v_{\rm out} \sim 0.13\ c$ (shown in red). **Right:** XRISM will easily distinguish between these two scenarios, as the narrow emission and absorption will be resolved.[30]

The relativistic redshift on a compact object surface is also one of the scientific targets of XRISM. Here we show an example of the symbiotic star detected by Swift/BAT T Coronae Borealis (T CrB), which is a recurrent nova.[9] This fact and the hard BAT spectrum indicate that its white dwarf is exceptionally massive, around 1.35 solar mass.

T CrB exhibits a strong 6.4 keV Fe-K line, partly from the reflection of the white dwarf surface. Therefore, T CrB is an ideal target to investigate the compact object's mass and radius by measuring the gravitational redshift. This simulated spectrum is guided using the 46 ks Suzaku observation obtained in 2006.[31] The XIS data were reproduced well with a model absorbed by a partial covering absorber, with a single, narrow Gaussian at 6.396 keV. If it is, the inset shows that the XRISM Resolve has the statistical quality necessary to detect the expected gravitational redshift of 4 eV of the neutral iron-K line (Fig. 4).

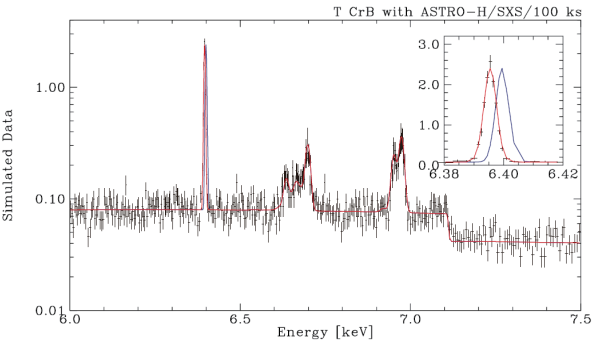

Fig. 4. Simulated 100 ks observation of T Cr B in the Fe-Kα region. The inset showing a close-up spectrum around the energy of 6.4 keV. It shows the Resolve has a capability to detect the expected gravitational redshift of 4 eV (see text). Reprinted by courtesy of the authors from Figure 2 of "ASTRO-H White Paper – White Darf"[9]

3. Mission Status and Observation Plan

All the instruments produced under the international collaboration are being delivered to the JAXA Tsukuba Space Center. The Resolve calorimeter sensor insert was delivered and installed in the dewar produced in SHI, Japan. The integrated dewar system equipped with the mechanical coolers was transferred to Tsukuba Space Center with the cooler drivers. The XMA is under calibration and is planned to be delivered to Japan in January 2022. All CCD chips for the Xtend were screened in Osaka University and were integrated into the camera system at MHI. The camera was transferred to Tsukuba Space Center. In 2022, these mission instruments will be installed on the satellite in the first half. Then we conduct the proto-flight test. XRISM will be launched in the Japanese Fiscal Year 2022 or the early calendar year 2023 from Tanegashima Space Center.

Table 2. XRISM observation phases

Initial phase	3 months
critical operation comissioning	$\sim$ 1 week until 3 months after launch
Nominal phase	until 3 years after launch
initial calibration & test observations calibration & performance verification observation nominal observation (Guest observations)	1 month 6 months 26 months

Observation phases defined in the operation plan are summarized in Table 2. At the beginning of the nominal observation phase, the performance verification (PV)

observations are conducted. The initial observation phase is planned to verify the performance to show the XRISM capability to the astrophysics community. The PV observation target objects list was recently released on the XRISM website for researchers.[b] The XRISM Science Team consists of contributors to develop instruments, data processing software, and calibration and observation plan to carry out the PV observations. In addition to the XRISM Science Team, unlike Hitomi, XRISM introduced the XRISM Guest Scientist Program to the PV phase observation. The XGSs will be solicited by the three agencies — JAXA, NASA, and ESA independently — in 2022 and contribute to PV observation planning, data analysis, and produce science output with the XRISM Science Team. The guest observer phase is open 10 months after the launch. The announcement of opportunity for the guest observations is planned to be submitted at the end of the commissioning.

The approved nominal mission term is 3 years. After the 3 years, the XRISM project is to have a mission completion review. At the moment, if the satellite, including the mechanical cooling system, functions well and the mission extension review approve, the latter phase operation will be conducted in the latter half of the 2020s.

Acknowledgments

XRISM is a JAXA mission joint with NASA in collaboration with ESA. The XRISM Science Team studies the science cases described in this paper based on the previous research by the ASTRO-H Science Working Group.

The Sino-French space mission *SVOM* is mainly designed to detect, localize and follow-up Gamma-Ray Bursts and other high-energy transients. The satellite, to be launched mid 2023, embarks two wide-field gamma-ray instruments and two narrow-field telescopes operating at X-ray and optical wavelengths. It is complemented by a dedicated ground segment encompassing a set of wide-field optical cameras and two 1-meter class follow-up telescopes. In this contribution, we describe the main characteristics of the mission and discuss its scientific rationale and some original GRB studies that it will enable.

Keywords: *SVOM*; High-Energy Astrophysics; Multi-Messenger Astrophysics; Gamma-Ray Bursts.

1. Why a New Gamma-Ray Burst Mission?

SVOM (Space-based multi-band astronomical Variable Objects Monitor) is a Sino-French mission devoted to the study of gamma-ray bursts (GRBs) to be launched in 2023.[1] Its main goals are the detection and multi-wavelength study of high-energy transients, and the search for the electromagnetic counterparts of non-photonic transient sources detected in gravitational waves or neutrinos. Before describing *SVOM* in Section 2, we briefly discuss in this section the rationale for a new GRB mission in the coming years.

1.1. *High-energy Astrophysics*

The astrophysics of high-energy transients is essential for the study of several major questions of modern astrophysics.

High-energy transients offer a unique view at extreme stellar explosions with relativistic jets. High-energy observations reveal the presence of a 'central engine' able to launch relativistic jets, and as such they are essential to clarify key issues like the complex zoology of GRBs (which encompasses long and short duration GRBs,

low-luminosity GRBs and ultra-long GRBs), the nature of the GRB-supernova (SN) connection or the distribution of GRB beaming angles. The jets themselves raise several unanswered questions, like their composition and geometry, the nature of the central engine (a magnetar or a black hole?) and the mechanism of their acceleration, the physical processes explaining their high radiative efficiency, and their role in the acceleration of Very High-Energy cosmic rays. The jets have their origin in the universal accretion/ejection mechanism that takes place around accreting compact objects. However, GRB jets being extremely relativistic with Lorentz factors of the order of one hundred, they probe a regime that is not accessible with other phenomena.

Sometimes, high-energy transients are associated with the birth of stellar mass black holes (BHs). BH astrophysics has emerged as a major topic after the discovery of dozens of binary black hole mergers by the LIGO Scientific Collaboration and Virgo Collaboration (LVC).[2] Black hole demography and zoology, their mass & spins distribution and their birth places are key questions which are now actively studied. In this context, GRBs are of high interest because they offer a complementary view on the birth of stellar mass BHs across the history of the universe.

Gamma-ray bursts are so intense that some of them are detectable out to high redshift ($z \geq 5$).[3] They illuminate regions of the young universe (at z=6 the universe is about 950 Myr old), pinpointing galaxies that would otherwise remain undetectable and measuring their chemical enrichment and physical state, as well as the properties of the intergalactic medium at such high redshifts. Additionally, the history of GRB formation provides crucial insight into the formation rate of massive stars in the early universe, and pushing the redshift limit a bit further may permit the identification of GRBs from the first generation of stars (usually called population III stars) giving us a glimpse at the formation of the first stellar mass black holes. The current GRB samples probably contain a small fraction of very distant GRBs that have not been recognized in the absence of NIR spectra of their afterglows, this emphasizes the need for fast NIR followup of GRB afterglows.

Neutron stars (NSs) are prolific sources of high-energy transients, which can be emitted by very different mechanisms in accreting neutron stars, magnetars and in mergers of neutron stars. Fundamental questions like the equation of state of neutron star, the mass gap between neutrons stars and black holes, the radiation process of magnetars are active fields of research which require continued observations of violent phenomena involving neutron stars.

Finally, GRBs are powerful tools to test the Lorentz invariance over very large distances and they may also become a privileged tool for cosmography if we manage to standardize them.

1.2. *Multi-messenger Astrophysics*

The detection of transient gravitational wave signals from cosmic explosions has opened a new window on violent phenomena involving compact objects like neutron

stars and black holes. The complementarity of gravitational wave (GW) astrophysics and HE astrophysics has been wonderfully illustrated by the joint detection of GW170817 and GRB 170817A[4] followed by the discovery of the kilonova AT 2017gfo. These discoveries opened the era of multi-messenger astrophysics. This new context raises new questions for HE astrophysicists, like the geometry of the jets of short GRB, the compared demography of BNS mergers and short GRBs, the compared demography of BBH mergers and long GRBs, the masses of BHs involved in galactic HE transients, in BBH mergers and in GRBs, the photonic emission of BNS mergers, BHNS mergers, and BBH mergers, the delay between a merger and the emergence of a GRB, or the comparison of the speed of gravitational waves with the speed of light. This non-comprehensive list illustrates a renewed interest for transient HE observations in the multi-messenger era.

1.3. *A Rich Instrumental Panorama*

Additional motivations to develop new instruments for the exploration of the transient high-energy sky are the diversity of sources that emit bursts of HE photons, the fact that some of them are rare events that do not repeat, and the rapid evolution of the instrumental panorama.

The transient manifestations of black holes at high energies involve galactic and extragalactic X-ray binaries, GRBs of all types, Active Galactic Nuclei (AGNs), Relativistic Tidal Disruption Events (TDEs), and possibly BHNS mergers. Neutron stars, on the other hand, manifest themselves as galactic and extragalactic X-ray binaries, magnetars or soft gamma repeaters eventually associated with FRBs, and of course as BNS mergers. The diversity of these manifestations calls for different observing strategies, in terms of energy range, sensitivity, pointing strategy, follow-up, etc., which cannot be accommodated with a single mission.

The construction of novel missions is further justified by the fact that the coming years are expected to be a golden age for transient sky astronomy and for multi-messenger astrophysics, with a number of large facilities surveying the sky for photons at all wavelengths and for non-photonic messengers. In the electromagnetic domain, we can mention the Cherenkov Telescope Array (CTA[5]), the High-Altitude Water Cherenkov Observatory (HAWC[6]) and the Large High Altitude Air Shower Observatory (LHAASO[7]) for Very High-Energy gamma-rays. In X-rays, eROSITA[8] will establish a reliable map of the X-ray sky, allowing the fast identification of new sources. In the visible the already operating Zwicky Transient Facility (ZTF[9]) and the future Vera Rubin Observatory[10] will map the visible transient sky every night allowing meaningful comparisons with the transient high-energy sky. In the meantime, new spectrometers on large telescopes, like SOXS[11] or NTE[a] will increase our capacity to measure the redshifts of extragalactic transients. In the radio domain, the counterparts of HE transients will be observed with very good sensitivity with

[a] https://nte.nbi.ku.dk/

the precursors of SKA, like ASKAP[12] or MEERKAT,[13] while instruments like the Canadian Hydrogen Intensity Mapping Experiment (CHIME[14]) or the Commensal Real-time ASKAP Fast Transients Survey (CRAFT[15]) will monitor the transient radio sky for Fast Radio Bursts (FRBs).

The true revolution, however, comes from the instruments looking for non-photonic messengers from violent events, in particular the gravitational waves interferometers LIGOâ VIRGO, GEO and KAGRA, which have opened the exploration of the transient gravitational wave universe.[16] As shown with the detection of GW170817 and GRB 170817A, the joint operation of gravitational wave detectors and HE detectors brings crucial information on transient gravitational wave sources. The field of neutrino astronomy is also evolving very quickly and the large neutrinos observatories like ICECUBE[17] or KM3NeT[18] have started to constrain the physics of GRB jets.[19]

After this short introduction, we now present the SVOM mission (Section 2) and some of its science capabilities for the study of GRBs (Section 3).

2. The *SVOM* Mission

The *SVOM* mission (Figure 1) is the result of a bilateral collaboration between France (CNES) and China (CAS, CNSA).[20,21] It involves several research institutes from these two countries and contributions from the University of Leicester, the Max Planck Institut für Extraterrestische Physik and the Universidad Nacional Autónoma de México. *SVOM* is led by J.Y. Wei from NAOC in China and B. Cordier from CEA in France. The mission has been designed to survey the high-energy sky and to follow-up cosmic transients at optical and X-ray wavelengths. It encompasses a space segment, with four instruments embarked onboard a low Earth orbit satellite and a strong ground segment[22] with two sets of wide-field optical cameras, two 1-meter class ground follow-up telescopes, and a network of $\sim$ 45 VHF receiving stations distributed along the footprint of the orbit. The launch of *SVOM* is scheduled mid 2023 with three years of nominal operations and a possible extension of two years.

The main science drivers of *SVOM* are high-energy transient astrophysics with a focus on gamma-ray bursts, multi-messenger astrophysics, and time domain astronomy. The "core program" is dedicated to GRB detection and follow-up, aiming to improve our understanding of these phenomena. Between GRBs, *SVOM* will carry out other programs driven by the narrow-field instruments: a target of opportunity program focused on multi-messenger astrophysics and a general program focused on multi-wavelength astronomy. A detailed description of the *SVOM* mission and its science objectives can be found in Wei et al.[1] and in the website of the mission[b]. We now briefly describe the space and ground instruments developed for *SVOM*.

[b] http://www.svom.fr/

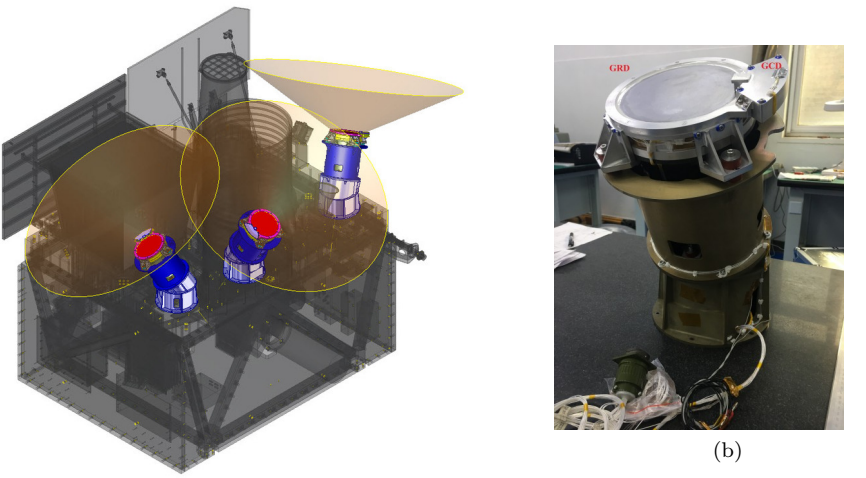
2.1. *Space-based Instruments*

2.1.1. *Gamma-Ray Monitor – GRM*



(a) (b)

Fig. 2. The GRM instrument. (a) Schematic drawing showing the position and orientation of the three GRD detectors on the science platform. (b) One of three GRD detection modules of the GRM.

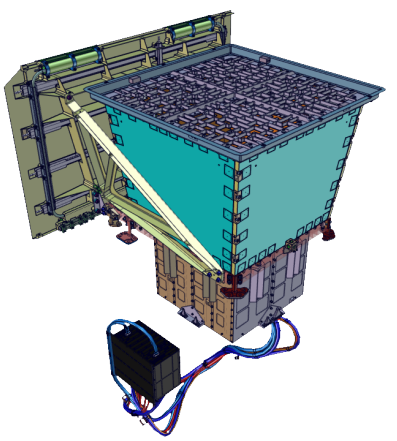
The Gamma-ray monitor (GRM) is a wide-field gamma-ray spectrometer.[23–25] It encompasses three NaI-based detection modules (called GRDs) looking at different regions of the sky. The pointing directions of the three GRDs are 30° from the

pointing axis of the satellite and they are separated by 120° in azimuth (Figure 2). The main characteristics of the instrument are given in Table 1. The GRM allows the detection of GRBs with a good sensitivity within a large field of view (2.6 sr), a feature which is especially important for the detection of short/hard GRBs in the era of transient gravitational wave detectors. It will also nicely complement ECLAIRs to measure the GRB spectral parameters over a large energy range (4 keV–5 MeV).[26]

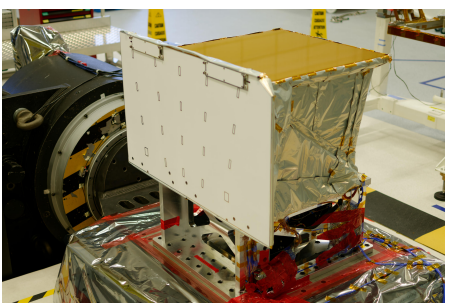
Table 1. GRM main characteristics.

Energy range (keV)	15 – 5000
Number of GRD modules	3
Detection area (cm^2, 1 of 3 modules)	200
Field of View (sr, all 3 modules)	2.6
Expected GRB rate (yr^{-1})	90 ($\sim$ 17% short[27])
Additional features	14 detection times from 5 ms to 40 seconds in 5 energy bands
	6 mm plastic scintillator to monitor particles & reject particle events
	Crude localization capability

2.1.2. *ECLAIRs*



(a)



(b)

Fig. 3. The ECLAIRs instrument. (a) Schematic drawing showing the radiator on the left, the coded mask (dark blue), the shield (light blue), the detection plane electronics (grey) and the onboard calculator (black). The detection plane itself is not visible, it is located 45 cm below the coded mask at the bottom of the shield. (b) ECLAIRs during vibration tests.

ECLAIRs is the hard X-ray imager and trigger of SVOM. The instrument is based on a coded-mask placed in front of a CdTe detection plane with 6400 4x4 mm^2

pixels,[28,29] its main characteristics are summarized in Table 2. An interesting feature of ECLAIRs is its low energy threshold at 4 keV. Reaching this threshold was a significant technological challenge for the detectors and their readout electronics, but also for the mask, whose holes have to be transparent at these energies, and for the trigger software which has to deal with non-GRB transient sources (e.g. X-ray bursters), which are numerous at energies of a few keV. When it detects an excess in a sky image, ECLAIRs sends an alert to the satellite in order to start a slew towards the source (if the conditions are met) and to start followup with the onboard narrow-field instruments MXT & VT. In parallel, the alert is broadcast by the onboard VHF antennas allowing to trigger followup observations from the ground. All the photons detected by ECLAIRs are sent to the ground, allowing to look for faint transients with improved detection methods after a typical delay of few hours.

Table 2. ECLAIRs main characteristics.

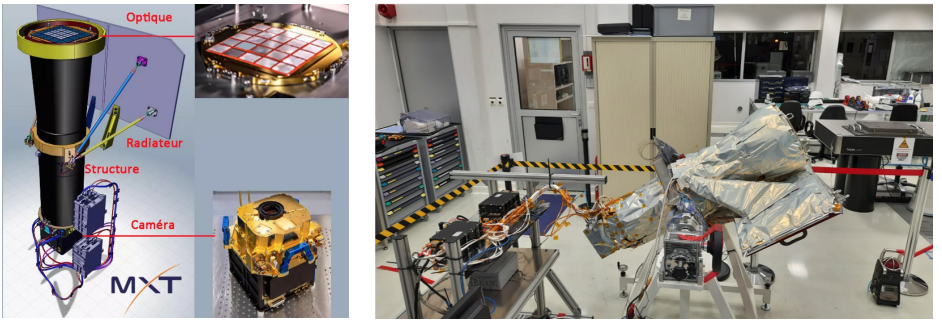
Energy range (keV)	4.0 – 150.0
Detection area (cm^2)	1000
Number of CdTe detectors	6400
Median FWHM at 60 keV (keV)	1.3
Field of View (total, sr)	2.0
Mask open fraction (%)	40
Localisation accuracy at detection limit (arcminute)	12.0
Expected GRB rate (yr^{-1})	65
Additional features	18 detection times from 10 ms to 20 min. in 3 energy bands

2.1.3. *Microchannel X-ray Telescope – MXT*

The Microchannel X-ray Telescope (MXT) is a focusing X-ray telescope using an innovative focusing "Lobster-Eye" micro-pores optics and a fully-depleted frame-store silicon pnCCD camera read out by two ASICs.[30,31] Its main characteristics are summarized in Table 3. The MXT will observe the X-ray afterglow promptly, improving ECLAIRs localization by a factor $\geq 10^3$.

Table 3. MXT main characteristics.

Energy range (keV)	0.2 – 10.0
Focal length (cm)	100
Field of View (arcminute)	64 x 64
Effective area (cm^2 at 1 keV)	27
Energy resolution at 1.5 keV (eV)	80
Localisation accuracy (arcsecond)	13.0
(for 50% of GRBs, within 5 minutes of the trigger)	
Additional features	Micro-pores "Lobster Eye" optics with square 40 μm pores
	Silicon pnCCD based camera

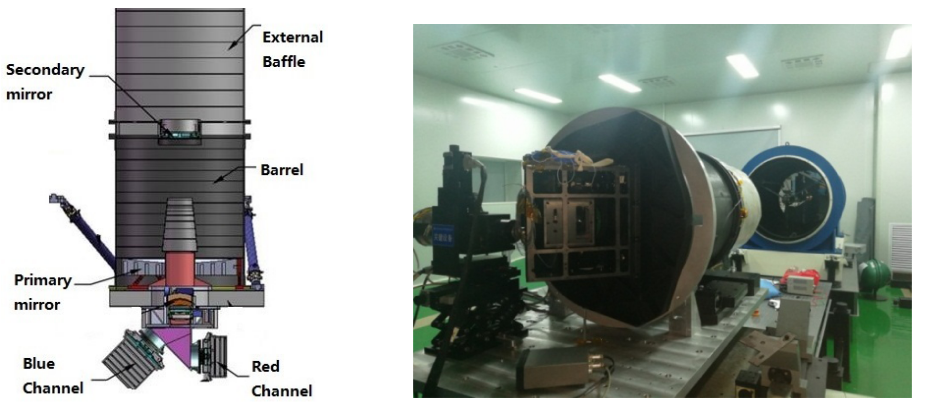


(a) (b)

Fig. 4. The MXT instrument. (a) Schematic drawing showing the radiator in light blue, the lobster eye optics (top inset), the shield (black), the camera (bottom inset), and the onboard calculator. (b) MXT during tests.

2.1.4. *Visible Telescope – VT*

The Visible Telescope (VT) is a Ritchey-Chretien optical telescope with two channels, able to detect GRBs up to redshift z $\sim$ 6.5.[32,33] It will observe SVOM GRBs quickly (in less than 5 minutes), providing an arcsecond localization of the afterglow or a deep limit ($M_v = 22.5$) very quickly after the burst.



(a) (b)

Fig. 5. The VT instrument. (a) Schematic drawing showing the various components except the onboard calculator. (b) VT during tests.

Table 4. VT main characteristics.

Diameter (mm)	400
Focal length (mm)	3600
Two channels	blue (400-650 nm) and red (650-1000 nm)
Field of View (arcminute)	26 x 26
Localisation accuracy (arcsecond)	≤ 1.0
Sensitivity (300 s integration)	$M_v = 22.5$
Additional features	Ritchey-Chretien telescope
	Two 2k x 2k CCD detectors
	Will detect 80% of ECLAIRs GRBs
	Fully covers ECLAIRs error boxes

2.2. *Ground-based Instruments*

2.2.1. *Ground Wide Angle Cameras – GWAC*

The Ground Wide Angle Cameras (GWAC)[34] is a set of several units, each made of 4 wide-angle optical cameras (called JFoV) and a small photographic camera (called FFoV) on a single fast-moving mount (Fig. 6). Each unit covers instantaneously about 12% of the ECLAIRs field of view, five of them have been installed at Xinglong Observatory (China) and 4 more will be installed at Muztagh Ata Observatory (China). The characteristics of JFoV and FFoV cameras are given in Table 5, the FFoV extends the optical flux coverage by ~ 6 mag in R-band, at the bright end. GWACs will scan the entire accessible sky each night to detect optical transients, offering the unique capability to detect precursor optical emission for *SVOM* GRBs. Three robotic telescopes on the same site (two 60 cm diameter and one 30 cm diameter) can quickly follow interesting events detected by GWAC. The GWACs are in commissioning phase, they have already participated in the search for counterparts of gravitational wave events during the O2 and O3 runs of LIGO/VIRGO.[35]

Fig. 6. Four GWAC units at the Xinglong Observatory (on the right of the picture).

Table 5. GWAC main characteristics.

Number of units	5 (Xinglong) + 4 (Muztagh Ata)
Number of telescopes per unit	4 (JFoV) + 1 (FFoV)
Diameter (mm)	180 (JFoV) – 35 (FFoV)
Detector	4k x 4k CCD (JFoV) – 3k x 3k CCD (FFoV)
Field of View (degrees)	12.8 x 12.8 (JFoV) – 30 x 30 (FFoV)
Sensitivity (σ)	R $\sim$ 16 (JFoV) – R $\sim$ 12 (FFoV)
Location	Xinglong and Muztagh Ata Observatories (China)
Additional features	Self triggering capability The FFoV performs guiding.

2.2.2. *Ground Followup Telescopes – GFT*

Two Ground Followup Telescopes (GFT, Fig. 7) aim at observing quickly the high-energy transients detected by *SVOM*, to precisely measure their light curves and their positions. The two GFTs are respectively located in China and Mexico, about 120° apart in longitude, to maximise the probability of immediate observations in response to *SVOM* alerts. Upon reception of an alert, the GFT which is in the night (if any) will start observing the source - if it is above the horizon - in less than 1 minute. The GFTs will also be used to perform joint observations with the satellite as well as non-*SVOM* observations. The main characteristics of the Chinese GFT (CGFT[c]) and of the French-Mexican GFT (Colibri[36]) are given in Table 6.

Table 6. GFTs main characteristics.

	C-GFT	Colibri
Diameter (mm)	1200	1300
Focal ratio	8	3.75
Number of channels	3 (g ; r ; i)	3 (g/r/i ; z/y ; J/H)
Field of View (arcminute)	21 x 21	26 x 26 (grizy) ; 21 x 21 (JH)
Sensitivity (r channel, 300 s, 10σ)	$m_{AB} \approx 20$	$m_{AB} \approx 22$

2.3. *The Mission*

2.3.1. *Orbit and Pointing Strategy*

The *SVOM* satellite will be launched by a Long March 2C launch vehicle, on a 29° inclined orbit, at an altitude of 630 km. The pointing strategy has been designed to favour the detection of extragalactic transients and their immediate observability by ground based telescopes. This calls for a nearly anti-solar pointing (Fig. 8a) with some excursions to avoid SCO-X1 and the galactic plane.[37] In the following this pointing strategy is called "the B1 law". The resulting 1 year sky coverage of ECLAIRs is shown in Fig. 8b, it favours the galactic poles, with exposure times

[c]https://www.svom.eu/en/#filter=.instrumentsarticle.portfolio217load

(a) (b)

Fig. 7. The two GFTs. (a) Chinese GFT at Jilin observatory. (b) French-Mexican GFT (aka Colibri) under test at the "Observatoire de Haute Provence" in France, before its installation at the Mexican National Astronomical Observatory in San Pedro Mártir.

reaching 3 to 4 Ms. The B1 law will be the rule during the nominal part of the mission (the first three years), with three exceptions: to point GRBs detected onboard, to point targets of opportunity, and to observe few remarkable sources as part of the general program (cf. Section 2.3.2).

(a) (b)

Fig. 8. *SVOM* pointing strategy. (a) Illustration of the anti-solar pointing that allows telescopes on the night side of the Earth to observe SVOM alerts promptly. (b) ECLAIRs one year exposure map in galactic coordinates.

2.3.2. *Observing Programs*

The observing time of *SVOM* is divided into three components: the *Core Program* (CP), which is the observation of HE transients detected onboard, the *General*

Program (GP), which is the observation of pre-selected sources close to the B1 law with the narrow field instruments, and the *Target of Opportunity* program (ToO) to observe active sources upon request from the ground.[1] The GP is selected by a TAC every six months and uploaded every week for the next two weeks. The ToOs are approved by the PIs of the mission and uploaded as soon as possible (see Sec. 2.3.3). Figure 9 shows the time allocated to each of the three programs during the nominal mission and during the extended mission.

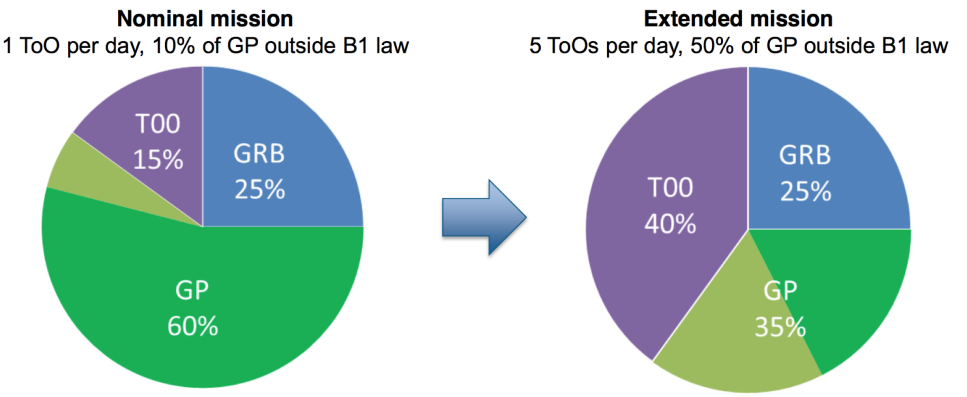


Fig. 9. Fraction of observing time attributed to the three observing programs of SVOM. Left: during the nominal 3-yr observing phase. Right: during the 2-yr extended phase. Light green indicates the time devoted to the General Program outside the B1 law.

2.3.3. *Alerts and ToOs*

SVOM alerts will be distributed promptly to the community through the GCN network. Alerts can report a count rate excess or the detection of a new source or both. The detection of a count rate excess triggers the construction of a sky image and the search for a new source. A catalog of known sources onboard permits differentiating new transients from known sources,[38] the slew threshold for known sources is set very high in order to slew towards a known source only when it is in a truly exceptional state. Alerts validated onboard will be broadcast by two onboard VHF antennas, hopefully detected by one of the $\sim$ 45 VHF receiving stations distributed around the world (Fig. 10) and forwarded to the French Science Center, which will format them as GCN Notices and VOEvents and transmit them immediately to the GCN.[39]

On the way up, commands can be sent quickly to *SVOM* with the Beidou short messages communication service.[40] This will be used to program target of opportunity observations towards active high-energy sources or towards neutrinos or gravitational waves transient sources.

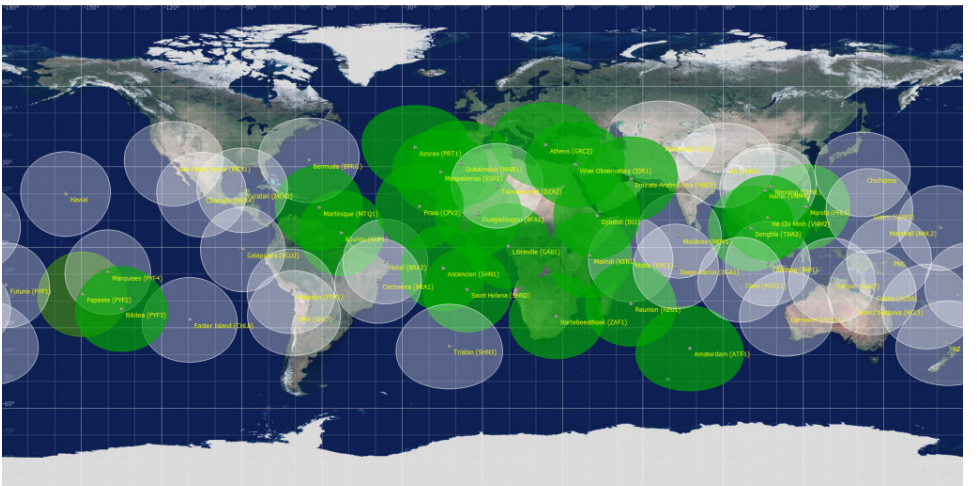

Fig. 10. *SVOM* network of VHF receiving stations. In green the stations installed and fully operational at the end of 2021.

2.3.4. *Burst Advocates and Instrument Specialists*

Like other GRB missions (e.g. *Swift* or *Fermi*), the management of *SVOM* alerts will be assigned to *Burst Advocates* who will survey all activities connected with the alert, act as points of contact for the non-*SVOM* world, and eventually take decisions about the follow-up of the source. Considering the large number of space and ground instruments involved in the detection and follow-up of transients and the number of burst advocates needed to ensure the proper follow-up of the alerts, it is needed to complement the pool of burst advocates with a few *Instrument Specialists* (2 or 3 per instrument) that can be contacted at any time by a burst advocate who has questions about the details of an instrument's operation.

2.3.5. *Mission Status*

All *SVOM* instruments have been constructed, they have undergone environment testing and full characterization, which have demonstrated their nominal performance. They are ready to be shipped to Shanghai to be integrated on the satellite in the first half of 2022. The full satellite will then undergo complete testing, before the launch planned mid 2023. The complex *SVOM* system (satellite operations and programming, observation sequences with and without triggers, satellite slews, alert reception and distribution, data management, etc.) has also been tested during extensive "system tests" lasting several days, that reproduced realistic operating conditions. These tests have demonstrated the capability of the *SVOM* collaboration to manage all aspects of this complex mission.

3. *SVOM* & GRB Science

We conclude this presentation with a subjective list of GRB science topics that could make good progress in the coming years thanks to *SVOM*. A presentation of the complete list of scientific objectives of the mission can be found in Wei et al.[1]

3.1. *GRB detection*

Thanks to its low energy threshold and a thorough onboard image processing, ECLAIRs will be particularly sensitive to long and soft GRBs. As such, it provides a unique opportunity to increase the sample of X-Ray Flashes[41,42] (XRFs) that may hold the key to the connection between SNIbc supernovae and classical long GRBs. This is also the guarantee to detect several high-redshift GRBs ($z \geq 5$) during the nominal mission,[1] despite the relatively small size of ECLAIRs. This is important because SVOM has the potential to quickly identify high-z GRBs as explained below.

The pointing strategy of the satellite will guarantee long periods of stable pointing, allowing the detection of long, faint transients like the ultra-long GRBs. A study by Dagoneau et al.[43] shows that *SVOM* may double the number of detected UL-GRBs (Figure 11b), allowing detailed multi-WL studies of these mysterious events and their host galaxies.

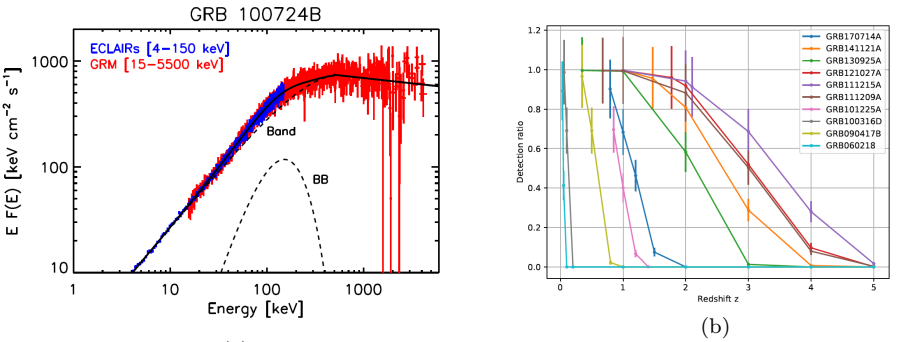
Finally, all ECLAIRs and GRM photons are sent to the ground, allowing the construction of various delayed off-line triggers that will benefit of more computation power than available onboard and a much better knowledge of the context (solar activity, particles, pre- and post- count-rate evolution...), and could be used to search for classical HE transients with better sensitivity as well as new types of HE transients.

3.2. *Physics of the Prompt Emission*

The unique combination of observations with GRM, ECLAIRs and GWAC for some GRBs will provide a unique coverage of the prompt emission. The systematic broadband time-resolved spectroscopy of the prompt GRB emission with ECLAIRs+GRM (and occasionally GWAC) will offer a renewed view of this phase, allowing to disentangle the role of the photosphere from internal shocks and other dissipation processes[26] (Figure 11a). For some GRBs, the prompt coverage may be extended to VHE gamma-rays with Fermi/LAT and CTA, allowing crucial diagnostic on the physics of GRB relativistic jets.[44,45]

3.3. *Physics of the Afterglow*

SVOM has two features that will permit to study the physics of GRB afterglows systematically with more detailed data. The first one is a good coverage of the prompt-afterglow transition for GRBs longer than 2-3 minutes, in X-rays thanks to



(a) (b)

Fig. 11. Predicted *SVOM* performance. (a) Joint reconstruction of GRB spectra with ECLAIRs and GRM.[26] (b) ECLAIRs sensitivity to ultra-long GRBs.[43]

the overlap of ECLAIRs and MXT energy ranges, and in the optical thanks to the combination of GWAC + GFT + VT. The second is the multi-wavelength coverage of the afterglow with MXT, VT and GFT, with a good sensitivity balance between VT & MXT, ensuring that $\sim 70\%$ of the afterglows of *SVOM* GRBs will be detected by both instruments. In addition, it is expected that most *SVOM* GRBs will have their redshift measured (see below), giving us access to the energetics of the bursts.

3.4. *Redshifts of GRBs*

SVOM will provide arcsecond GRB localizations in less than 5 minutes with the GFTs and the VT, and the majority of *SVOM* GRBs will be immediately observable with telescopes in the night hemisphere. These localizations will permit fast spectroscopic observations with mid- or large-size telescopes with the goal of measuring the redshifts of a large fraction ($\geq 2/3$) of *SVOM* GRBs. *SVOM* will also provide quick indications of intermediate redshift GRBs[46] ($3 \leq z \leq 6$), and of high-z GRBs candidates, when the afterglow is undetected in the VT. In all cases, dark bursts in the VT will indicate GRBs of interest, deserving additional observations with powerful telescopes.

3.5. *SN-less GRBs*

The detection of two SN-less GRBs with *Swift* in 2006[47–50] raised a lot of attention, since the association of long GRBs with SNIbc was by then considered secure. In 2011, another SN-less GRB was detected by *Swift*: GRB 111005A[51] at 57 Mpc (z=0.01326). These events raise the question of the nature of SN-less GRBs: are they the result of the explosion of the core of a massive star or a merger? Since GRB 111005A was well within the detection volume of GW detectors for NSNS or BHNS mergers and easily detectable with ECLAIRs (Figure 12), the occurrence of

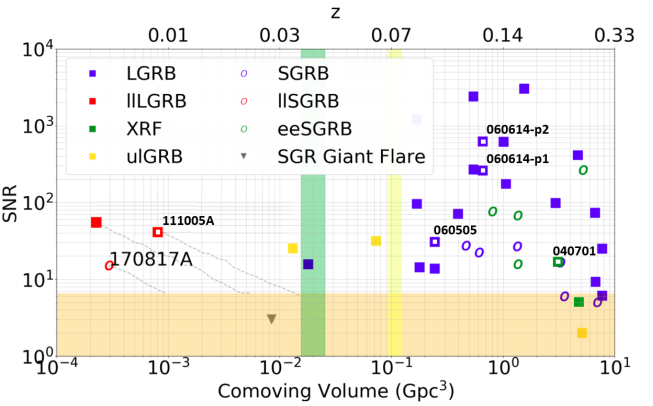


Fig. 12. ECLAIRs on-axis count SNR for GRBs in the local universe ($z \leq 0.3$). The orange horizontal band represents the detection limit of ECLAIRs at SNR = 6.5. The green and yellow bands represent the O4 LIGO detection limits for NS-NS and BH-NS mergers respectively. The light grey trails represent the evolution of the on-axis count SNR with the redshift.[52]

another event of this type within the field of view of ECLAIRs during the operation of GW interferometers would provide crucial data to solve this mystery.[52]

4. Conclusion

The operation of *SVOM* simultaneously with powerful instruments in the 2020's decade will certainly bring new crucial data for our understanding of GRBs. We have already mentioned the diagnostic brought by gravitational waves for nearby events, like short GRBs, sub-luminous GRBs or XRFs. We can also mention the search for GRBs coincident in time and direction with afterglow candidates that will be detected by the Vera Rubin Observatory. The operation of *SVOM* simultaneously with large neutrino detectors like ICECUBE or KM3NeT may also bring its share of surprises. Last but not least, the discovery of VHE gamma-ray emission from GRBs by HESS and MAGIC raises the hope to increase the number of such detections with CTA in the SVOM era, revealing key information about the composition and physical processes at work in ultrarelativistic jets.

Observing GRBs, AGNs, TDEs and transient sources of gravitational waves, SVOM will become a key player in the fields of High-Energy Astrophysics, Time Domain Astronomy and Multi-Messenger Astrophysics, after its launch mid-2023.

Quantum field theory with boundary conditions at the horizons*

Gerard 't Hooft

Faculty of Science, Department of Physics,
Institute for Theoretical Physics,
Princetonplein 5, 3584 CC Utrecht, The Netherlands
g.thooft@uu.nl

A procedure to derive a unitary evolution law for a quantised black hole has been proposed by the author. The proposal implies several assumptions, which seem almost unavoidable to this author. We start off with the question how to describe the energy eigenstates of a black hole. The background metric required for this cannot be the Vaidya metric let alone the metric proposed by Hawking, who included the effect of the final evaporation of the black hole. This however leads to the formation if firewalls at both the future and the past event horizon, unless one anticipates the effects that the firewalls have. These effects can be handled as new boundary conditions at the horizons, describing the flow of the participating particles. It is subsequently explained how these boundary conditions must involve the antipodes of the outside world. Imposing unitarity and continuity then automatically leads to a unique, unitary evolution operator. We exhibit the resulting, quite coherent picture.

Keywords: Quantum black hole; past and future event horizon; firewall; Penrose diagram; eternal black hole; time slices; entanglement; vector representation; Shapiro shift; Cauchy surface; boundary condition; antipodal identification.

1. Introduction

There is a general agreement that a theoretical study of black holes in a regime, where quantum mechanical effects play a role, is important for a more complete understanding of general relativity and/or some modifications of this theme, in its relation to quantum mechanics.[1,2] There are several problems and disagreements, however. What is the classical limit from where one should start adding quantum corrections? The first thing many investigators assume is that there is a classical metric describing a black hole from beginning to end, and after that, the dynamical variables should be subject to some quantum mechanical replacement.[3] This should give the "quantum black hole".

However, there is a difficulty concerning the way these quantum variables would evolve. First, in accordance with the no-hair theorem, the evolution of these

*Based on a talk presented at the Sixteenth Marcel Grossmann Meeting on Recent Developments in Theoretical and Experimental General Relativity, Astrophysics and Relativistic Field Theories, online, July 2021.

"quantum corrections" would quickly fade away, together with all other quantum field theoretical degrees of freedom. There seems to be just a single state that survives: the Hartle–Hawking state.[4] We do have evolution in this Hartle–Hawking state in a quantum mechanical manner, which is why investigators did continue along such directions, but, entanglement or not, only a single state seems to survive, and this appears to be incompatible with unitarity.

Second, if there is a quantum mechanical evolution law, it should also apply both during the initial implosion and the final puff of the evaporation process. These depend on quantum processes, and demanding their tie evolution to be fixed destroys unitarity.

Third, the quantum states will be entangled with particles entering or leaving the scene far from the black hole.

There is a way out of these difficulties, which is to consider more carefully how ingoing particles assemble near the past event horizon, and how the emitted Hawking particles are prepared near the future event horizon. They form what has become to be known as *firewalls*.[5–7] This is the subject of the present investigation. Already years ago, the author reported about what seems to be considerable progress along these lines,[8] but there continue to be communication barriers that should be overcome.

Particle states emerging from the past event horizon will be shown here to generate a rich spectrum of different possible quantum states of out-going particles, and, considering the equally rich spectrum of in-going particles, the quantum mechanical interactions between the two horizons can be seen to restore unitarity.

There will be limitations to what we can do presently, as will be briefly explained later.

2. The Background Metric

The Penrose diagram[9,10] for the eternal black hole is depicted in Fig. 1(a). This diagram is the unique analytic extension of the Schwarzschild metric that solves Einstein's equations without matter effects added. In line of arguments just sketched above, and clarified further below, this is the only metric that we believe can be used for the quantum theory.

The metric often considered in quantum speculations for black holes, is the Vaidya metric of the kind sketched in Fig. 1(b). It was suspected to be superior since it includes the black hole formation process, so it may seem to contain more freely adjustable parameters that can be subject to quantisation.

Adding to that the gravitational effects of the Hawking evaporation, Hawking proposed to substitute this by Fig. 1(c). This diagram,[11] like the others, has the singularity at $r = 0$ absorbing in-going material, which is problematic since unitarity would demand information to be returned in the entire process. Anyway, one should

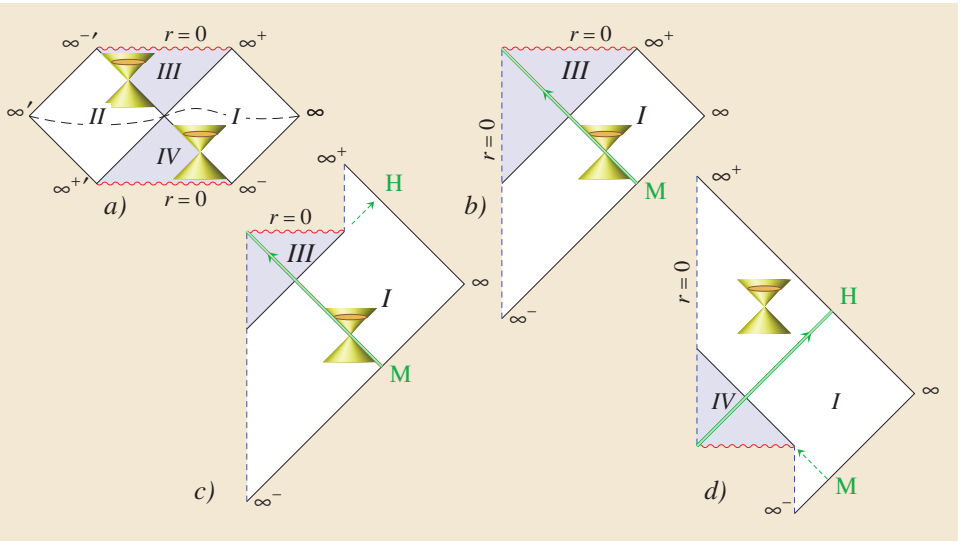

Fig. 1. Different Penrose diagrams for the Schwarzschild black hole. M stands for matter moving in, H for Hawking radiation going out. See text.

realise that the underlying equations, both for general relativity and for quantum mechanics, are invariant under time reversal, so that Fig. 1(d) should at least be considered as possibility as well.

We shall later conclude that only Fig. 1(a) can be used for the quantum process, but the arguments will be more convincing after we have treated the details of our theory. At this point, let us emphasise here that Fig. 1(a) for the eternal black hole is the most suitable one to use for the description of the stationary modes of a black hole, in particular its energy eigenstates, which make use of beams of in-going and out-going particles asymptotically far away, so as to make up for the evaporation.

To set up our program, we momentarily return to Schwarzschild coordinates, we divide the Schwarzschild time coordinate t in equal slices, each lasting for at most one period $\Delta t \approx M_{\rm BH}$ in Planck units, see Fig. 2. Within each of these time slices, the physical variables are defined to consist of all standard model particles and the slightly hidden degrees of freedom such as dark matter and gravitons. These particles are following their (quantum) trajectories, but, and this is essential for our procedure, particles that venture too close to either the future or the past horizon, will *not* be included. The idea is that such particles will become more manifestly observable in future or past slices (where they belong).

This paper is about stitching these slices back together in order to get the complete picture. Particularly at the horizons, this is a nontrivial procedure.

There may be some misunderstanding as to the quantum state of the Hawking particles. The Hawking particles are seen to be entangled, and as such it may appear

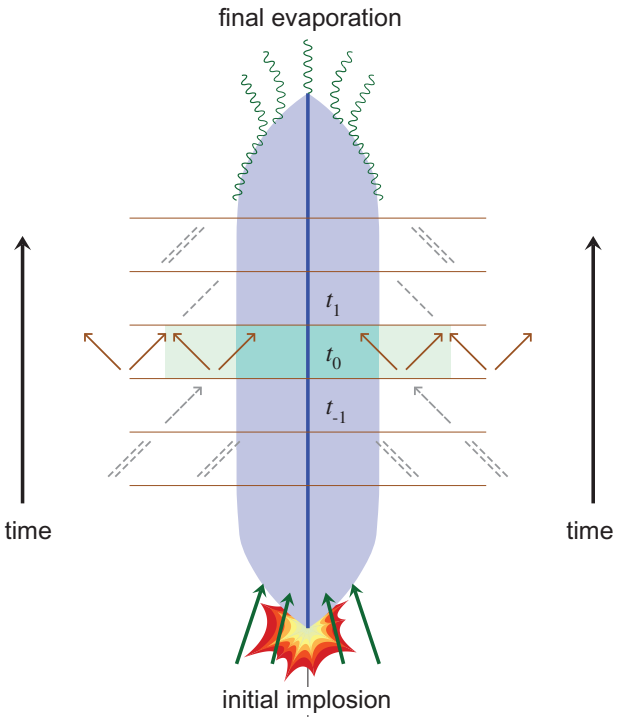

Fig. 2. Slicing the Schwarzschild coordinates in sequences of short periods. The quantum variables can be defined on each slice, lasting not longer than $\mathcal{O}(M_{\rm BH})$ in Planck units.

that they can only form a single quantum state. This happens only, however, if none of the Hawking particles are subject to observation, and if nothing is thrown into the black hole for large stretches in time. This will become more clear below.[a]

Quantum field theory (QFT), projected on this background of time-slices, will reveal how particles propagate and interact. At any safe distance (of the order of a couple of Planck lengths), the outcomes of QFT calculations will be decisive as to what happens. Up to this point, it should be clear that the metric of an eternal black hole serves just fine as a background.

However, particles inevitably will approach the horizons more closely. There are particles entering the future event horizon, and particles emerging from the past event horizon. A theory is needed that *dictates* how particles appear out of the past horizon, and how, if at all, this is determined by the in-going ones.

At this point, it seems that Hawking's original calculation[1] cannot be the entire story since it puts all out-particles into just one state, the Hartle–Hawking state.

[a]For a better understanding of these aspects of quantum mechanics, it may be helpful to view quantum mechanics itself as a *vector representation* of physically observable objects, see the author's ideas about this, in Refs. 12 and 13.

In contrast, we expect that different states of particles entering the future horizon should lead to different states of out-particles.

It suffices to produce a prescription that holds just for a few Planck lengths away from the intersection point of future and past event horizons. There, we expect "something" that causes in-particles to bounce against, or turn into, out-particles. So-far, in this treatment, we have only used the physically accessible or observable part of the Schwarzschild metric. Quantum gravity has been used only in its perturbative regime, so it only enters in the form of some stray gravitons. But now, this is going to change.

What has been found is that *interactions* between in- and out-particles can do the job. We need interactions that become sufficiently strong only at tiny distances. Which force acts more strongly at close distances than the renormalizable interactions in the Standard Model? Of course, the answer is: the gravitational force.

3. The In–Out Interaction Caused by Gravity

Indeed, the gravitational effect of an in-going particle on an out-going one is that the wave function of the out-particle is modified. This is illustrated in Fig. 3: the dashed arrowline marked "in", going through the future event horizon very early in time, carries a large momentum δp^-. Coming from region (IV) in the diagram, a Hawking particle was on its way out (wiggled line marked "out"). Due to δp^-, a shock wave[14] from the in-particle drags the out-particle along, displacing it by a distance δu^-, which is proportional to δp^- and a Green function $F(\theta)$ depending on the transverse, angular, distance θ between the particles. This function $F(\theta)$ has been calculated.[15]

This effect is closely related to the Shapiro effect,[16] the fact that a light or radio signal from an astrophysical source or a spacecraft, grazing the Sun, experiences a delay due the solar gravitational field. All Hawking particles are delayed in a different way, depending on their transverse positions, and so it happens that the entire quantum state describing the out-particles is modified.

The modification operator is easy to calculate, in principle

$$U = e^{i\delta p^-\ \sum_{\rm out} p^+_{\rm out} GF(\theta_{\rm out})} = e^{i\ \sum_{\rm in,out} p^+_{\rm out} p^-_{\rm in} GF(\theta_{\rm out},\varphi_{\rm out},\theta_{\rm in},\varphi_{\rm in})}, \tag{3.1}$$

where G is Newton's constant, and furthermore, in the second part we replaced δp^- by $\sum_{\rm in} p^-_{\rm in}$ since *all* in-particles have this effect on *all* out-particles.

It must be emphasised that the dependence of U on the in-particle momenta increases exponentially with Schwarzschild time, because, the later the time t where we study the particles in the background metric, the closer the older in-particles squeeze against the past horizon, so the larger their influence will be. The very first in-particles in fact were the particles that formed the black hole by imploding. Since they came in very early, their exponentiated in-momenta p^- are gigantic, in terms

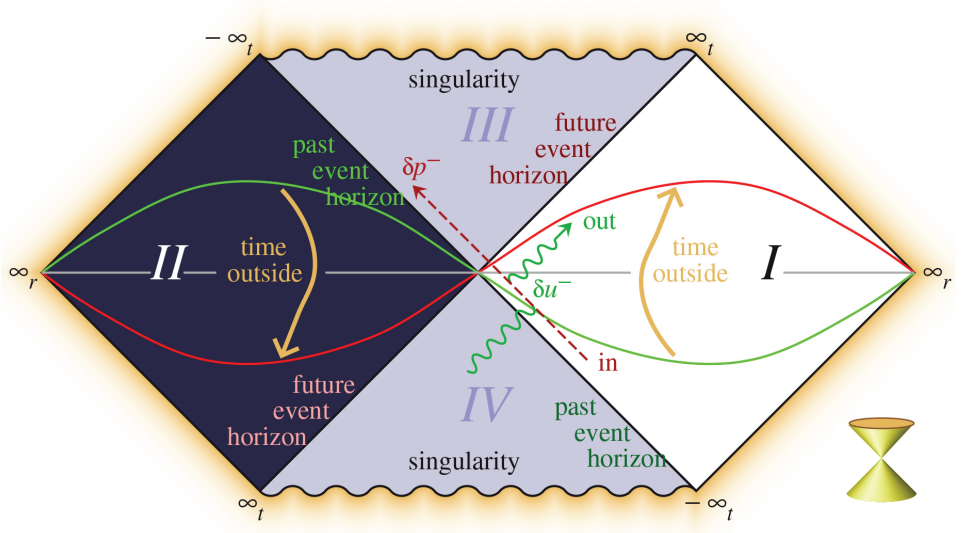

Fig. 3. The Penrose diagram for the eternal black hole, see text. Light cones everywhere in the diagram are oriented the same way as the one shown.

of the Penrose coordinates for the particles later in time, *but this is nothing to worry about*: they caused the wave functions of the early out particles to be separated by equally large separation variables $u^-_{\rm out}$.

The increase of u^- changes from exponential to linear in time as soon as the out-particles move out of the direct gravitational influence of the black hole. They are joining the other distant out-particles that no longer play any role for us. Our complete quantum states of course include the early out-going particles, and our calculations show that they are entangled with the later particles, but from this moment onwards we can just re-arrange the basis of quantum states for the out-particles, and describe their wave functions any way we please.

The reader may have felt something strange in the emerging picture: the time dependence of all particle states is such that the outgoing particles move away exponentially from the past and future event horizons, but there are *two* regions in which they can escape. The Penrose diagram used so-far is twice the size of the universe that we usually consider as the home universe of this black hole. We labelled these two regions (I) and (II) in Fig. 3. What happens to a particle that makes its way out in region (II)? If we ignore it, we make a mistake. The operator U derived in Eq. (3.1) is the operator for the Fourier transform (apart from the Green function F that will be treated later). *The Fourier transformation process is unitary*, which means that we can use it to describe a unitary quantum evolution of the black hole, *but it is only unitary if we consider in- and out-wave functions to cover the entire line* $[-\infty, +\infty]$, and not just the half-lines that form the boundaries of region (I) or region (II) of a black hole.

Indeed, the Shapiro effect can easily transport the geodesic of a particle across the other horizon. This is the real reason why we are destined to use the entire, double, Penrose diagram for our considerations. Before disclosing the *physical* role of region (II), we sketch the picture obtained so-far.

A time boost for an outside observer, $t \Rightarrow t+\Delta t$, corresponds to a *Lorentz boost*, $(u^+,\, u^-) \Rightarrow (u^+ e^{-t/4GM_{\rm BH}},\ u^- e^{t/4GM_{\rm BH}})$ for an observer close to the origin of this diagram. This implies that Cauchy surfaces for the particles in the regions (I) and (II) take the shape of the green curve in Fig. 3, that evolves into and beyond the red curve as time continues.

The Cauchy surfaces never enter into the regions (III) or (IV) in the Penrose diagram. They pivot around the origin. This is where our procedure contrasts with other work.[3]

However, we do have to pay for this — in an interesting way. Our general finding is that, when particles go into and out of the black hole, they cause shifts along the horizons. During black hole formation, these shifts are large. Effectively, we are using the eternal Penrose diagram, but the *boundary conditions*, by which the horizons connect different domains of the spacetime metric, are strongly affected by the gravitational force: the Shapiro effect.

Now, we have to address the question what region (II) stands for physically. It cannot just be ignored. It also cannot just be there to describe another black hole. That other black hole would not only be strongly entangled with the first one, as some investigators argue, but the two black holes exchange information. Entangled particles do *not* exchange information without violating locality.

Mathematically, it is easy to "cure" our theory. We have to find an isometry transformation in spacetime, whose square is the identity. We can write it as $\mathbb{Z}_2$. One such transformation is the identity itself, or, regions (I) and (II) are then assumed to represent the same spacetime. Our problem is then that this does not work since the Shapiro shift would not commute with such a mapping, or, it would generate cusp singularities near the origin. However, such cusp singularities do not arise if we accompany the $\mathbb{Z}_2$ mapping with an antipodal mapping:

$$(\theta,\, \varphi) \leftrightarrow (\pi - \theta,\ \varphi + \pi). \tag{3.2}$$

In flat Minkowski spacetime, this would also generate a cusp singularity at the origin, but for Schwarzschild (and its rotating and charged relatives), it does not. This is because in the entire spacetime that we are using, $r \geq 2\mathrm{GM_{BH}}$ so that angular positions never come close to their antipodes. Only deep inside the regions (III) and (IV), $r \to 0$, and points coincide with their antipodes. We never venture more than infinitesimal distances into these unphysical regions.

Nevertheless, at the beginning of this paragraph, we put the word "cure" in quotation marks. The fact that a solution looks mathematically pleasing does not automatically mean that it embodies the physical solution.

This antipodal mapping procedure may help us to avoid the "quantum no-cloning" condition, but does it? We do see a potential danger. In region (II),

compared with the time variable for a local observer, the arrow of time for the distant observer will flip over. *Time runs backwards there!* This means that, if, near the antipodes, an observer sees a particle, the same particle will appear to move backwards in time, or, have negative energy, when viewed by an observer in region (II).

Our resolution to that problem is to redefine energy by a constant. A particle in region (II) has energy $E_{\rm II} = E^{\max} - E_{\rm I}$, where $E^{\max}$ is the *energy of the "anti-vacuum" state.* The antivacuum is the state completely filled with particles, having the largest possible amount of energy.

Better understanding is obtained by adhering to expansions in partial harmonics, item 9 in the next section, but this we leave for future considerations.

4. On the Complete Theory

We hope the above can serve as a more elaborate explanation as to the various ingredients for a consistent theory of quantum black holes. It can be viewed as a "package deal": there are several postulates that by now sound natural and unavoidable by this author, but seem to meet with considerable skepticism from other researchers:

(1) Up to a few Planck lengths from the horizon, matter particles may be handled using conventional quantum field theory, only during small time steps, each lasting for the "scrambling time", $T_{\rm scrambl} = \mathcal{O}(M_{\rm BH})$. This is far too short to include collapsing matter or late evaporation. These would act as projection operators that ruin unitarity. In practice, we can only handle modest amounts of matter going in and/or out during any of these short time spans.
(2) One has to use the metric of the eternal black hole as background.
(3) The metric must be divided by $\mathbb{Z}_2$, to restore a single asymptotic region.
(4) The only way to do that is by *antipodal identification.*
(5) Time outside runs *backwards* in region (II). This implies that the local states to be compared with the black hole states must approach the *antivacuum* in region (II). Creating a particle near the black hole corresponds to creating a particle in (I) or annihilating a particle in (II).
(6) During the time stretch around time $t \approx t_0$ for the distant observer, in-particles at $t \ll t_0$ are seen to generate a Shapiro shift along the past event horizon; out-particles at $t \gg t_0$ generate Shapiro shift along future event horizon.
These form *firewalls* that can be removed by re-arranging the corrections at the horizons (cut-and-paste procedures that effectively modify the boundary conditions there).
(7) This links the *positions* of the out particles to the momenta on the in-particles, and *vice versa.* That opens the way to define a unitary evolution law.
(8) Initial imploding matter and the final evaporating matter have decisive effects at the horizons; rather than merely shifting the geodesics, these may *initiate*

the links between the antipodes there. Initial and final black holes are mere *seeds*, to be described as gravitational *instantons*. This is as yet a suspicion; it is not known how to substantiate that with calculations.

(9) To do explicit calculations, it is advisable to expand the in-going momenta and the out-going momenta or positions at the horizons in *spherical harmonics* for optimal use of linearity of the equations. The Green function $F(\theta, \varphi, \theta', \varphi')$ then diagonalises, much like Schrödinger's equation for the hydrogen atom.
Note that these spherical harmonics are not to be confused; in our case, we are dealing with *operators*. Since these operators involve all of the in-going and out-going particles, it is not appropriate to try to "second quantise" them. At every (ℓ, m), we have only one position operator and one momentum operator.

The mathematics works correctly only when these views are all combined. In particular, we may *only* compare states in a background metric to states as seen from the outside, if the mapping on the Cauchy surfaces is 1 to 1.

This enforced the antipodal mapping (it cannot be avoided).

Note that this mapping keeps all information visible on the Cauchy surfaces; we have no information loss.

The procedure described above can lead to an accurately defined scattering matrix linking every in-state to an out state in a unitary manner. Unitarity may follow because, at every (ℓ, m) mode, where ℓ must be odd because of the antipodal identification, the Fourier transformation is a unitary operation.

It is important to emphasise that the Shapiro effect only acts on energy and momentum, not on other quantum numbers. This means that further analysis is needed to establish how data other than positions and momenta are transported across horizons.

Thus, we are not yet ready to consider the complete Standard Model to describe the interactions in the immediate vicinity of the black hole. This is somewhat reminiscent to the situation in string theory. This theory also requires first to characterise all its excited states in terms of momentum and/or position operators, while its relation with the Standard Model can only be established by extensive studies of the relevant symmetry groups and algebras.

A new energetic generation of young students and ambitious postdocs is asked for to continue research along these lines.

The development of general relativity and the cosmological constant

Asghar Qadir

Abdus Salam School of Mathematical Sciences
Government College University Lahore, Pakistan
E-mail: asgharqadir46@gmail.com

There is much talk of a "mysterious form of energy", called "dark energy" that forms the bulk of the energy content of the Universe. Perhaps the most mysterious aspect of it is why it should be regarded as mysterious in the first place. This question is discussed in the context of the development of relativity and relativistic cosmology. It will be argued that there is no good reason to treat it as other than Einstein's cosmological constant.

Keywords: Cosmological constant; dark energy; geodesic equation; geodesic deviation; Einstein equations; Planck units; vacuum energy.

1. Introduction

It is often taken that there is no need to hark back to a subject and one only needs to consider current developments. However, people like Julian Barbour[1] point out that the past debates and the process of the development of a subject might provide the correct direction in which to proceed. He was talking of the problem of combining quantum theory and general relativity, which has not been achieved despite the best efforts of the best scientists for about a century. This problem is at the base of, or contributes significantly to, many other important problems that Physics is facing today. I would agree with Barbour that when we are so badly stuck, we should look back to see where we took a wrong turn. Very often we do not realize that some hidden assumptions have been made and proceed forward in various erroneous directions. We should look back lest, in our headlong rush forward, we miss the lessons lying in the past. This is especially true if it is argued that we cannot require experimental verification because it is beyond our current technology, and must instead rely on the concept of "naturalness" — reminiscent of Aristotle's "self-evident truths". This argument is appealed to for the attempted merger of the two major theories, which have so far resisted a union — the so-called "quantum-gravity problem". The problem is exacerbated by the current trend to publish as much as possible, which encourages wild speculation, instead of scientific progress based on adequate experimental evidence. One might fruitfully apply the same caution, to look back, for other recent developments.

I am, here, concerned with the so-called "dark-energy problem". In an attempt to see significant effects of his general theory of relativity, Albert Einstein applied it to the Universe in the large.[2] The equations in his seminal paper on general

relativity[3] implied a non-static Universe, and he firmly believed that it should be static (see[4] for a more detailed explanation of why he believed it). In this paper he added a constant to his Lagrangian and obtained a static Universe model. However, in 1929 Edwin Hubble found that further away galaxies are redder. Treating the reddening as a Doppler shift, he deduced the Hubble Law,[5] that galaxies are generally receding from us at a rate proportional to their distance. (Einstein called his modification "the greatest blunder of my life".) This fitted with Friedmann's solutions for Einstein's field equations,[6] which provided three universe models: two expanding forever; and one contracting later; but all expanding at more or less the same decreasing rate currently. Thus, if the scaling factor for the distance between galaxies is given by $a(t)$, the Hubble parameter that relates the speed of expansion with the distance is $H = \dot{a}(t)/a(t)$. As the scale is increasing this is positive. However, the dimensionless acceleration $q = a(t)\ddot{a}(t)/\dot{a}^2(t)$, would be negative. For the model which contracts later, H would become zero later, and then negative.

Observations strongly supported the Friedmann models, but the fact that the Universe consists mainly of hydrogen and helium and all other elements are essentially "cooked" in stars, seemed to be a stumbling block in the theory till George Gamow[7] suggested that there must have been radiation in the early Universe that stopped nucleosynthesis but allowed some deuterium, tritium, helium$_3$ and normal helium to form. Later observations further supported the Friedmann open model.[8] Gamow's "hot big bang model predicted that there would then be a remnant of that radiation still left over as the Universe cooled. A rough estimate was of 3°K. It was confirmed in 1965 when Penzias and Wilson discovered a microwave background radiation,[9] which turned out be in a Planck spectrum, as predicted. Fitting the observed primordial abundance of elements with the radiation gave very precise estimates of the amount of baryonic matter in the early Universe.

In 1997 new observations of the further reaches of the Universe, obtained by studying type Ia supernovae, indicated that the Universe is expanding at an exponential rate.[10,11] As it happens, much earlier in 1927, Georges Lemaître[12] had independently derived the Friedmann solutions, but with an extra feature allowing for an exponential expansion in later times. He had derived the solution using Einstein's equations with a cosmological constant. This was what Perlmutter and Reiss[10,11] had referred to. Nevertheless, a flurry of papers appeared in the journals about evidence for a "mysterious form of dark energy", despite the fact that Riess' paper explicitly mentions the cosmological constant. In this paper I will try to demonstrate that it is because of not looking back to the past, that theory is still blundering down *dark* blind alleys, instead of accepting the obvious solution. It is that, and *the dark side of the force*, forcing many people to publish many papers. The current standard model of cosmology[13] is called the ΛCDM model, the CDM stands for "Cold Dark Matter" — and the "Λ" is Einstein's "greatest blunder"!

2. Generalizing Special Relativity

Soon after Einstein published his paper on special relativity,[14] his one-time teacher Hermann Minkowski (whose classes he had skipped), wrote the theory in terms of a four-dimensional spacetime (a space with an indefinite metric).[15] Einstein was not pleased with the development at the time, regarding the physics of the theory as being obfuscated by the mathematical formalism. However, the theory was restricted to uniform linear motion, and he needed to generalize it. On considering small accelerations along the direction of motion he was able to derive the physical consequence of a deflection of light due to gravity, which amounts to a bending of a straight line by acceleration. He considered uniform circular motion and found that it entailed a change in the geometry implying that one needed non-Euclidean geometry (see for example[16] for an explanation of the reasoning).

Isaac Newton[17] had defined the world-view that held sway before Einstein, according to which there is an absolute space and an absolute time, whereby space exists in itself independent of any matter or any observer in it. God was explicitly given the role of the Universal observer to provide reality to space. Time was taken to "flow at a constant rate". What sense would that phrase make? A stream can flow at a constant rate, meaning that in equal intervals of time the particles in the stream would flow equal distance. How could points of *time* flow at a constant rate in equal units of *time*? When Einstein had challenged this so-called "common sense" view with his special theory, non-physicists found it impossible to come to terms with the new view. However, while he challenged the absolute time more directly, and allowed lengths to decrease for moving observers, he had not altered the basic picture of a rigid grid. With a change of geometry that picture would become untenable. Before the Newtonian revolution, the world-view of Aristotle (c. 350 BC) held sway. In that view, space only existed as the distance between bodies. To give it reality, Aristotle had postulated an all-pervading aether. Further, time only gave a chronology of events, and precise measures of time were not assumed. If Newton's absolute grid had to go, then we should expect space to be defined by its matter content. Measures of space and time would depend on the procedures specified to measure them and would not be automatically defined.

Einstein had another problem, this time with Newton's law of gravitation. According to it, if a body moves away from its position, another body will *instantaneously* feel the change in the gravitational force between the two bodies. However, this militates against the basic precept of his special theory, as *all* information must obey the speed of light limit. Somehow, Aristotle's aether would be needed. However, he had managed to get rid of the luminiferous aether. As such, the spacetime would have to carry the information across at a speed limited by that of light. Instead of being Newton's rigid grid, or a rotated version of it (causing distances to appear shrunk), Einstein needed a more malleable spacetime that could be distorted by its matter content. Over time it became clear to him that he needed to use the geometry taught by Minkowski that he had skipped.

3. The Einstein-Grossmann Collaboration

Einstein had already arrived at the key to his generalization by, what he had called "the happiest thought of my life". This was the realization that gravity would not be felt in a freely falling frame, since all objects would fall together, as Galileo had shown. Hence, in that frame a ball released would not fall but float. This led him to a prediction of the bending of light by gravity,[18] as an experimenter in a fixed frame would see light sent across a falling lift hit the other side lower than if the lift is falling.[16] The effect turns out to be half what he later derived from the full general theory. He proposed that the effect could be seen by looking at the bending of the light from a star near the edge of the solar disc, seen during a full solar eclipse. (Fortunately for him, World War I broke out and prevented the expedition to observe the solar eclipse in South America. By the time it finally became possible, he had the correct answer.) In that paper he also obtained the gravitational red-shift, which is unaltered in the full theory. However, the effect is so small that it was not till 1956 (after Einstein's death) that the experiment could actually be performed and not till 1959 that the effect was finally verified.[19]

His friend, Marcel Grossmann (who is commemorated in these meetings) had not only attended Minkowski's lectures, but was proficient in non-Euclidean geometry, so Einstein asked him to help. Though Einstein had tried other non-Euclidean extensions of Geometry, Grossmann taught him Riemann's extension using differential calculus — what is nowadays called differential, or Riemannian, geometry. This turned out to be especially fruitful. Though "the happiest thought" had come earlier, in many ways "the happiest *development*" came in the first paper of their collaboration,[20] where Newtonian's scalar gravitational potential is replaced by the geometrical metric tensor. Thus *the spacetime itself becomes the medium to carry the gravitational field*, participating in dynamics as was needed. This set the base for the theory. In it, the gravitational "force" is nothing but the curvature of the four-dimensional spacetime. Paths are bent due to the warping of the spacetime, rather than a mysterious force acting instantaneously from a distance. In the second paper of the collaboration,[21] the basic field equations were set up and shown to be covariant. This was well before the derivation of the equations from a variational principle. In it, the Einstein tensor was defined by using the divergence-free condition for the conservation of the stress-energy tensor and the second Bianchi identities. However, they limited themselves to those transformations that left the determinant of the metric tensor invariant. In other words, instead of the symmetry group being $GL(4)$, $SL(4)$ was used. Since that reduces one of the degrees of freedom, the field equations were not correctly identified there.

There remains a crucial step in obtaining the field equations that was not made explicit in their derivation. How do we suddenly jump to relating the curvature tensor to the stress-energy tensor, without it coming from the bending of the path due to the presence of matter-energy as the warping of the spacetime? I will derive them the way I think Einstein must have done, but unfortunately left hidden.

4. Derivation of the Einstein Field Equations by Using Geodesic Deviation

To follow the argument, one needs to think of one of a family of observers looking at another observer of the same family, i.e. both in the same frame. I hope the reader will bear with me while I go through basic differential geometry, so that the reasoning can be seen in full clarity. The observers will follow *geodesics*, the straightest available paths. If the tangent vector to the path is $\mathbf{t}$, treating it as a derivative operator, $\mathbf{t}(\mathbf{t}) = 0$, so that the direction does not change, i.e. $d\mathbf{t}/ds = 0$. This is the *geodesic equation*. In terms of the components of $\mathbf{t}$, $t^a = dx^a/ds$, where x^a is the position vector of the observer, the geodesic equation is $t^b t^a_{;b} = 0$, where the summation convention that repeated indices are summed over, has been used and ";" is the covariant derivative, $t^a_{;b} = t^a_{,b} + \Gamma^a_{bc} t^c$, "," being the partial derivative $\partial/\partial x^a$. Thus, in this index notation, the geodesic equation becomes

$$\ddot{x}^a + \Gamma^a_{bc} \dot{x}^b \, \dot{x}^c = 0 \ , \tag{1}$$

where Γ^a_{bc} is the Christoffel symbol, given in terms of the metric tensor, g_{bc}, by

$$\Gamma^a_{bc} = \Gamma^a_{cb} = \frac{1}{2} g^{ad} (g_{bd,c} + g_{cd,b} - g_{bc,d}) \ , \tag{2}$$

and g^{ad} is the inverse of g_{bd}, so that $g_{bd} g^{ad} = \delta^a_b$.

Let $\mathbf{p}$ represent the position vector of observer B, as seen by observer A. If the geodesics are radial lines on a plane and A is an ant moving outward at a constant rate on one line at angle θ_A, looking at an ant B on another line at θ_B, $\mathbf{p}$ will increase at a constant rate as the two move out, so $\ddot{\mathbf{p}} = 0$. Instead, let A be a jet plane flying due South on longitude ϕ_A and B another on longitude ϕ_B. For the sake of definiteness, let them both start at a latitude θ_1 in the northern hemisphere. Even if the two jets fly at the same speed $\mathbf{p}$ will increase, $\dot{\mathbf{p}} > 0$, as θ decreases, but the rate of increase of $\dot{\mathbf{p}}$ will *decrease* at a constant rate, i.e. $\ddot{\mathbf{p}} < 0$. As the rate of change of position is the velocity, $\dot{\mathbf{p}}$ is the velocity and *its* rate of change, $\ddot{\mathbf{p}}$, is the acceleration, $\mathcal{A}$. Thus curvature is seen to be related to acceleration in kinematic terms. To see precisely how the two are related, one needs to require that the position vector $\mathbf{p}$ be "carried along" by the tangent vector to the geodesic, $\mathbf{t}$. We say that $\mathbf{p}$ is *Lie transported* along $\mathbf{t}$. In the above example, if A starts at point P and goes on to point Q, then the position vector of B at Q will be given by $\mathbf{t}(\mathbf{p})$. Further, if B starts at R and ends at S, then S is given by $\mathbf{p}(\mathbf{t})$. But the position of S relative to Q is also given by $\mathbf{t}(\mathbf{p})$. Hence they commute, i.e. $\mathbf{t}(\mathbf{p}) = \mathbf{p}(\mathbf{t})$.

The curvature of a space over a small area is measured by carrying a vector field, v^a along one direction in the locally flat coordinate system and then the other, and subtracting the result from carrying it in the reverse order. (Carrying along the map, rather than on the curved space itself, is called *parallel transport*.) This is seen most easily on the surface of the Earth with one direction along a line of longitude and the other a line of latitude. Carrying equal *distances* and not angles (which would be the case for Lie transport), as defined in the local coordinate system of a map,

the rectangle carrying the vector will not close, because the cosine of the latitude will enter into the distance. Also the final direction of the vector will be different for the two, as it gets "twisted around more at a higher latitude than a lower one. Thus the Riemann curvature tensor is defined in index notation by

$$2v^{a}_{\ ;[c;d]} = R^{a}_{\ bcd}v^{b} \ , \tag{3}$$

where $S_{[ab]} = (S_{ab} - S_{ba})/2!$.

For our purposes we need to use a four-dimensional spacetime. Since the geodesic of A is the path of a test particle, $\mathbf{t}$ must be a timelike vector, and since $\mathbf{p}$ is the position vector of a neighbouring test particle seen at some time in the rest-frame of A, it must be a spacelike vector. I use the metric signature convention $(+,-,-,-)$, so that $\mathbf{t}.\mathbf{t} > 0 > \mathbf{p}.\mathbf{p}$. Thus the physical acceleration of B relative to A is

$$\mathcal{A} = \ddot{\mathbf{p}} = \mathbf{t}[\mathbf{t}(\mathbf{p})] \ . \tag{4}$$

In the geometrical context it is called the *geodesic deviation*. We now use the Lie transport and geodesic equations to get the relation between the curvature tensor and the acceleration.[4] First, we use the Lie transport for the acceleration, written in index notation, by commuting the expression inside the bracket to get

$$\mathcal{A}^{\mu} = t^{\rho}(t^{\nu}p^{\mu}_{\ ;\nu})_{;\rho} = t^{\rho}(p^{\nu}t^{\mu}_{\ ;\nu})_{;\rho} \ , \tag{5}$$

and then expand the bracket to obtain

$$\mathcal{A}^{\mu} = t^{\rho}p^{\nu}_{\ ;\rho}t^{\mu}_{\ ;\nu} + t^{\rho}p^{\nu}t^{\mu}_{\ ;\nu;\rho} \ . \tag{6}$$

Next, we use the Lie transport equation again for the first term to write it as

$$\mathcal{A}^{\mu} = p^{\rho}t^{\nu}_{\ ;\rho}t^{\mu}_{\ ;\nu} + t^{\rho}p^{\nu}t^{\mu}_{\ ;\nu;\rho} \ . \tag{7}$$

Notice that

$$p^{\rho}(t^{\nu}t^{\mu}_{\ ;\nu})_{;\rho} = p^{\rho}t^{\nu}_{\ ;\rho}t^{\mu}_{\ ;\nu} + p^{\rho}t^{\nu}t^{\mu}_{\ ;\nu;\rho} \ , \tag{8}$$

so we and add and subtract $p^{\rho}t^{\nu}t^{\mu}_{\ ;\nu;\rho}$, using the positive part to rewrite the first term and obtain

$$\mathcal{A}^{\mu} = p^{\rho}(t^{\nu}t^{\mu}_{\ ;\nu})_{;\rho} - p^{\rho}t^{\nu}t^{\mu}_{\ ;\nu;\rho} + t^{\rho}p^{\nu}t^{\mu}_{\ ;\nu;\rho} \ . \tag{9}$$

Now use the geodesic equation to get rid of the first term. Interchanging dummy indices and using the definition of the Riemann tensor, we finally arrive at

$$\mathcal{A}^{\mu} = -R^{\mu}_{\ \nu\rho\pi}t^{\nu}p^{\rho}t^{\pi} \ . \tag{10}$$

If the curvature is due to gravity, then this is the tidal acceleration, or the acceleration of one test particle as seen by an observer on the other. If the mass of the test particle is m, $m\mathcal{A}^{\mu}$ is the tidal force, which is the gravitational force equivalent to the curvature, which has been called the pseudo-Newtonian, or ψN-, force.[4,22]

Since the acceleration is taken to be physically "caused" by the distribution of matter and energy, represented by the stress-energy tensor, $T^{\mu\nu}$, and geometrically by the Riemann tensor, $R^{\mu}{}_{\nu\rho\pi}$, the two must be functionally related. Thus

$$T^{\mu\nu} = f^{\mu\nu}(R^{\alpha}{}_{\beta\gamma\delta}) \ . \tag{11}$$

The problem is that the former is a second rank tensor while the latter is a fourth rank tensor. The trace of the Riemann tensor, called the *Ricci* tensor, $R_{\beta\delta} = R^{\alpha}{}_{\beta\alpha\delta}$, is a second rank tensor which could be used in place of the Riemann tensor. Further, for mass-energy conservation the stress-energy tensor must be divergence-free, i.e. $T^{\mu\nu}{}_{;\nu} = 0$, which requires that $f^{\mu\nu}{}_{;\nu} = 0$. Now the Riemann tensor satisfies the second Bianchi identities (for a proof of which, see for example[4])

$$R^{\alpha}{}_{\beta\gamma\delta;\epsilon} + R^{\alpha}{}_{\beta\epsilon\gamma;\delta} + R^{\alpha}{}_{\beta\delta\epsilon;\gamma} = 0 \ , \tag{12}$$

contracting which yields the divergence-free *Einstein* tensor

$$\mathcal{E}_{\beta\delta} = R_{\beta\delta} - \frac{1}{2} g_{\beta\delta} R \ , \tag{13}$$

$R = g^{\mu\nu} R_{\mu\nu}$ being the *Ricci scalar*. Integrating $f^{\mu\nu}{}_{;\nu} = 0$, the simplest function $f^{\mu\nu}$ would be a constant, which means a constant times the covariantly constant metric tensor, $g^{\mu\nu}$, but that would "throw the baby out with the bath-water". The simplest meaningful expression is to add in a constant times the Einstein tensor, which yields the relation between curvature and matter-energy as

$$R_{\mu\nu} - \frac{1}{2} g_{\mu\nu} R + \Lambda g_{\mu\nu} = \kappa T_{\mu\nu} \ , \tag{14}$$

where Λ is a constant of integration and the overall proportionality constant, κ, is put in with the matter-energy tensor, rather than the geometrical tensor.

5. What Difference Does It Make?

So what have we achieved? Just an alternate derivation of the Einstein field equations with a cosmological constant? I believe that this derivation had already been arrived at by Einstein. Undoubtedly, Einstein first *published* his field equations by using the variational principle. If he had got them earlier by this method, why did he not publish that derivation? I think that he felt that the Physics community was not so readily adopting the geometrical work of Grossmann and him, and wanted a derivation that would convince the community, and so waited till he had the field theoretic derivation worked out. Why would he not, then, have inserted the cosmological constant in there? There seem to be some letters between Hilbert and him that indicate he *had* done so in an earlier draft, but removed it later. The reason would be that the jewel in the crown of relativity was the explanation of the perihelion shift of Mercury by a theory with no free parameters. Had he put in the cosmological constant, there *would* be a free parameter. He was convinced that the theory was right. In this derivation the cosmological constant would *have to be there.*

In the derivation from the variational principle, it would have to be inserted by hand and so Hilbert was not getting it.

Even if this was the original derivation by Einstein, what difference does it make in any case? The point is that if we accept that Einstein inserted the constant later, by hand for his paper on cosmology a couple of years later,[2] it appears artificial and not part of the original theory, that had been verified. I have made much of the constant of integration coming with the geometry and not with the (physical) stress-energy tensor. It could, apparently, equally well have been inserted on the right side of the equation. In that case it would be an all-pervasive vacuum energy and not part of the geometry. Thus, it would need to be included in quantization. It is then assumed that the renormalization effect would come at the cut-off where quantum gravity takes over. On dimensional arguments one can argue that neither quantum mechanics nor relativity can be neglected when $\hbar, G, c^{-1}$ are non-negligible. Using them to make dimensional quantities, we get *Planck units*. It is further argued that "hence quantum gravity will set in *at* the Planck scale". Using the Planck energy density, which has the same units as the cosmological constant, *one gets a value about 126 orders of magnitude off from observation!* Hawking called this "the worst prediction in the history of Physics", and one cannot but agree with him. However, the original argument says that it must be invoked *by* the Planck scale, not *at* it. There is no reason that it should not set in *well before* the Planck scale. As I mentioned earlier, there is no theory of quantum gravity in any case, so one can only say what a valid theory for it *might* say. In that context Husain and Qureshi[23] have pointed out that the claimed problem does not arise. They point out that the argument is based on quantization of energy that is well defined in Minkowski space but is ambiguous in an arbitrarily curved spacetime. *There is no vacuum instability problem.*

So, what difference did the history make, if Einstein *had* got the cosmological constant earlier? It would have been perceived as part of the geometry, as a constant curvature, and the question of quantizing it would not arise till we had a "quantum geometrical" description of spacetime. One could then try to see what it would say, if anything, about the matter. The point is that it may be just our perception of what is "natural" that leads to the problems.

6. Conclusion and Discussion

In this paper it has been argued that it makes a huge difference whether the cosmological constant is regarded as part of the geometry or part of the stress-energy tensor. In the former role, as shown by Willem de Sitter,[24] it yields a static, constant curvature spacetime. Though this universe model does not change with time, an observer looking at the geodesic of a neighbouring test particle sees it accelerating *away* and so sees an expansion of this universe. Transforming to a cosmological time, using which one could talk of what is happening in a distant part of this universe "at the same time", the expansion would seem to be exponential (see for example[4]).

Put with the stress-energy tensor it would be an all-pervasive vacuum energy which gives a repulsive force for positive Λ.

Which way *should* it be looked at? Well, it was the expression involving the curvature that had to be determined, and so it is natural to keep the constant on the left side of the equation with the geometry. There is then no energy field causing the expansion — which appears as a kinematic effect. As such it cannot be considered for quantization without quantizing the rest of the spacetime. In that case the renormalization of the quantization of the rest of the curvature might, for example, balance that of the cosmological constant, so that there would be no net renormalization effect. I am not claiming that this *must* be so, only that we do not know and it could even be so. In fact, Maxwell had pointed out that his electromagnetic force, and hence energy, is opposite to the gravitational. Thus all gravitational effects should be expected to behave opposite to electromagnetic effects. Now the net mass-energy, material and gravitational, of the Universe is zero. That is what made it possible for Brout et al.[25] to propose that the Universe may be a vacuum fluctuation. In fact, have argued that there is reason to believe that any quantum gravitational effect should act opposite to other quantum fields.[26]

The current speculation is that the exponential expansion is due to a "mysterious form of dark energy" with thoroughly counter-intuitive properties. In fact, in some ways it is reminiscent of the luminiferous aether with any number of properties inserted by hand, with no evidence for them. This introduces any number of free parameters, reminiscent of Aristotle's epicycles. Regardless of these problems, let us go ahead and see what the claim is. The argument goes that if it were due to a cosmological constant, it would be orders of magnitude too small — *hence it must be zero*. You might well wonder how zero would be closer to the Planck value than the small observed value? Surely, that should be infinitely many orders of magnitude off! Why should it be zero in any case? If there is a constant appearing in the equations, should one not naturally look to the observational data to provide the value? The response normally given is that "it must be zero for some hitherto unknown reason, which will emerge later, but in the meantime we should assume that it is zero."

The standard model of cosmology is called the "Λ-CDM model", of which the latter stands for "cold dark matter" and the former for the cosmological constant. Thus, within observational errors, the data gives a behaviour of the Universe identical with what would be expected with a cosmological constant. To argue that it is a dynamical field seems perverse. Alternatively, we can say that the Almighty has set it to behave that way just to confuse us — transferring the perversity to Him (as we tend to do for most of our sins). Perhaps He is busting a rib up in Heaven, laughing at how "He has confused these arrogant blighters!" Why do we not simply accept the obvious explanation of the cosmological constant and determine it, just as we do Newton's constant of gravity? I am forced to conclude that it is because we would then eliminate a whole spew of papers and students supervised, based on wild speculations. In this conference "the Hubble tension" has been taken to imply

that the "dark energy" underwent a phase transition and started to behave like the cosmological constant.[27] The essence of the argument was because "the ΛCDM is correct, and if it does not fit at the very early stage then the Λ cannot be constant", despite the fact, as pointed out,[28] that the accuracy of the measurements for it are not yet sufficient for any definite conclusion. As we have no idea of the Physics of the CDM, why should there not be a phase transition for *it*? That would appear to be far more natural as matter *does* undergo phase transitions. Because people have got wedded to "the mysterious dark energy" — the dark side of the force.

Acknowledgments

I am most grateful for very useful comments to Francesco De Paolis, Viqar Husain, Babar Qureshi and Khalid Saifullah. I am also most grateful to the Organizing Committee of MG 16 for providing me a Registration fee waiver to participate in the Virtual Meeting.

The irreducible mass of Christodoulou-Ruffini-Hawking mass formula

Yuan K. Ha

Department of Physics, Temple University
Philadelphia, Pennsylvania 19122 U.S.A.
E-mail: yuanha@temple.edu

We reveal three new discoveries in black hole physics previously unexplored in the Hawking era. These results are based on the remarkable 1971 discovery of the irreducible mass of the black hole by Christodoulou and Ruffini, and subsequently confirmed by Hawking.
1. The Horizon Mass Theorem shows that the mass at the event horizon of any black hole: neutral, charged, or rotating, depends only on twice its irreducible mass observed at infinity.
2. The External Energy Conjecture proposes that the electrostatic and rotational energy of a general black hole exist completely outside the horizon due to the nature of the irreducible mass.
3. The Moment of Inertia Property shows that every Kerr black hole has a moment of inertia. When the rotation stops, there is an irreducible moment of inertia as a result of the irreducible mass.
Thus after 50 years, the irreducible mass has gained a new and profound significance. No longer is it just a limiting value in energy extraction, it can also determine black hole dynamics and structure. What is believed to be a black hole is a physical body with an extended structure. Astrophysical black holes are likely to be massive compact objects from which light cannot escape.

Keywords: Black holes; quasi-local energy; irreducible mass; Kerr metric; moment of inertia.

1. 50th Anniversary 1971–2021

This article is to celebrate the 50th anniversary of the discovery of the mass-energy formula of a Kerr-Newman black hole in 1971 by introducing three new results recently found in black hole physics. Surprisingly, these results all invove the concept of the irreducible mass.

First, congratulations to Demetrios Christodoulou and Remo Ruffini for their remarkable discovery of the *irreducible mass*[1] of the black hole and confirmed by Hawking,[2] one of the most important concepts in black hole physics.

This year is also the 50th anniversary of the renormalization of Yang-Mills theory[3] in 1971. Congratulations to Gerard 't Hooft and the late Martinus Veltman for their elucidation of the quantum structure of electroweak interactions, one of the great achievements in 20th Century physics.

The irreducible mass formula discovered by Christodoulou and Ruffin in 1971 is the following:[1]

$$M^2 = \left(M_{irr} + \frac{Q^2}{4GM_{irr}}\right)^2 + \frac{J^2c^2}{4G^2M_{irr}^2}. \quad (1)$$

Here M is the total mass of the Kerr-Newman black hole, M_{irr} is the irreducible mass; Q is the electric charge and J is the angular momentum. All quantities are reckoned according to the distant observer. When Q and J are zero, the irreducible mass is the mass of a Schwarzschild black hole. 50 years later, the irreducible mass has gained unexpected new and profound significance besides energy extraction. It can also determine black hole dynamics and structure.

It is especially appropriate to explain the many definitions of a black hole in physics.[4] The mathematical black hole in general relativity has a singularity hidden by a horizon. However, neither singularity nor horizon has been observed. Compact objects like the one at the center of our galaxy are also called black holes in common usuage, even though their nature is still unknown. This is pointed out in the 2020 Nobel Prize in Physics citation. To Roger Penrose, the citation is 'for the discovery that black hole formation is a robust prediction of the general theory of relativity'. To Reinhard Genzel and Andrea Ghez, the citatation is 'for the discovery of a supermassive compact object at the center of our galaxy'. The term black hole is avoided. Strictly speaking, the black hole has not been discovered, but only a black hole-like object has been observed in astyrophysics. The Laplace 'dark star' introduced the concept of the black hole as a massive body from which light cannot escape due to its strong gravity.

Between 1965–1985, several important theorems on classical black holes were gradually discovered. They are known as:

(1) Singularity Theorem (1965),[5]
(2) Area Non-decrease Theorem (1972),[6]
(3) Uniqueness Theorem (1975),[7]
(4) Positive Energy Theorem (1983).[8]

These theorems have been well discussed for many years in general relativity and accepted as basic properties of the classical black hole. In recent years, three new results on black holes previously unexplored in the Hawking era are found. They were developed using the quasi-local energy approach and angular momentum consideration. Remarkably, they all contain the irreducible mass of Christodoulou and Ruffini. They are:

(5) Horizon Mass Theorem (2005),[9]
(6) External Energy Conjecture (2017),[10]
(7) Moment of Inertia Property (2018).[11]

These results are derived completely within general relativity and therefore legitimate. They add new properties to the classical black hole with potential to resolve several long-standing paradoxes in black hole physics.

2. Horizon Mass Theorem

Theorem. *For neutral and charged black holes, the horizon mass is always twice the irreducible mass observed at infinity.*

For rotating black holes, the horizon mass is found to be extremely close to twice the irreducible mass for all rotations. It is conjectured that a rigorous proof will eventually show that the horizon mass is exactly twice the irreducible mass.

In notation, it is simply

$$M(r_+) = 2M_{irr} \tag{2}$$

where r_+ is the horizon radius of the black hole. The theorem relates the mass of a black hole observed at the event horizon to its irreducible mass observed at infinity. The irreducible mass does not contain electrostatic and rotational energy. The Horizon Mass Theorem is the final outcome of quasi-local mass applied to black holes.

The quasi-local energy is one of the most important concepts in general relativity after decades of searching for a consistent definition of gravitational energy. It was finally obtained in 1993. The Brown and York expression[12] for quasi-local energy is given in terms of the total mean curvature of a surface bounding a volume for a gravitational system in four-dimensional spacetime. The total energy E , including binding energy, is given in the form of an integral,

$$E = \frac{c^4}{8\pi G}\int_{^2B} d^2x\sqrt{\sigma}(k - k^0), \tag{3}$$

where σ is the determinant of the metric defined on the two-dimensional surface ^2B ; k is the trace of the extrinsic curvature of the surface, and k_0 , the trace of the curvature of a reference space. For asymptotically flat reference spacetime, k^0 is taken to be zero. The expression in Eq.(3) is the basis for establishing the Horizon Mass Theorem.

For a Schwarzschild black hole, the total energy contained in a sphere enclosing the black hole at a coordinate distance r is calculated,[12–14]

$$E(r) = \frac{rc^4}{G}\left[1 - \sqrt{1 - \frac{2GM}{rc^2}}\right]. \tag{4}$$

At the Schwarzschild radius, $r = r_+ = 2GM/c^2$, the above equation reduces to

$$E(r) = \left(\frac{2GM}{c^2}\right)\frac{c^4}{G} = 2Mc^2, \tag{5}$$

giving the first case of the Horizon Mass Theorem in Schwarzschild spacetime, i.e. $M(r_+) = 2M$.

For a Reissner-Nordström black hole enclosed within a radius at coordinate r, the total energy calculated is now [9],

$$E(r) = \frac{rc^4}{G}\left[1 - \sqrt{1 - \frac{2GM}{rc^2} + \frac{GQ^2}{r^2c^4}}\right]. \tag{6}$$

Here M is the total mass of the black hole including electrostatic energy observed at infinity, and Q is the electric charge.

The irreducible mass is the final mass of the black hole when its charge is neutralized by adding oppositely charged particles, extracting energy from the black hole. It is defined as in electrostatics,

$$M = M_{irr} + \frac{Q^2}{4GM_{irr}}. \tag{7}$$

Inverting the equation to solve for M_{irr}, we find

$$M_{irr} = \frac{M}{2} + \frac{M}{2}\sqrt{1 - \frac{Q^2}{GM^2}}. \tag{8}$$

The horizon radius of a Reissner-Nordström black hole is known to be

$$r_+ = \frac{GM}{c^2} + \frac{GM}{c^2}\sqrt{1 - \frac{Q^2}{GM^2}}. \tag{9}$$

Combining Eq.(6) and Eq.(9), we find the mass contained within the horizon to be

$$\frac{E(r_+)}{c^2} = M(r_+) = M + M\sqrt{1 - \frac{Q^2}{GM^2}}, \tag{10}$$

i.e. $M(r_+) = 2M_{irr}$. This is the second case of the Horizon Mass Theorem in Reissner-Nordström spacetime. It is seen that the horizon mass of the charged black hole depends only on the energy of the black hole when it is neutral.

We proceed next to the case for a slowly rotating black hole with mass M and angular momentum J . The total energy contained within a sphere of radius r can only be given by an approximate expression. This is due to the complexity of the Kerr metric, and more importantly, due to the fact that the Kerr metric only has axial symmetry instead of spherical symmetry. At the horizon, it is found that,[15]

$$\begin{aligned} E(r) = {} & \frac{rc^4}{G}\left[1 - \sqrt{1 - \frac{2GM}{rc^2} + \frac{\alpha^2}{r^2}}\right] \\ & + \frac{\alpha^2 c^4}{6rG}\left[2 + \frac{2GM}{rc^2} + \left(1 + \frac{2GM}{rc^2}\right)\sqrt{1 - \frac{2GM}{rc^2} + \frac{\alpha^2}{r^2}}\right] + \cdots \end{aligned} \tag{11}$$

where $\alpha = J/Mc$ is the angular momentun length paraneter. The leading term of the expression is similar to the energy expression in the Reissner-Nordström case,

suggesting that the mass at the horizon is twice the irreducible mass. The next term depends on α^2, adding a small contribution to the leading term.

The irreducible mass of a Kerr black hole is the final mass when its rotational energy is completely extracted by adding external particles, such as in the Penrose process.[16] It is given in the form

$$M_{irr}^2 = \frac{M^2}{2} + \frac{M^2}{2}\sqrt{1 - \frac{J^2c^2}{G^2M^4}}. \tag{12}$$

The horizon radius in this case is,

$$r_+ = \frac{GM}{c^2} + \frac{GM}{c^2}\sqrt{1 - \frac{J^2c^2}{G^2M^4}}. \tag{13}$$

An approximate relation for the horizon energy is therefore found,

$$E(r_+) \approx 2M_{irr} + O(\alpha^2). \tag{14}$$

The conclusion is that there is very little rotational energy insiide the Kerr black hole.

It is natural to extend the quasi-local energy investigation to include higher rotations, and logically, all rotations. However, a severe challenge appeared at this stage and progress on black hole rotation in this approach stopped. The calculations became extremely difficult to perform. No analytical expression or numerical evaluation could achieve an *exact* expression for the horizon mass of the Kerr black hole. An analysis of the horizon mass in the teleparallel equivalent formulation of general relativity[17] reveals that it is strikingly close to twice the irreducible mass $2M_{irr}$ for all range of the parameter $0 \leq \alpha < GM/c^2$. The tiny discrepancy is likely due to evaluating method and describing the spherical horizon region in a system with intrinsic axial symmetry. A general principle based on equipartition of energy at the horizon also suggests the horizon mass result for the Kerr black hole[18] by invoking one-half of the horizon mass for compensating the negative gravitational potential energy and the other half for supplying the irreducible mass.

We give a heuristic argument for the Horizon Mass Theorem with the area concept of a black hole.[9] It has been known from the Kerr metric that the area at the event horizon of a Kerr black hole for all rotations is[1]

$$A = 4\pi(r_+^2 + \alpha^2) = \frac{16\pi G^2 M_{irr}^2}{c^4}, \tag{15}$$

and the area of a Schwarzschild black hole of mass M_S and radius R_S is

$$A = 4\pi R_S^2 = 4\pi\left(\frac{2GM_S}{c^2}\right)^2 = \frac{16\pi G^2 M_S^2}{c^4}. \tag{16}$$

The two areas can be related by invoking Hawking's Area Non-decrease Theorem in the energy extraction process. The theorem asserts that the area of a Kerr black hole is the same as the area of the final Schwarzschild black hole when rotational energy is extracted in a smooth and reversible process. Since the horizon mass of the

Schwarzschild black hole is proven to be twice its asymptotic mass M_S, the horizon mass of the Kerr black hole in this process is therefore $2M_{irr}$. The result applies to all rotations. It is believed that a rigorous mathematical proof will eventually show that the horizon mass is *exactly* twice the irreducible mass.

The Horizon Mass Theorem is crucial for understanding processes occuring near the horizon, such as the merging of two black holes,[19] and quantum emission of Hawking radiation.[20]

3. External Energy Conjecture

Proposition. *The electrostatic energy and rotational energy of a general black hole exist completely outside the horizon.*

The conjecture is a direct consequence of the irreducible mass in the Horizon Mass Theorem.

By definition, the irreducible mass does not contain rotational energy or electrostatic energy. A rotating black hole does not have rotational energy inside the horizon; therefore rotational energy exists outside the surface. Similarly, an electrically charged black hole does not have electrostatic energy inside. Electrostatic energy exists only outside, like that of a conductor. When quantum particles carrying electric charges and spins reach the black hole, they are forbidden to enter inside. They can only stay outside or at the surface. Since all matter particles in Nature are quantum particles, this makes the interior of the black hole completely hollow. Classical particles do not exist in Nature; they are a tool in classical mechanics.

We may generalize the External Energy Conjecture to include other energies of a black hole and introduce a new paradigm.[11]

External Energy Paradigm:

> *All energies of a black hole are external quantities. They include: constituent mass, gravitational energy, electrostatic energy, magnetic energy, rotational energy, heat energy, etc.*

The validity of this paradigm will be demonstrated in the next section in which the moment of inertia of a black hole is presented.

4. Moment of Inertia Property

Statement. *A black hole with an angular momentum and an angular velocity at the event horizon has a moment of inertia given by:*

$$\textit{coefficient} \times \textit{Kerr mass} \times \textit{(ergosphere radius)}^2 \ .$$

When rotation stops, there is an irreducible moment of inertia given by:

$$\textit{irreducible mass} \times \textit{(Schwarzschild radius)}^2 \ .$$

The result of this statement is derived solely from the Kerr metric and is therefore a *bona fide* property of general relativity. Every black hole has a moment of inertia, even when it is not rotating. Moment of inertia indicates structure of the black hole.

The Kerr metric[21] discovered in 1963 ushered in a new epoch in general relativity and in astrophysics. It is absolutely indispensable for the study of rotating black holes. We demonstrate the existence of moment of inertia uniquely from the Kerr metric, using angular momentum and angular velocity consideration. We present the Kerr metric in an *explicit* form of the Boyer-Lindquist coordinates[22] (t, r, θ, ϕ) so that the metric coefficients can be readily extracted for calculation. It contains two constants $\alpha = J/Mc$ and $m = GM/c^2$ for the stationary case,

$$\begin{aligned} ds^2 = &\left(\frac{r^2 + \alpha^2 cos^2\theta - 2mr}{r^2 + \alpha^2 cos^2\theta}\right) c^2 dt^2 + \left(\frac{4m\alpha r sin^2\theta}{r^2 + \alpha^2 cos^2\theta}\right) c d\phi dt \\ &- \frac{[(r^2 + \alpha^2)(r^2 + \alpha^2 cos^2\theta) + 2mr\alpha^2 sin^2\theta]}{r^2 + \alpha^2 cos^2\theta} sin^2\theta d\phi^2 \\ &-(r^2 + \alpha^2 cos^2\theta)\left(d\theta^2 + \frac{dr^2}{r^2 + \alpha^2 - 2mr}\right). \end{aligned} \tag{17}$$

The Kerr spacetime rotates with different angular velocities at different locations. The angular velocity at a point is defined as the change in azimuthal angle ϕ with respect to the change in coordinate time t. It can be expressed in terms of the metric coefficients as

$$\Omega = \frac{d\phi}{dt} = -\frac{g_{t\phi}}{g_{\phi\phi}}. \tag{18}$$

where $g_{t\phi} = g_{\phi t}$. At the equatorial region, $\theta = 90^\circ$, the angular velocity expression at a distance r can be written as

$$\Omega = \frac{2m\alpha rc}{(r^2 + \alpha^2)r^2 + 2mr\alpha^2}. \tag{19}$$

Further simplification can be achieved at the event horizon $r = r_+$, using the identity $r_+^2 + \alpha^2 = 2mr_+$, i.e.

$$\Omega_+ = \frac{\alpha c}{r_+^2 + \alpha^2}. \tag{20}$$

In terms of actual physical quantities, we have an exact algebraic relation for the angular velocity of the Kerr black hole,

$$\Omega_+(J) = \frac{\dfrac{J}{M}}{\dfrac{2G^2M^2}{c^4}\left[1 + \sqrt{1 - \dfrac{J^2c^2}{G^2M^4}}\right]}. \tag{21}$$

Given an angular momentun J and a Kerr mass M determined by a distant observer, the angular velocity at the event horizon can be obtained in radians/sec.

Equivalently, we can express the angular momentum J in terms of the angular velocity Ω through the moment of inertia $I(\Omega)$ in the form

$$J(\Omega) = I(\Omega) \cdot \Omega. \tag{22}$$

We find, from Eq.(21), after substantial algebra,

$$J(\Omega_+) = \frac{M\left(\frac{2GM}{c^2}\right)^2}{1+\left(\frac{2GM}{c^2}\right)^2 \frac{\Omega_+^2}{c^2}} \cdot \Omega_+. \tag{23}$$

The crucial step here is to extract a radius factor in the above relation. It is recognized that the factor $2GM/c^2$ is the ergosphere radius at the equator, since M is the Kerr mass which includes rotational energy. Accordingly, the moment of inertia of the Kerr black hole is

$$I(\Omega_+) = \frac{M\left(\frac{2GM}{c^2}\right)^2}{1+\left(\frac{2GM}{c^2}\right)^2 \frac{\Omega_+^2}{c^2}}. \tag{24}$$

It is further recognized that the entire denominator in the above expression becomes a dimensionless number and acts as a numerical coefficient. The structure of the Kerr black hole is therefore,

$$\textit{coefficient} \times \textit{Kerr mass} \times \textit{(ergosphere radius)}^2.$$

As angular momentum is continually reduced in the energy extraction process, a slowly rotating black hole is formed. In the static limit, the quantity $\Omega_+^2 \to 0$ first, the Kerr mass becomes the irreducible mass, $M \to M_{irr}$ and the coefficient becomes exactly equal to 1. The moment of inertia of a Schwarzschild black hole is derived. It is the limiting value of the moment of inertia of the Kerr black hole in Eq.(24), given by

$$I = M_S R_S^2. \tag{25}$$

There is an irreducible moment of inertia of the Kerr black hole as a result of the irreducible mass. It is the rotatonal analogue of the rest mass of a moving body $E = mc^2$.

A further observation that leads quickly to the irreducible moment of inertia is by considering the angular momentum definition in the Kerr metric $J = M\alpha c$ and the angular velocity Ω_+ at the horizon found in Eq.(20). We find,

$$I = \frac{J}{\Omega_+} = M\left(r_+^2 + \alpha^2\right) = \sqrt{M_{irr}^2 + M_{rot}^2}\left(r_+^2 + \alpha^2\right). \tag{26}$$

As the rotational parameter $\alpha \to 0$, the rotational mass $M_{rot} \to 0$; while the horizon radius $r_+ \to R_S$. In the limit, $I = M_{irr} R_S^2 = M_S R_S^2$. If one directly puts $J = 0$ and

$\Omega_+ = 0$ in the definition $I = J/\Omega_+$, one would get an undefined result 0/0. The static limit of the Kerr black hole hole has the structure,

$$\textit{irreducible mass} \times \textit{(Schwarzschild radius)}^2.$$

A Schwarzschild black hole does not have an axis of rotation. Introducing an axis destroys its spherical symmetry. The center is therefore the point of symmetry. The moment of inertia $I = M_S R_S^2$ is a statement about the mass distribution of a body with respect to the center in that the total mass is to be located at the Schwarzschild radius. A natural interpretation is that the static black hole is a hollow massive shell. This would go against the Equivalence Principle and the Singularity Theorem. It is possible that the static black hole resulting from the energy extraction process of a Kerr black hole is fundamentally different from the original Schwarzschild black hole. The static black hole derived from a Kerr black hole may be a quasi-black hole. A quasi-black hole has the same exterior spacetime as that of the Schwarzschild black hole but without the conceptual difficulties associated with the latter.[23] Singularity does not exist because particles are forbidden to cross the horizon by the very presence of the moment of inertia. The black hole firewall is such a scenario.[24] The quasi-black hole would also provide a physical surface where electric charges can stay instead of hovering without cause in the case of the charged black hole. In addition, if the surface area is identified as the entropy of a black hole according to Bekenstein[25] and Hawking,[6] then it is logical to expect that all mass of the quasi-black hole is at the surface. The moment of inertia is a new property of the Kerr black hole.

5. Epilogue

After 50 years, the irreducible mass has progressed from the gedanken Penrose process to quantum energy extraction in gamma-ray bursts and active galactic nuclei emissions.[26] Instead of being a cold and inert body, the real black hole is a highly active object. The irreducible mass further plays a central role in newly discovered black hole properties. These results may resolve some of the long-standing paradoxes in black hole physics.

We study the non-linear structure formation in cosmology accounting for the quantum nature of the dark matter (DM) particles in the initial conditions at decoupling, as well as in the relaxation and stability of the DM halos. Differently from cosmological N-body simulations, we use a thermodynamic approach for collisionless systems of self-gravitating fermions in General Relativity, in which the halos reach the steady state by maximizing a coarse-grained entropy. We show the ability of this approach to provide answers to crucial open problems in cosmology, among others: the mass and nature of the DM particle, the formation and nature of supermassive black holes in the early Universe, the nature of the intermediate mass black holes in small halos, and the *core-cusp* problem.

Keywords: Dark Matter; Galaxies: Super Massive Black Holes - Halos; Self-gravitating Systems: fermions

1. Introduction

In the particle DM paradigm, different particle candidates (e.g. WIMPS, axions, sterile neutrinos, etc.) have different early Universe histories that, in turn, translates into different evolution of primordial perturbations in the cosmic plasma which seeds the formation of galaxies at later stages.[1] The effects of the DM microphysics is, in these cases, often quantified only by the (linear) matter power spectrum: a measure of the distribution of density perturbations before non-linear processes are involved. Such non-linear processes typically include the gravitational collapse of primordial structures, key to the formation of the observed structures in the late Universe, such as galaxies and clusters.

From the point of view of structure formation, the quantum nature of particle DM has been traditionally involved only in the initial conditions before self-gravity comes into play, neglecting any role it may have in the dynamics of the formed systems. However, whether or not this DM microphysics affects the overall structure of DM halos has been questioned in recent works. That is, our ignorance about its potential (quantum) effects through the innermost regions of the halos and their stability, may represent a hole in our knowledge of these systems.

Indeed, the limited inner spatial resolution of DM halos inherent of cosmological N-body simulations implies huge uncertainties on the DM central distribution. It includes the open questions on how the DM is correlated with baryonic matter on such inner scales, and ultimately, how is the relation with the supermassive black hole (SMBH) at the center of large galaxies, and how they can co-exist in a steady state. Moreover, the use of classical point masses as the building blocks of matter (without considering the quantum nature of the particles) in traditional N-body simulations within the LCDM paradigm does not allow for any new possible sources of quantum-pressure in DM halos (e.g. as recently shown within 3D numerical simulations for bosons 2 or fermions 3). The arising of these quantum effects at the center of equilibrium systems of self-gravitating quantum particles (either bosons or fermions) is a long-known physical phenomenon.[4]

Motivated by these open issues, we here present an alternative mechanism of structure formation in cosmology based on thermodynamics of self-gravitating fermions. In such a scenario, the quantum nature of the DM particles is duly taken into account in the physics of decoupling in the early Universe (with corresponding effects in the linear power spectrum), as well as at DM halo formation and subsequent stability and morphology.

2. DM halo formation: A thermodynamic approach

The thermodynamic approach for DM halo formation used here is motivated by the seminal work of *Lynden-Bell* on violent relaxation.[5] This approach was originally applied for collisionless stellar systems, and few decades later extended to indistinguishable particles such as massive neutrinos in Ref. 6. Relevant extensions to Lynden-Bell theory allowing for out of equilibrium effects (i.e particle evaporation), were performed in Refs. 7, 8 using the framework of kinetic theory. Quasi-stationary solutions to such equations (see Eq. (2) below), lead to a most-probable, coarse-grained distribution function (DF) at (violent) relaxation, of more realistic applications than the original Lynden-Bell's version: a tidally truncated Fermi–Dirac DF of the form

$$\bar{f}(\epsilon \leq \epsilon_c) = \frac{1 - e^{(\epsilon-\epsilon_c)/kT}}{e^{(\epsilon-\mu)/kT} + 1}, \qquad \bar{f}(\epsilon > \epsilon_c) = 0\,, \tag{1}$$

where $\epsilon = \sqrt{c^2p^2 + m^2c^4} - mc^2$ is the particle kinetic energy, μ is the chemical potential with the particle rest-energy subtracted off, T is the effective temperature, k is the Boltzmann constant, c is the speed of light, and m is the DM fermion mass. The full set of dimensionless-parameters of the model are defined by the temperature, degeneracy and cutoff parameters, $\beta = kT/(mc^2)$, $\theta = \mu/(kT)$ and $W = \epsilon_c/(kT)$, respectively (when these parameters are evaluated at the center of the configuration, they will be written with a subscript 0).

DM halos built upon such a fermionic DF in a cosmological framework, naturally lead to finite-sized halos which can be stable, extremely long-lived, and holding key implications to supermassive BH formation from DM as shown here (and detailed in Ref. 3).

In the limiting case of $\epsilon_c \gg \epsilon$, there is no particle escape, and (1) takes the form of the traditional (coarse-grained) Fermi-Dirac DF obtained in the original work of Lynden-Bell. Indeed, this DF is a stationary solution of the Vlasov-Poisson (VP) equation governing collisionless systems,[7] that is a solution of Eq. (2) shown below, with $\mathbf{J} = 0$, usually called 'VP dynamically-stable' solutions. The more realistic "tidally-truncated" DF (1) is another kind of quasi-stationary solution of the more general *convection-diffusion* kinetic equation (2), as demonstrated in Refs. 7, 9. This accounts for the 'microphysics' of the long-range particle-particle interactions[a] involved in the diffusion current $\mathbf{J}$, caused mainly by the rapid fluctuations of the gravitational potential (proper of violent relaxation processes):

$$\frac{\partial \bar{f}}{\partial t} + \mathbf{v}\frac{\partial \bar{f}}{\partial \mathbf{r}} - \nabla\Phi\frac{\partial \bar{f}}{\partial \mathbf{v}} = -\frac{\partial \mathbf{J}}{\partial \mathbf{v}}. \tag{2}$$

When the gravitational fluctuations die down at the end of relaxation, the diffusion current approaches zero (i.e. no more evaporation), and the DF (1) remains as a stationary solution of the VP equation. Now, these dynamically-stable VP solutions can be easily used to build DM halos in (hydrostatic) equilibrium able to reproduce galaxy rotation curves (as shown in Refs. 10, 11). However, such analysis does not explain neither *how* such a collisionless self-gravitating system reaches the required steady state, nor if they maximize the coarse-grained entropy S of such a fermion-gas, nor if they are just transitional (unstable/unreachable) states. This stems from the fact that VP dynamical stability *does not* necessarily imply thermodynamical stability, therefore some dynamically stable solutions for DM halos in hydrostatic equilibrium can be more likely to occur in Nature than others!

[a]For isolated systems made of fermions, such a current can make (2) to be of the form of a fermionic Landau equation, conserving mass and energy, and continuously increase the Fermi-Dirac entropy functional (i.e. fulfilling H-theorem).[9]

In order to find dynamically and thermodynamically stable configurations of collisionless self-gravitating fermions in General Relativity (GR), able to model realistic DM halos, it is needed to solve the problem of finding solutions that maximize the global entropy $S = \int_0^R s(r) e^{\lambda/2} 4\pi r^2 \mathrm{d}r$ (at fixed total energy and particle number), where $s(r)$ is the entropy density given by the Gibbs-Duhem relation

$$s(r) = \frac{P(r) + \rho(r) - \mu(r) n(r)}{T(r)}, \tag{3}$$

$e^{\lambda/2} 4\pi r^2 dr$ is the proper volume, being e^{λ} the spatial component of the spherically-symmetric spacetime metric: $\mathrm{d}s^2 = e^{\nu} c^2 \mathrm{d}t^2 - e^{\lambda} \mathrm{d}r^2 - r^2 \mathrm{d}\Theta^2 - r^2 \sin^2\Theta \mathrm{d}\phi^2$, with $(r,\, \Theta,\, \phi)$ the spherical coordinates, and ν and λ depend only on r.

The mass-energy density $\rho(r)$, pressure $P(r)$ and particle number density $n(r)$ are directly obtained as the corresponding integrals of $\bar{f}(p)$ over momentum space (bounded from above by $\epsilon \leq \epsilon_c$) as detailed in Ref. 3. This makes a four-parametric equation of state $(\rho(r),\, P(r))$ depending on (β, θ, W, m) according to the dimensionless parameters in (1). The stress-energy tensor is the one of a perfect fluid with the above density and pressure, so the self-gravitating configurations of fermions are solutions of the hydrostatic equilibrium equation, with the local $T(r)$ and $\mu(r)$ fulfilling, respectively, the Tolman and Klein equilibrium relations (see Ref. 3 for details). We shall analyze which of such solutions are thermodynamically stable and of astrophysical interest regarding realistic DM halos in cosmology.

The above stability analysis can be solved in an elegant manner via the 'Katz criterion'.[12] This allows to find the full set of thermodynamically-stable solutions (i.e. maxima of global entropy S) along the full series of equilibrium solutions of self-gravitating fermions. This is a powerful and rigorous method which relies only in the derivatives of the caloric curve given by total energy $E = c^2 M(R)$ vs. $1/T_{\infty}$ (like in Fig. 1), and without the need of calculating explicitly the (rather involving) second order entropy variations $\delta^2 S$. This is a commonly used method to calculate the stability of self-gravitating systems (see e.g. Refs. 9, 3). We work in the microcanonical ensemble applied for isolated systems since, as explained in detail in Ref. 9, it is the most appropriate for astrophysical applications. The relevant thermodynamic potential to be extremized in this ensemble is the coarse-grained entropy S.

In order for such a maximization entropy problem to be well defined, the self-gravitating solutions with given particle number $N = \int_0^R n(r) e^{\lambda/2} 4\pi r^2 \mathrm{d}r$ and total energy $E = c^2 M(R)$ must be bounded in radius, as occurring when working with the tidally-truncated DF (1). We recall this is not the case for the standard Fermi-Dirac DF (i.e coarse-grained solution of the VP equation), which instead leads to unbounded systems. Therefore, our approach is well posed and without the need to invoke unrealistic bounding boxes.[3]

3. Astrophysical & cosmological applications

We use the following method to assure that the fixed boundary conditions — such as N and corresponding $M(R)$ required to maximize the global entropy S — do correspond to values of a given fermionic halo in a realistic cosmological framework: **(i)** calculate the linear matter power spectrum for such fermionic (quantum) candidates; **(ii)** apply the corresponding Press-Schechter formalism to obtain the virial halo mass, $M_{\rm vir} \equiv M(R \equiv R_{\rm vir})$, with associated redshift $z_{\rm vir}$ for such a particle mass; and then **(iii)** use the the most probable coarse-grained DF (1) obtained at the end of violent relaxation (valid for that redshift), to obtain the full families of DM (equilibrium) profiles in agreement with above virial constraints. Having done this, we can analyze the (thermodynamic) stability of such halos using the Katz criterion in a given cosmological framework, and further check their astrophysical applications.

This strategy was recently applied in Ref. 3 within a WDM cosmology for fermion masses of $\mathcal{O}(10)$ keV, and exemplified here for an average DM halo of mass $M_{\rm vir} \approx 5 \times 10^{10} M_{\odot}$, which started to form at $z_{\rm vir} \approx 10$ according to the Press-Schechter formalism in our cosmological setup.

We show in Fig. 1 the caloric curve in dimensionless variables, $-\hat{M}$ vs. $1/\hat{T}_{\infty}$, for an average DM halo (with corresponding $\hat{N} = 76.25$, and $W_0 - \theta_0 = 24$ typical of average-size galaxies[3]) and for a particle mass of $m = 48$ keV. The stability analysis is based on the Katz criterion and follows the global procedure **(i-iii)** mentioned above. A practical *rule of thumb* to understand how the Katz criterion works is: (a) an unstable mode (coming from stable ones) arises when the caloric curve *rotates clockwise* (i.e. when the negative slope in the $(-\hat{M},\, \hat{T}_{\infty}^{-1})$ curve becomes infinite for then turning into positive), (b) when the same curve *rotates counterclockwise* a stable mode has been re-gained (the later implying that a positive slope turned into negative just after becoming vertical). In this sense, once in a given unstable branch of the caloric curve, it is necessary as many counterclockwise turns of the curve as clockwise passed, to regain the thermodynamic stability (see Appendix A in Ref. 3 for details).

In Fig. 1, we display the full family of thermodynamically-stable (i.e. maxima of S) solutions in continuous-blue line, and the thermodynamically unstable ones (i.e. minimum or saddle points of S) in dotted-violet. Interestingly, there are two spiral features in this caloric curve. The upper one arises due to the fermion (quantum) degeneracy which avoids the *gravothermal catastrophe* typical of Boltzmannian distributions (as first shown for classical systems in Ref. 13). The second spiral feature is of relativistic origin and lead to the turning point criterion for gravitational collapse discussed below.

We now highlight the main conclusions of this stability analysis, and its cosmological and astrophysical consequences in three different subsections.

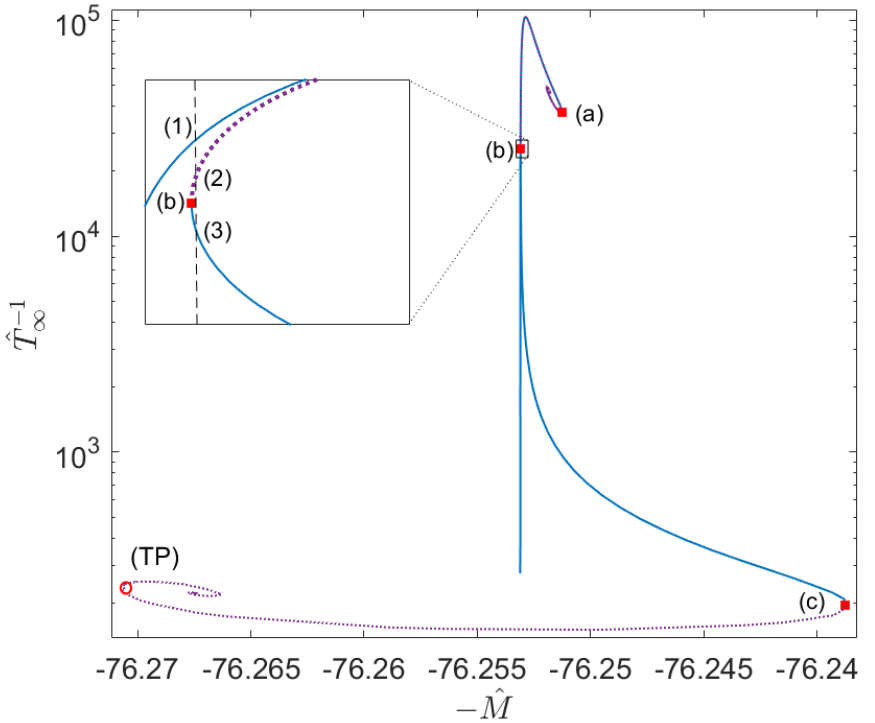

Fig. 1. Series of equilibrium solutions along the caloric curve for tidally-truncated configurations of $mc^2 = 48$ keV fermions, for typical DM halos of $M_{\rm vir} \approx 5 \times 10^{10} M_\odot$. The equilibrium states within the continuous-blue branches are thermodynamically (and dynamically) stable, while the dotted-violet branches — between (a) and (b) and after (c) — are unstable, according to the Katz criterion. Figure taken from Ref. 3.

3.1. *The shape of the fermionic DM halos*

We analyze from the caloric curve of Fig. 1 all the different kinds of density profiles for a conveniently fixed value of the total energy $\hat{M}$ (see vertical black-dashed line in the inset-box of Fig. 1, leading to the associated profiles of Fig. 2). There are two different families of stable and astrophysical DM profiles in a $\mathcal{O}(10)$ keV cosmology, arising from our (thermodynamic) halo-formation approach. They are either King-like, as the solution (1) in Fig. 1 (resembling the Burkert profile), or they develop a *core-halo* morphology (like the solution (3) in Fig. 1). Importantly, both kinds of solutions can agree with the observational DM surface density relation of galaxies (the latter $\propto \rho(r_{pl})\, r_h$, with $\rho(r_{pl})$ the density at plateau, and r_h the one-halo scale-length of such profiles), as demonstrated in Ref. 3. In the first case, the fermions are in the dilute regime (i.e. $\theta_0 \ll -1$) and correspond to a global maxima of entropy, while in the second case, the degeneracy pressure (i.e. Pauli principle) is holding the quantum core against gravity, and correspond to a local

maxima of entropy. This kind of fermionic *core-halo* solutions are usually referred as the Ruffini-Argüelles-Rueda (RAR) model.[10,14] They are extremely long-lived, meta-stable states as demonstrated in Ref. 3, with a lifetime $\propto e^N$, and more likely to arise in Nature than the former as argued in Ref. 9.

Remarkably, solutions like (3) in Fig. 1 can fit the rotation curve in galaxies, such as in the case of the Milky Way as shown in Fig. 3, while their dense quantum core can work as an alternative to the SMBH in non-active galaxies.[10,11,15,16] Indeed, this latter statement was analyzed in the case of our own Galaxy in Ref. 15 within the extended RAR model for $mc^2 = 56$ keV. It has been there shown that the gravitational potential of the DM dense core of such a configuration leads to better fit of the orbits of the S2 and G2 objects around Sgr A*, with respect to the one obtained by the central BH model (see Figs. 4 and 5). Furthermore, a geodesic in the gravitational field of the DM profile of the extended RAR model naturally predicts the post-pericenter slowing down phenomenon observed in G2 (see Fig. 5), result that contrasts with the BH hypothesis where it has been proposed that G2 is being slowed down by a drag force caused by an accretion flow onto the massive BH over which G2 should move.[17,18] Finally, strengthening this DM interpretation of the Galactic Center, in Ref. 16, this result has been extended to the up-to-date astrometry data of the 17 best-resolved S-stars orbiting Sgr A*, achieving to explain the dynamics of the S-stars with similar (and some cases better) accuracy compared to a central BH model (see Fig. 6), strengthen the alternative nature of Sgr A*.

Another key consequence of such a thermodynamic approach for DM halo formation is that, on inner halo scales, the $\mathcal{O}(10)$ keV fermionic density profiles develops an extended plateau (similar to Burkert profiles, with or without the innermost quantum core depending on the degree of central degeneracy), thus not suffering from the core-cusp problem associated to the standard ΛCDM cosmology.[19] Interestingly, while in N-body simulations (within the CDM paradigm) it is possible to obtain 'cored' profiles when including for DM self-interactions (see e.g. Ref. 20), here the flatness on inner halo scales are obtained due to the fulfillment of an entropy maximization. The later can be achieved thanks to the long range particle-particle interactions involved in the diffusion-current term of equation (2) (see also footnote a) as shown here, or complementarily it could be enhanced by (short-range) DM self-interactions as well.

3.2. *Gravitational core-collapse of DM and SMBH formation*

Another striking consequence of the present DM halo formation approach is that it predicts a novel SMBH formation mechanism from DM. Namely, a galactic quantum core made of DM (like in solution (3) of Fig. 2) might become so densely packed that, above a threshold critical mass, the quantum pressure can not support it any longer against its own weight, leading to its gravitational collapse and forming a SMBH. Such threshold solution correspond to the last-stable configuration depicted

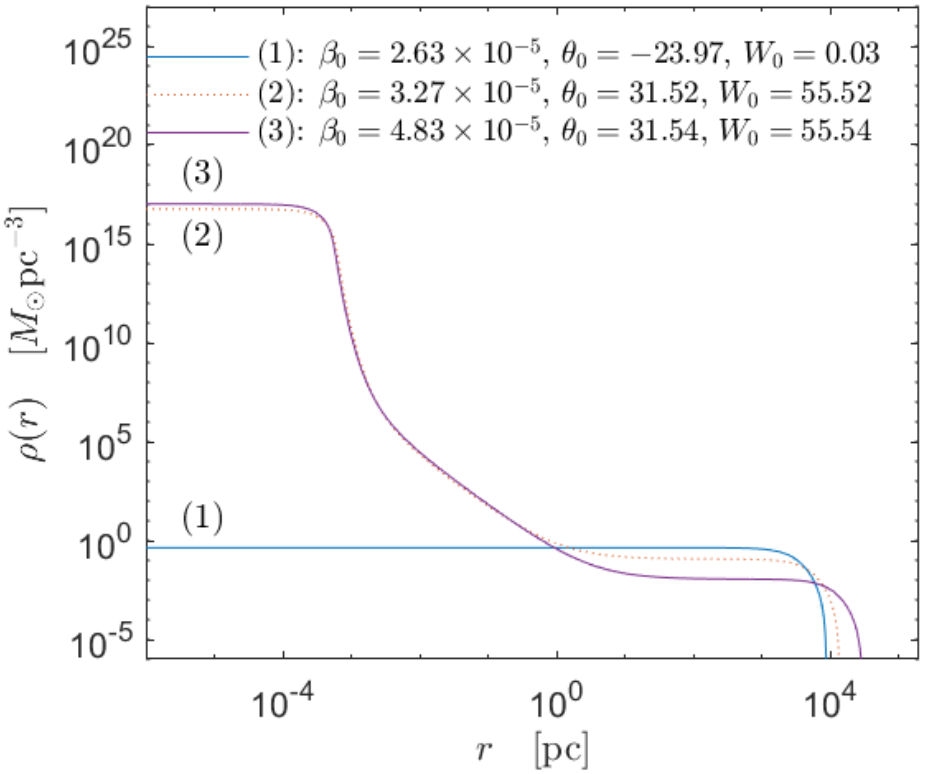

Fig. 2. Density profiles for $mc^2 = 48$ keV corresponding with three different solutions along the caloric curve in Fig. 1 at a fixed energy. Only the profiles (1) (resembling a King distribution) and the *core-halo* one (3) are stable, while profile (2) is thermodynamically unstable. Solutions like (3) are successfully applied to explain the Milky Way rotatoin curve (see Fig. 3). They are stable, extremely long-lived and fulfill with different observational probes. Figure taken from Ref. 3.

by the point (c) in the caloric curve of Fig. 1, below which there is no possible accessible state (see Ref. 3 for details). Moreover, such a collapse occurs *prior* to the turning point in the (traditional) *total mass* vs. *central density* diagram (see Fig. 7). This result, occurring here for self-gravitating systems of neutral fermions at finite T_∞ in GR, agrees with similar findings within rotating perfect-fluid stars,[25] and generalizes the traditional result applied to compact objects (such as neutron stars) based on full degeneracy ($T \to 0$).

This kind of DM core-collapse can only occur when the total particle number exceeds the so-called Oppenheimer-Volkoff limit (i.e. $\hat{N} > \hat{N}_{\mathrm{OV}} \approx 0.4$, as fulfilled in the case here exemplified of $\hat{N} = 76.25$). However, as explained in Sec. 3.1, it can also exist a stable branch of *core-halo* solutions for such $\hat{N} > \hat{N}_{\mathrm{OV}}$ as exemplified through the solution (3) in Fig. 1, before the last stable one (c). This fact is characteristic of self-gravitating solutions of fermions at finite T (as in the RAR model), which

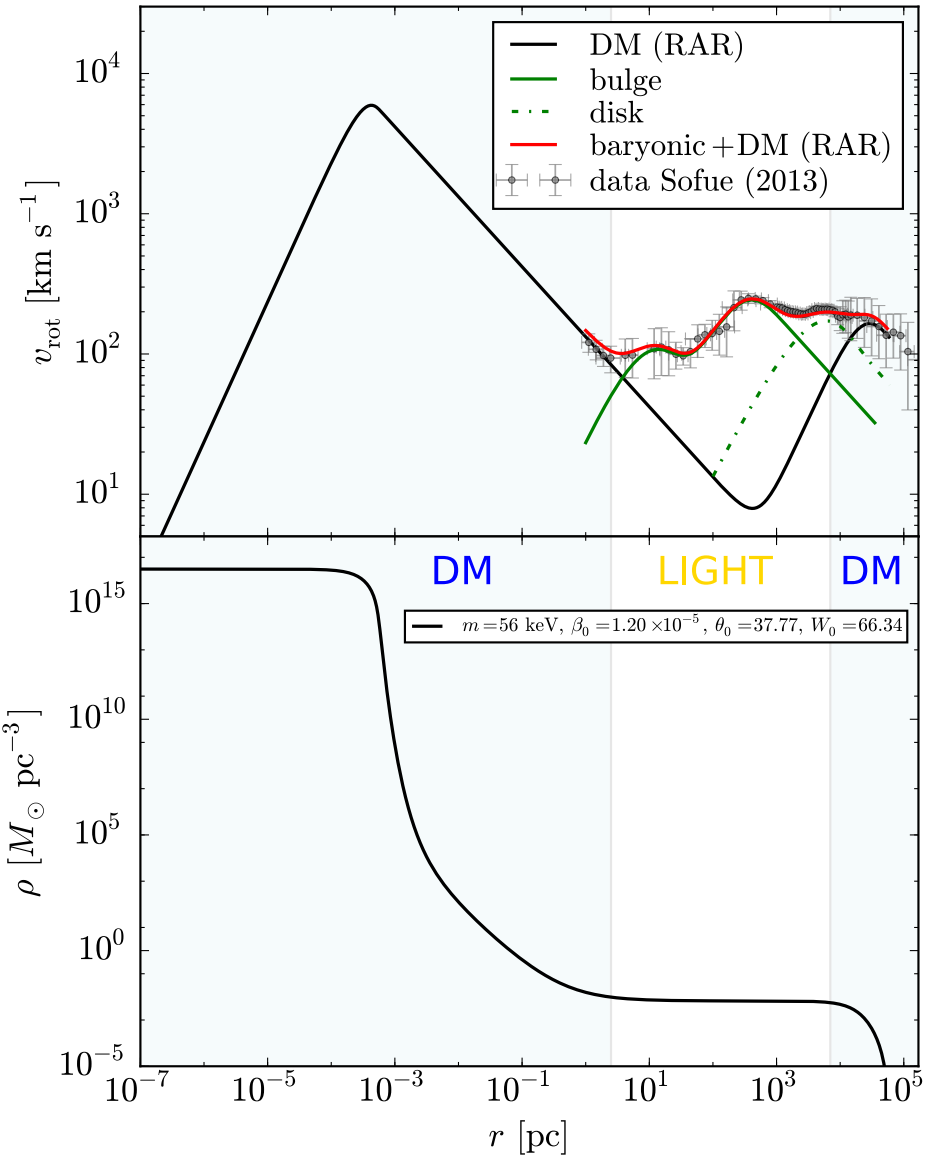

Fig. 3. Milky Way rotation curve and DM density profile within the core-halo DM RAR profiles for $mc^2 = 56$ keV, with a DM quantum core of mass of $M_c = M(r_c) = 3.5 \times 10^6 M_\odot$. Top: DM (black) and baryonic (bulge + disk) contribution to the rotation curve $v_{\rm rot}$ (total in red). Bottom: corresponding DM density profile. Figure taken from Ref. 15.

differ from the traditional $T \to 0$ limit where the system must necesarily collapse when $\hat{N} > \hat{N}_{\rm OV}$ (see Ref. 3 for further details).

In cases when $\hat{N} > \hat{N}_{\rm OV}$ as the one shown here, and for $mc^2 \approx 50$ keV, it is possible to form a SMBH of $M_c^{\rm cr} \approx 2 \times 10^8 M_\odot$ at the center of a realistic DM halo:

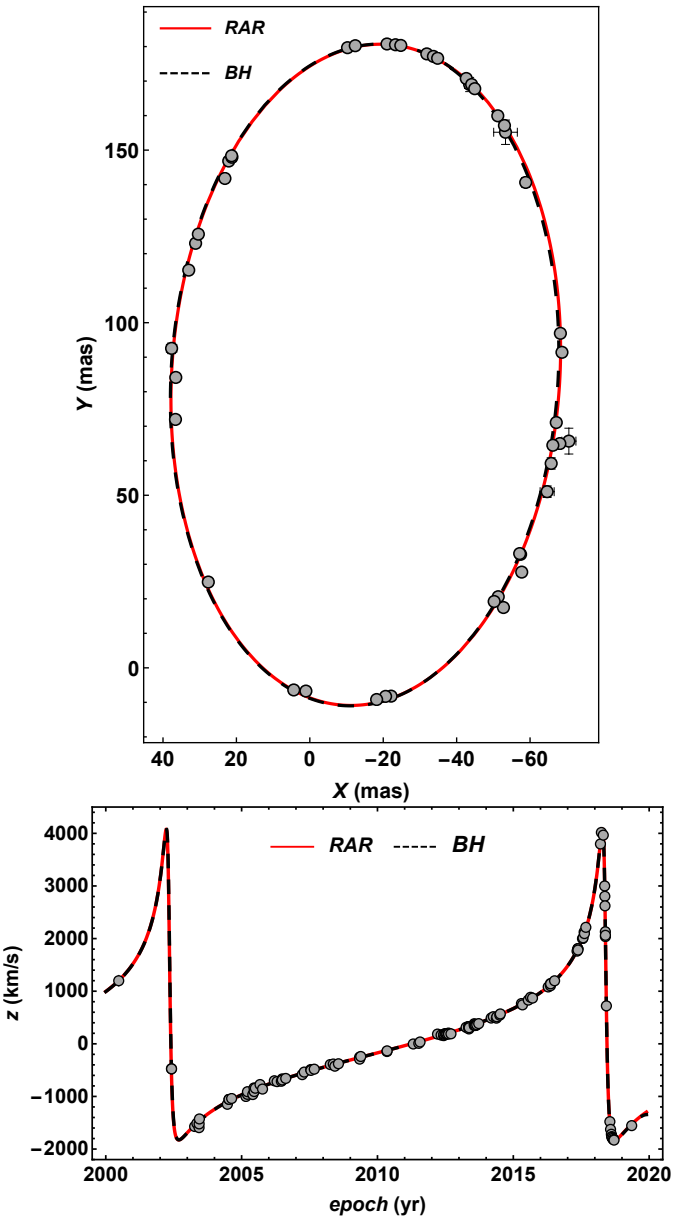

Fig. 4. Theoretical and observed orbit and radial velocity (z) of S2 around Sgr A* (wiht data taken from Ref. 21). Top panel: shows the projected orbit on the sky, X (Right Ascension) vs. Y (Declination). Bottom panel: shows the line–of–sight radial velocity as a function of time. The theoretical models are calculated by solving the equations of motion of a test particle in the gravitational field of: (i) a Schwarzschild BH of $4.075 \times 10^6\ M_\odot$ (*black dashed curve*), and (ii) the fermionic DM distribution obtained from the core-halo RAR model with $mc^2 = 56$ keV fermions (*red curves*). Figure adapted from Ref. 15.

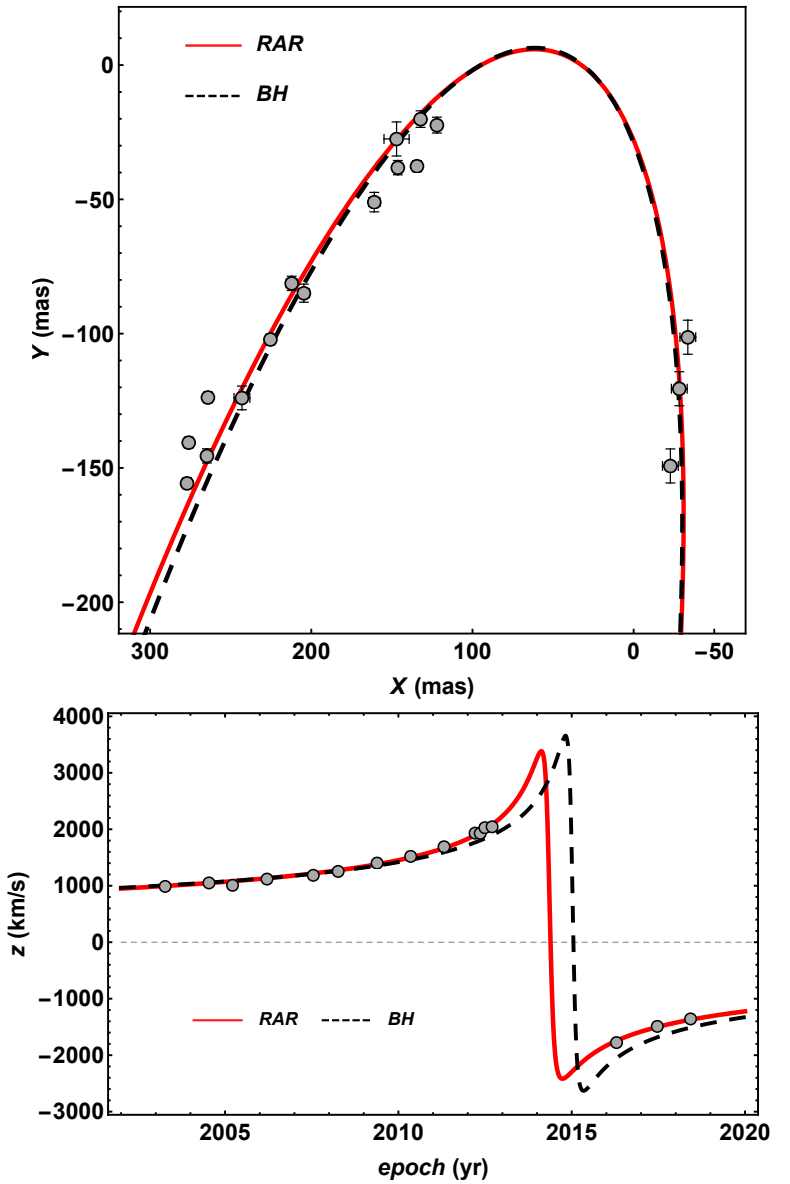

Fig. 5. Theoretical and observed orbit and line-of-sight radial velocity of G2 around Sgr A*. *Top panel*: shows the projected orbit on the sky, X (Right Ascension) vs. Y (Declination). *Bottom panel*: shows the redshift function z as a function of time. The theoretical models are calculated by solving the equations of motion of a test particle in the gravitational field of: (1) a Schwarzschild BH of $4.075 \times 10^6\,\mathrm{M}_\odot$ (*black dashed curve*), and (2) the DM distribution obtained from the extended RAR model for 56 keV fermions (*red curves*). The mass of the quantum core in the RAR model is $3.5 \times 10^6\,\mathrm{M}_\odot$. The observational data are taken from Refs. 17,18,22. Figure adapted from Ref. 15.

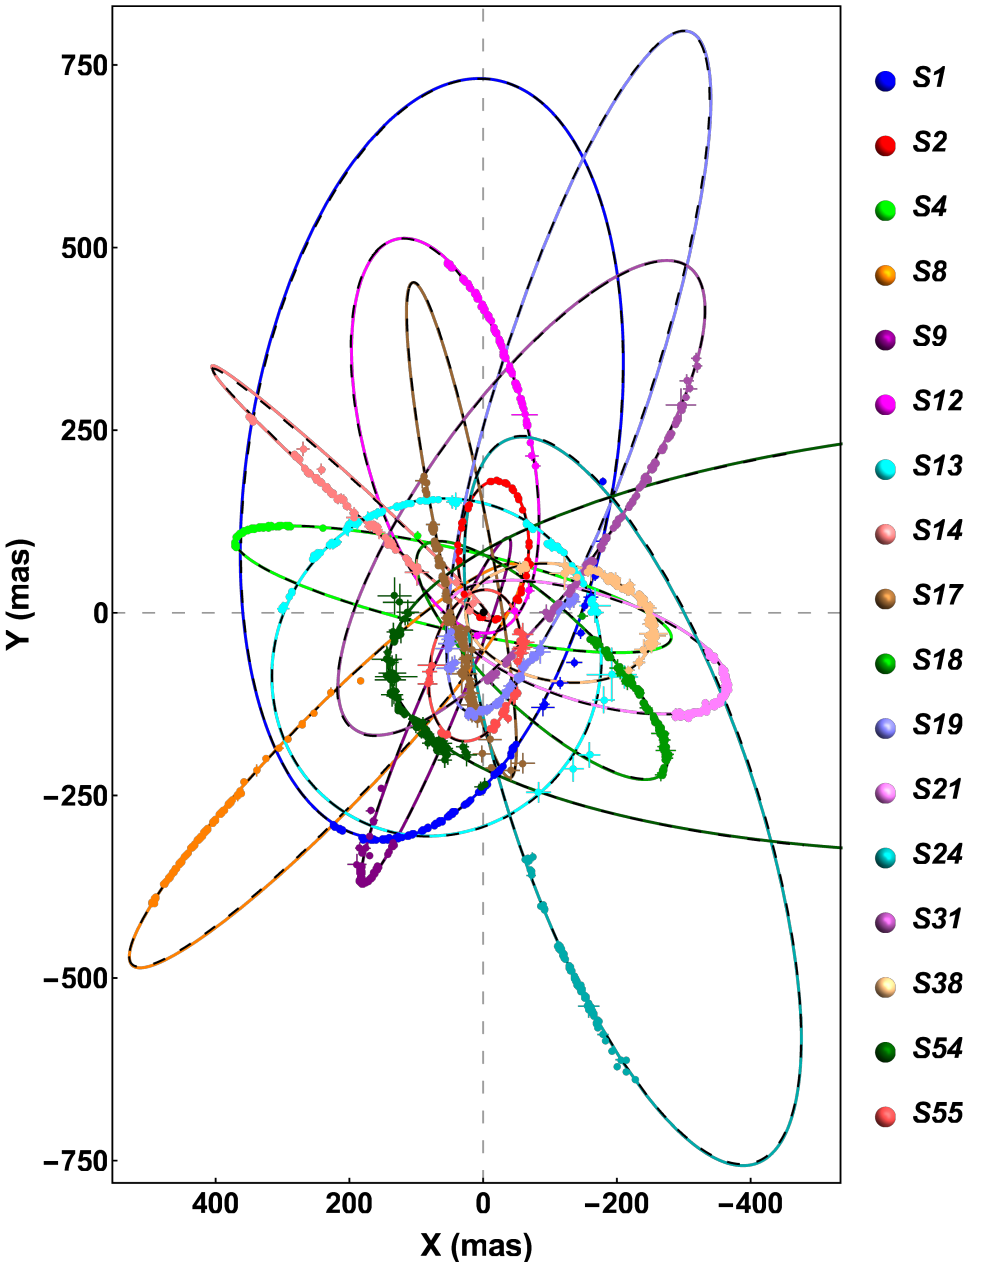

Fig. 6. Best-fit orbits for the 17 best-resolved S-star orbiting Sgr A*. It shows the projected orbit on the sky, X vs. Y, where X is right ascension and Y is declination. The *black dashed curves* correspond to the BH model and the *colored curves* to the RAR model for $m \approx 56$ keV fermions. The astrometric data was taken from Refs. 21, 23, 24. Figure taken from Ref. 16.

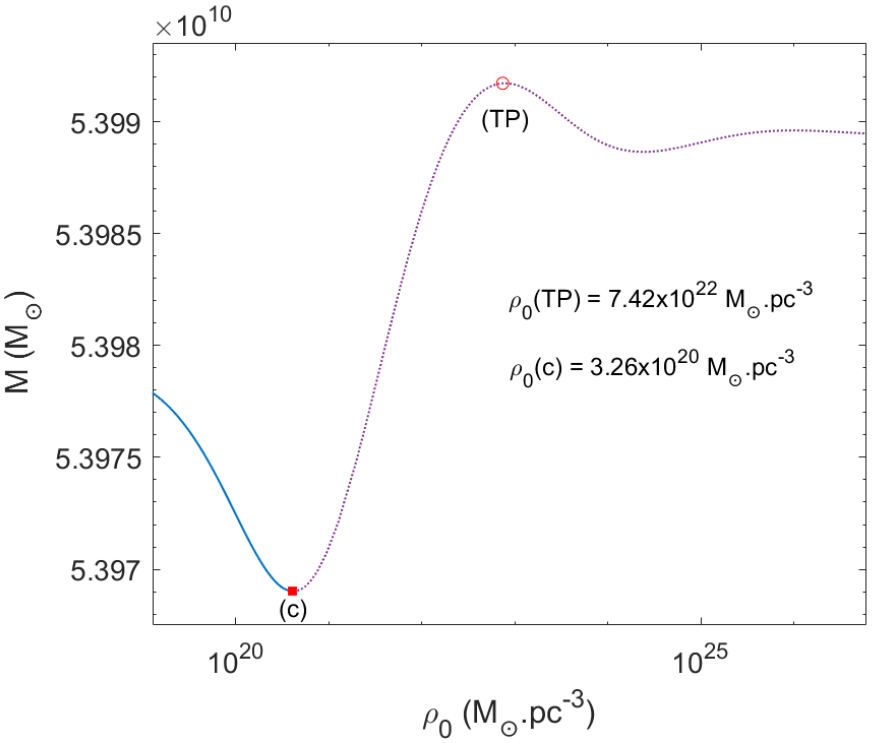

Fig. 7. Series of equilibrium states with $N > N_{\rm OV}$ are shown along a ρ_0 vs. M curve, in correspondence with the caloric curve of Fig. 1. The last stable configuration at the onset of the core-collapse occurs at the minimum of this curve and *prior* to the turning point instability (corresponding with point (c) in Fig. 1). Such a critical solution has a critical core mass $M_c^{\rm cr} \approx 2 \times 10^8 M_\odot$, and thus a forming a SMBH from DM core-collapse. Figure taken from Ref. 3.

that is, the last stable configuration at the onset of the core-collapse (point (c) in Fig. 1) correspond to a critical core mass $M_c^{\rm cr} = 2.17 \times 10^8 M_\odot$, and thus a forming a SMBH from DM core-collapse (see Ref. 3 for more details). This is an interesting number, since the majority of the SMBHs are comprised within $\sim 10^8 M_\odot$,[26] in some way separating active from non-active galaxies. Moreover, the relevance of such a DM core-collapse scenario, is that it can occur within the high $z \sim 10$ Universe when such halos start to form, without the need of prior star formation or any BH seed mechanisms involving (likely unrealistic) super-Eddington accretion rates. This may provide the long-sought solution to the problem of SMBH formation in the early Universe, which deserves further detailed investigations.

Such a critical value triggering core-collapse can be written in a more familiar way in terms of the Planck mass m_{pl} and the fermion mass m as $N_{\rm OV} \approx 0.398\, m_{pl}^3/m^3$, corresponding to a critical (total) mass $M_{\rm OV} \approx 0.384\, m_{pl}^3/m^2$ which for $m \approx 50$ keV yields $M_{\rm OV} \sim 10^8 M_\odot$. Therefore, equilibrium configurations of fermions at finite T_∞ with $M_{\rm vir} < 10^8 M_\odot$ can not undergo core-collapse towards a

SMBH within the present scenario. Indeed, the caloric curves in such cases never develop a last-stable solution (like (c) in Fig. 1), nor the second spiral of relativistic origin as shown in Ref. 3.

The above numbers imply another intriguing consequence for this new theory: the critical mass for collapse into a massive BH can not be reached for smaller DM halos, for example those surrounding typical dwarf galaxies with $M_{\rm vir} \lesssim 10^8 M_\odot$. Instead, this $\hat{N} < \hat{N}_{\rm OV}$ scenario would leave smaller dwarf galaxies with a central DM nucleus with a mass typically of $M_c \sim 10^5 M_\odot$ (or less) as shown in Ref. 11, thus offering a natural explanation for the so called 'intermediate-mass BHs'. Such a DM quantum-core can still mimic the gravitational signatures of a central BH, whilst the dark matter outer halo could also explain the observed galaxy rotation curves.[11]

4. Conclusions

We have shown that mechanisms of DM halo formation based on entropy maximization in which the quantum (fermionic) nature of the particles is accounted for, may provide answers to crucial open problems in cosmology. In particular they allow: to constraint the mass of the DM particles, to provide a novel mechanisms of supermassive BH formation from DM core-collapse, to understand the nature of the intermediate mass black holes in small halos, and to provide a solution to the *core-cusp* problem.

The approach applied here (and detailed in[3]) for DM halo formation in terms of self-gravitating fermions is self-consistent: the nature and mass of the DM particle involved in the linear matter power spectrum calculations (as obtained in Ref. 3 within a CLASS code for WDM cosmology of $\mathcal{O}(10)$ keV), are the same building blocks at the basis of virialized DM configurations with its inherent effects in the *core-halo* profiles. Importantly, such a fermion mass would produce the same ΛCDM power-spectrum on scales down to $\mathcal{O}$(Mpc), hence providing the expected large-scale structure (see Appendix B in Ref. 3). Moreover, for such typical fermion masses the number of sub-halos in the corresponding WDM cosmology is not in tension with the number of Milky Way satellites,[27] while being consistent with Lyman-α forest observations.[28] Another relevant consequence is that the maximum entropy approach for structure formation applying here for $\mathcal{O}(10)$ keV particles, can naturally avoid the so called 'catch-22' tension arising for fermionic halos within (N-body simulation-based) WDM cosmologies.[29] That is, the resulting fermionic profiles within our approach allow for 'cored' density profiles in dwarfs with right sizes and masses, and at the same time in agreement with Lyman-α bounds.[11]

To conclude, we believe the results shown here open new insights in the formation and stability of DM halos. Moreover, the quantum degenerate core at the center of the stable DM configurations, and its eventual core-collapse, may play crucial roles in helping to understand the formation of SMBHs in the early Universe, or in mimicking its effects without the need of a singularity at all. The astrophysical

consequences of the analysis here shown for $\mathcal{O}(10)$ keV — together with the recent results in Refs. 3, 10, 11, 15 — strongly suggest that such DM *core-halo* morphology are a very plausible scenario within the late stages of non-linear structure formation.

First results of LHAASO

Ruo-Yu Liu* for the LHAASO Collaboration
School of Astronomy and Space Science, Nanjing University, Nanjing, 210023, China
**E-mail: ryliu@nju.edu.cn*

The Large High Altitude Air Shower Observatory (LHAASO) has recently published the first results, including the discovery of 12 ultrahigh-energy gamma-ray sources (with emission above 100 TeV) above 7σ confidence level and a detailed analysis of Crab Nebula. This contribution gives a brief introduction to the LHAASO experiment and its recent discoveries.

Keywords: Gamma rays; Cosmic rays; Pulsar Wind Nebula

1. Introduction

The Large High Altitude Air Shower Observatory (LHAASO) is one of the key national science and technology infrastructure facilities of China, located in Mt. Haizi (29°21'27.6" N, 100°08'19.6" E, 4410 m above the sea level), Sichuan Province of China. It is a new generation instrument aiming for a deep investigation of the so-called "non-themral Universe'' at extreme energies. The observatory consists of three detectors: the Water Cherenkov Detector Array (WCDA) for gamma rays in 0.5 – 10 TeV, the Kilometer Square Array (KM2A) for gamma rays in 10 TeV – 1 PeV, and the Wide Field Chenrenkov Telescope Array (WFCTA) for cosmic rays from 1 TeV – 1 EeV.

KM2A comprises an array of 5195 electron detectors (ED) made by scintillation tiles, and an array of 1188 underground muon detectors (MD) each of which is a pure water Cherenkov detector enclosed within a cylindrical concrete tank. Both arrays cover an area of 1 km^2 with an additional 0.3 km^2 skirt array used to identify showers falling outside the central region. Once charged particles in an air shower enter an ED, they lose energy and excite the scintillation medium to produce a large amount of scintillation photons, which will be recorded by photomultiplier tubes and used to determine the number of electromagnetic particles N_e in a shower. Each MD is enveloped by a steel lid underneath soil. The thickness of the overburden soil is 2.5 m to absorb the secondary electrons/positrons and gamma rays in showers. Thus particles that can reach the water inside and produce Cherenkov signals are almost exclusively muons, although a few very energetic electrons/positrons or gamma rays in the central part of showers may have a chance to penetrate through the screening soil layer. To reduce the possible pollution from the high energy electromagnetic particles near the shower core, only MDs with a distance farther than 15 m from the core are used to count the number of muons N_μ in a shower.

Each air shower event is composed of many ED and MD hits with timing and charge information. In the reconstruction of primary particle event, only the ED hits are used for direction, core location, and energy reconstruction. Both ED hits and MD hits are used for composition discrimination. Gamma-ray-induced showers are muon-poor while cosmic-ray-induced showers are muon-rich. Therefore, the ratio between the measured muons and electrons can be used to discriminate primary gamma rays from cosmic protons/nuclei, which is defined as

$$R = \log\left(\frac{N_\mu + 0.0001}{N_e}\right). \tag{1}$$

0.0001 in the numerator is used to show the case with zero muon. Generally, a simple cut on the parameter R is used in the discrimination, where the detailed value of R depends on the energy of the reconstructed event and can be adjusted to maximize the detection efficiency.[1] This process is extremely important for the gamma ray detection because cosmic rays constitute the majority of the recorded events by KM2A and become a background for the gamma-ray observations. The rejection power of KM2A can be better than 10^4 above 100 TeV (i.e., reduce the background cosmic-ray flux by a factor higher than 10^4). The large collective area and the high rejection power make LHAASO the most sensitive detector for ultrahigh-energy (UHE) gamma rays with energy above 100 TeV.

Detection of UHE gamma-ray emission is crucial to understand the origin of Galactic cosmic rays. The measured cosmic-ray spectrum roughly maintains a power-law behaviour up to about 1 PeV. After that it shows a spectral break feature known as the "knee". This indicates the existence of astrophysical objects in our Galaxy capable of accelerating protons up to at least PeV energies (which is also known as proton "PeVatrons"). When these high-energy protons interact with matter inside or close to the accelerators, neutral pions are generated, which further decay into gamma-ray photons. These gamma-ray emission reveal the location of the cosmic-ray accelerators. Since each produced photon takes about 10% of the energy of the parent proton, we need to search for UHE gamma-ray sources in order to find out PeV cosmic-ray sources. In the rest of this artcile, we will introduce the first results of LHAASO, which are mainly based on[2] and.[3]

2. Discovery of 12 Ultrahigh-energy Gamma-ray Sources

The first results of LHAASO are mainly discovered by the half KM2A during the operation of 11 months in the year 2020. By reconstructing showers with zenith angle $< 50°$, we have detected 12 sources with emission above 100 TeV at the statistical significance exceeding 7σ level and the basic information of the sources are listed in Table. 1. All of these sources are located in the Galactic plane and hence very likely Galactic sources. Most of them show extended spatial structures with angular extensions up to 1°. Generally, there are multiple astrophysical objects proposed as potential PeVatron candidates in spatial association with these sources.

Table 1. UHE γ-ray sources. The celestial coordinates (R.A.,dec), the statistical significance of detection above 100 TeV (using a point-like template for the Crab Nebula and LHAASO J2108+5157 and 0.3° extension templates for other sources) are shown together with the corresponding differential photon fluxes at 100 TeV in unit of the Crab flux (1 CU=6.1×10^{-17} photons TeV^{-1} cm^{-2} s^{-1}) and the detected highest photon energies.

Source Name	R.A. (°)	dec (°)	Significance (σ) above 100 TeV	E_{Max} (PeV)	Flux (± error) (CU) at 100 TeV
LHAASO J0534+2202	83.55	22.05	17.8	0.88 ±0.11	1.00(0.14)
LHAASO J1825-1326	276.45	-13.45	16.4	0.42 ±0.16	3.57(0.52)
LHAASO J1839-0545	279.95	-5.75	7.7	0.21 ±0.05	0.70(0.18)
LHAASO J1843-0338	280.75	-3.65	8.5	$0.26\ ^{+0.16}_{-0.10}$	0.73(0.17)
LHAASO J1849-0003	282.35	-0.05	10.4	0.35 ±0.07	0.74(0.15)
LHAASO J1908+0621	287.05	6.35	17.2	0.44 ±0.05	1.36(0.18)
LHAASO J1929+1745	292.25	17.75	7.4	$0.71\ ^{+0.16}_{-0.07}$	0.38(0.09)
LHAASO J1956+2845	299.05	28.75	7.4	0.42 ±0.03	0.41(0.09)
LHAASO J2018+3651	304.75	36.85	10.4	0.27 ±0.02	0.50(0.10)
LHAASO J2032+4102	308.05	41.05	10.5	1.42 ±0.13	0.54(0.10)
LHAASO J2108+5157	317.15	51.95	8.3	0.43 ±0.05	0.38(0.09)
LHAASO J2226+6057	336.75	60.95	13.6	0.57 ±0.19	1.05(0.16)

Among these astrophysical objects, most of them are supernova remnants, pulsar wind nebulae and young massive star clusters.

The top-three brightest sources at 100 TeV are LHAASO J1825-1326, LHAASO J1908+0621 and LHAASO J2226+6057. The regions of the three sources have been extensively studied in the previous literature (e.g.,[4–27]). All of them are associated with both energetic pulsars and supernova remnants. Dense molecular clouds also appear in their region. LHAASO's observations extend their spectra up to several hundred TeV energies, demonstrating there exist efficient particle accelerators acting as PeV particle factories. The spectra present gradual softening towards high energies. The log-parabola function can describe the spectra better than power-law function, as can be seen in Fig. 1. However, we cannot tell whether these multi-hundred-TeV gamma rays arise from the leptonic process such as the inverse Compton (IC) scattering of electrons, or hadronic process such as the proton-proton (pp) collisions, based on the present data. Deep observations of multiwavelength instruments are needed to elucidate their natures.

We'd like to highlight that the energy of the most energetic photons detected from these sources is 1.42 ± 0.13 PeV in association with the Cygnus Cocoon, which is a energetic gamma-ray emitter at GeV – TeV band. It has been proposed that Cygnus Cocoon is powered by the O/B star association, Cygnus OB2, possibly via collisions of the stellar winds.[28–30] LHAASO's discovery may be considered as the evidence of Cygnus OB2 as a proton PeVatron.

It is also worth mentioning that among the 12 detected sources, there is a new source, LHAASO J2108+5157, without association with any of the previously detected very-high-energy sources. The position of its gamma-ray emission is correlated with a giant molecular cloud, which makes the hadronic origin of the

gamma-ray emission possible. Detection of this source also implies that there could be much more new UHE gamma-ray sources hiding in our Galaxy than we previously expected. Future observations of LHAASO with longer exposure can hopefully discovered more UHE gamma-ray sources or PeVatron candidates. We stress that the 12 sources reported here are UHE gamma-ray sources with significant emission above 100 TeV. There are much more sources with significantly detected by KM2A above 20 TeV, such as LHAASO J0621+3755[31] and LHAASO J0341+5258.[32]

Note that the only point-like source discovered in this survey, i.e., LHAASO J0534+2202, which is also the only identified source, is the Crab Nebula. The highest-energy photon from Crab Nebula reaches 0.88 ± 0.11 PeV, demonstrating it as an electron PeVatron. We will show more detailed analysis on Crab Nebula in the next section.

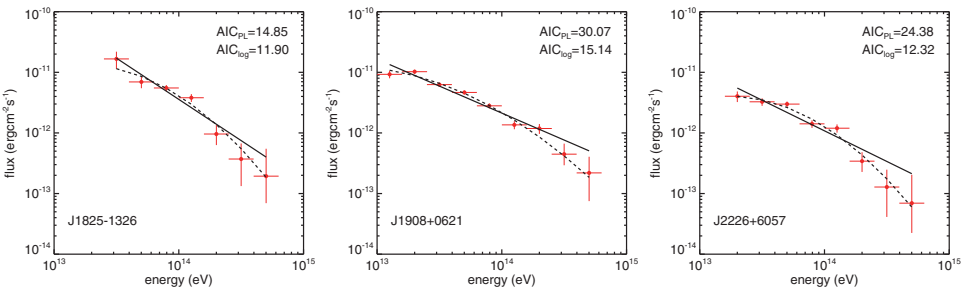

Fig. 1. The spectral energy distributions and significance maps of LHAASO J1825-1326 (panel a), LHAASO J1908+0621 (panel b), and LHAASO J2226+6057 (panel c) The spectral fits with a log-parabola function (solid lines) in the form of $(E/10\,\mathrm{TeV})^{[-a-b\log(E/10\mathrm{TeV})]}$ are compared with the power-law fits, $E^{-\Gamma}$: (a) $a = 0.92, b = 1.19$ vs $\Gamma = 3.36$; (b) $a = 2.27, b = 0.46$ vs $\Gamma = 2.89$, and (c) $a = 1.56, b = 0.88$ vs $\Gamma = 3.01$. The comparison of the two models with the Akaike Information Criterion[33] (AIC) gives: $\mathrm{AIC_{LOG}} = 11.6$ and $\mathrm{AIC_{PL}} = 14.8$ for LHAASO J1825-1326; $\mathrm{AIC_{LOG}} = 15.1$ and $\mathrm{AIC_{PL}} = 30.1$ for LHAASO J1908+0621; $\mathrm{AIC_{LOG}} = 12.3$ and $\mathrm{AIC_{PL}} = 24.4$ for LHAASO J2226+6057.

3. PeV Gamma rays from the Crab Nebula

The Crab Nebula was born from a supernova explosion occurring at Jul 4, 1054 A.D. It is the brightest pulsar wind nebula known so far, powered by the ultrarelativistic electron-positron wind launched by the Crab pulsar. It is a very important source in gamma-ray astronomy and considered as the standard candle. Previous observations revealed gamma-ray emission beyond 100 TeV.[34,35] LHAASO measured the spectrum of Crab Nebula in TeV – PeV range. The spectrum from 0.5 TeV to 13 TeV is measured using the WCDA pond, from September 2019 to October 2020. The KM2A data consists of that collected at the half array stage, which is the same as that used for the discovery of the twelve sources, and the data collected by three quarters of the array in about 3 months. The 0.88 PeV photon, as mentioned in the previous section, was detected on 11 January 2020. The shower of the event has

also triggered WCDA. Coincidently, the event occurred after local midnight and was recorded by WFCTA. The derived energy is $0.92^{+0.28}_{-0.20}$ PeV which is well consistent with that derived from KM2A's measurement, and demonstrates that LHAASO can cross check the results using multiple detection techniques, ensuring reliable and accurate results. In the stage of the 3/4 KM2A, the highest-energy photon detected from the Crab Nebula has an energy of 1.12 PeV, arriving at 4 January 2021. The spectrum between 0.5 TeV to 1.1 PeV can be described by a log-parabola function, where the local slope softens from 2.5 around 1 TeV to 3.7 around 1 PeV.

The gradual softening of the spectrum is consistent with the prediction of IC radiation of electrons where the Klein-Nishina effect operates at the highest energies and softens the spectrum. For gamma-ray emission above 100 TeV, cosmic microwave background is the dominant target radiation field for the IC radiation. The relation between the average energy of upscattered IC photons (from 2.7K CMB) and the energy of the parent electrons can be given by

$$E_{\rm e} \simeq 2.15(E_\gamma/1\ {\rm PeV})^{0.77}\ {\rm PeV}\ . \tag{2}$$

To account for 1.1 PeV photon via the IC radiation of electrons, the energy of electron needs to be about 2.3 PeV. The acceleration rate of electrons can be given by $\dot{E}_e = \eta eBc$,[36] where η is the ratio of the projection of the electric field to the mean magnetic field. Its value cannot exceed unity under the classical electrodynamics and ideal magnetohydrodynamics, and can be also regarded as the acceleration efficiency. On the other hand, electrons will lose energy via the synchrotron radiation when it propagates in the magnetic field. The maximum energy of electrons is then is determined by the balance between the acceleration and the energy loss rates, i.e.,

$$E_{e,\rm max} = 5.8\eta^{-1/2}\,(B/100\mu{\rm G})^{-1/2}\ {\rm PeV} \tag{3}$$

On the other hand, in the framework of the standard one-zone model, fitting to the multiwavelength data from X-ray to PeV gamma-ray energies results in a magnetic field of $B = 112^{+15}_{-13}\,\mu$G, as shown in Fig. 2. According to the relation between E_γ and $E_{\rm e}$ given by Eq.(2), we find the electron acceleration in the Crab Nebula must proceed at an extreme efficiency

$$\eta = 0.16(B/112\mu{\rm G})(E_\gamma/1.1\ {\rm PeV})^{1.54}\ {\rm PeV}\ . \tag{4}$$

in the framework of the standard one-zone model. For comparison, at the diffusive shock acceleration in young supernova remnants,[37] η is smaller by at least 3 orders of magnitude.

Note that although the standard one-zone model can generally give an acceptable fit to the overall spectrum of the Crab Nebula, the presence of the intense flare at MeV/GeV band (also known as "Crab flare",[40,41]) implies fast acceleration and synchrotron cooling of sub-PeV/PeV electrons in compact (with size < 0.01 pc) highly magnetized (with $B \gtrsim 1$ mG) regions inside the nebula, and is thus inconsistent with the standard one-zone picture. Actually, in the spectral fitting of the KM2A data in the standard one-zone scenario, we find that the one-zone model does not agree very well with the measured flux in the energy range of $60-500$ TeV,

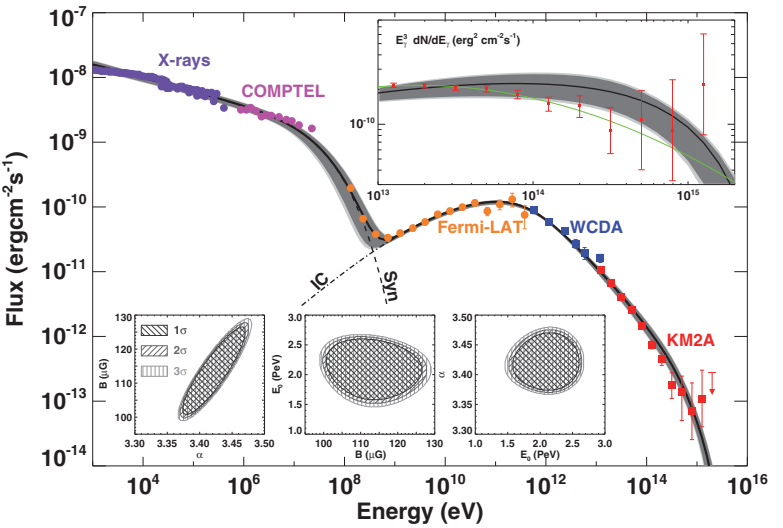

Fig. 2. **The Spectral Energy Distribution of the Crab Nebula.** The black curves represent the fluxes of the Synchrotron and IC components of radiation of an electron population calculated within the one-zone model. The electron spectrum above 1 TeV is assumed to be a power-law function terminated by an super-exponential cutoff, $E^{-\alpha}\exp[-(E/E_0)^2]$. The model's best fit parameters are: $\alpha = 3.42 \pm 0.05$, $E_0 = 2.15^{+0.55}_{-0.65}$ PeV, $B = 112^{+15}_{-13}\,\mu$G. The total energy in electrons above 1 TeV is $W_e = 7.7 \times 10^{47}$ erg. A break in the electron spectrum at $E_b = 0.76$ TeV is assumed to provide a consistency with the GeV γ-ray and low-frequency synchrotron data. The dark-grey and light-grey shaded regions show the 1σ and 3σ error bands, respectively. The insets in the bottom exhibit the 2-dimensional projected parameter spaces of the free parameters α, B and E_0. The green curve presents the log-parabola spectral fitting. The purple and the magenta circles show the X-ray and the MeV emission of the Crab Nebula.[38] The orange circles represent the Crab observations by Fermi-LAT in the non-flare state.[39] The blue and red squares represent WCDA and KM2A measurements reported in.[3] The inserted figure in the top right corner zooms the fluxes above 10 TeV in the presentation of $E^3\mathrm{d}N/\mathrm{d}E$.

nor it reproduces the spectral hardening above 500 TeV although the latter is not statistically sound at the present time. The fitting can be ameliorated by introducing a second spectral component, either produced by an extra population of PeV electrons or protons, which are accelerated presumably in different sites by different mechanisms. Based on the present observation, we expect that the full LHAASO array can detect $1-2$ PeV photons from the Crab Nebula per year. Hopefully, we can accumulate sufficient statistics to clarify whether such a spectral hardening truly exists in 2 years.

4. Conclusion

LHAASO is a dual-purpose complex of particle detectors for the measurements of gamma rays in sub-TeV to PeV energy range and cosmic rays in TeV to EeV energy range. It is designed to be operating continuously and steadily for many years in order to accumulate a large data sets. The first results of LHAASO introduced here are probably only the tip of the iceberg, but they demonstrate LHAASO's potential

to provide a deep insight into the mystery of cosmic-ray origin and related physics, especially when combined with the multiwavelength data of other instruments. The full LHAASO array has started to collect data since the end of July 2021. We anticipate more interesting discoveries by LHAASO in the coming years.

On Monday July 5, 2021 took place the official ceremony for the attribution of the 4 MG16 Individual Awards to Demetrios Christodoulou, Gerard 't Hooft, Tsvi Piran and Steven Weinberg, as well as for the attribution of the 3 MG16 Institutional Awards to the Spektrum-Roentgen-Gamma (SRG) mission of the Max Planck Institute for Extraterrestrial Physics (MPE), of the Space Research Institute (IKI) of the Russian Academy of Sciences and of the S.A. Lavochkin Association. The MG Awards consist in a silver casting of the TEST sculpture by the artist Attilio Pierelli. The MG16 Awards were presented to the Awardees by Prof. Roy P. Kerr.

Keywords: Black Holes; mass energy formula; Horizons; International scientific cooperation; Scientific space missions

1. The MG Awards

Since 1985, the MG Awards have been attributed on the occasion of the Marcel Grossmann meetings. The MG Award consist in a silver casting of the TEST sculpture by the artist Attilio Pierelli.

On the occasion of the MG4 meeting (July 1985, Rome, Italy) the Institutional Award went to the Vatican Observatory (presented to His Holiness Pope John Paul II), while the Individual Awards went to William Fairbank and to Abdus Salam. On the occasion of the MG5 meeting (August 1988, Perth, Australia) the Institutional Award went to the University of Western Australia (presented to the then Vice Chancellor, Prof. Robert Smith) while the Individual Awards went to Satio Hayakawa and to John Archibal Wheeler. On the occasion of the MG6 meeting (June 1991, Kyoto, Japan) the Institutional Award went to the RITP (presented to Prof. K. Tomita) while the Individual Awards went to Minoru Oda and to Stephen Hawking. On the occasion of the MG7 meeting (June 1994, Stanford, USA) the

Institutional Award went to the Space Telescope Institute (presented to Prof. Peter Stockman) while the Individual Awards went to Subrahmanyan Chandrasekhar and to Jim Wilson. On the occasion of the MG8 meeting (June 1997, Jerusalem) the Institutional Award went to the Hebrew University (presented to the then President M. Magidor), while the Individual Awards went to Tullio Regge and to Francis Everitt. On the occasion of the MG9 meeting (July 2000, Rome, Italy) the Institutional Award went to the Solvay Institutes (presented to Jacques Solvay), while the Individual Awards went to Cecile and Bryce Dewitt, Riccardo Giacconi and Roger Penrose. On the occasion of the MG10 meeting (July 2003, Rio de Janeiro, Brazil) the Institutional Award went to the Brazilian Center for Research in Physics - CBPF (presented to its founders Cesar Lattes, Josè Leite Lopez and Jayme Tiomno), while the Individual Awards went to Yvonne Choquet-Bruhat, to James W. York, Jr and to Yuval Ne'eman. On the occasion of the MG11 meeting (July 2006, Berlin, Germany) the Institutional Award went to the Freie Universitaet Berlin (presented to the then President Dr. Dieter Lenzen), while the Individual Awards went to Roy Kerr, George Coyne and Joachim Trumper. On the occasion of the MG12 meeting (July 2009, Paris, France) the Institutional Award went to the Institut des hautes études scientifiques - IHES (presented to Prof. Jean-Pierre Bourguignon), while the Individual Awards went to Jaan Einasto, to Christine Jones and to Michael Kramer. On the occasion of the MG13 meeting (July 2012, Stockholm, Sweden) the Institutional Award went to Albanova (presented to the Rector of the f Stockholm University, Prof. Kåre Bremer), while the Individual Awards went to David Arnett, to Vladimir Belinski and I. M. Khalatnikov and to Filippo Frontera. On the occasion of the MG14 meeting (July 2015, Rome, Italy) the Institutional Award went to the European Space Agency - ESA (presented to its Director General Johann-Dietrich Woerner), while the Individual Awards went to Ken'ichi Nomoto, to Martin Rees, to Yakov G. Sinai and to Sachiko Tsuruta. The 2 additional MG14 Individual Awards to Frank C.N. Yang and to T.D. Lee have been delivered on the occasion of the International Conference on Gravitation and Cosmology/the fourth Galileo-Xu Guangqi meeting in Beijing on May 4, 2015. On the occasion of the MG15 meeting (July 2018, Rome, Italy) the Institutional Award went to the Planck scientific collaboration - ESA (presented to the Principal Investigator of the High Frequency Instrument (HFI) Jean-Loup Puget) and to the Hansen experimental physics laboratory at Stanford University (presented to its Assistant Director Leo Hollberg), while the Individual Awards went to Lyman Page, to Rashid Sunyaev and to Shing-Tung Yau.

2. MG16 Individual Awardees

The MG16 Individual Awards went to Demetrios Christodoulou, Gerard 't Hooft, Tsvi Piran and Steven Weinberg.

2.1. *Demetrios Christodoulou*

Motivation: Professor **Demetrios Christodoulou** received the MG16 Award *"For his many lasting contributions to the foundation of mathematical physics including the dynamics of relativistic gravitational fields. Notably for: contributing in 1971, at the age of 19, to derive with Remo Ruffini the mass-energy formula of black holes as a function of their angular momentum, charge and irreducible mass. Christodoulou turned then to the study of partial differential equations and mathematical physics, to which he remained dedicated for the rest of his career. Highlights in this area include the theoretical discovery of the nonlinear memory effect of gravitational waves (Phys. Rev. Letters 1991), the monograph (1993) in collaboration with Sergiu Klainerman on the global nonlinear stability of the Minkowski spacetime, the monograph (2009) on the formation of black holes in pure general relativity by imploding gravitational waves, and the monographs (2007 and 2019) on the formation and further development of shocks in fluids."*

Scientific and historical background: It was back in 1967 that Achille Papapetrou mentioned the case of the 16 year old Demetrios Christodoulou to John Archibad Wheeler. Wheeler interviewed Demetrios in Paris and brought him immediately to Princeton where he was registered as an undergraduate at the university. After only one year he entered the graduate school and started collaborating with me. At the time I was working with Wheeler on the effective potential approach

to co-rotating and counter-rotating geodesics (see e.g. reference in The Classical Theory of Fields (Landau and Lifshitz, 1980) in the Kerr metric (later renamed as ISCO; see e.g. (Gravitation Misner, Thorne, Wheeler. 1973). In parallel, Frank Zerilli was working on the gravitational radiation emitted by a test particle falling into a Schwarzschild black hole (Zerilli 1970). From this limited conceptual arena Charles Misner and later Kip Thorne launched a program for the detection of gravitational waves on the Earth; see e.g. Misner 1974, Abbott et al. 2016, Abbott et al. 2017; see however Davis et al. 1972, Rodriguez et al. 2018 and J.A. Rueda et al. 2018. A new approach started with the arrival of Demetrios: he was just creating mathematics following his needs. We identified the reversible and irreversible transformations of a Kerr black hole. Wheeler advanced a thermodynamic analogy. I addressed the need to identify the concept of irreducible mass (from the Italian "irriducibile"), and was Demetrios's contribution to integrate, overnight, the differential equation for infinitesimal reversible transformations which led to the finite mass-energy formula for a Kerr black hole. That evening, while walking back home through the IAS woods, I expressed to Wheeler the great relevance of the newly found formula by Demetrios and proposed to let Demetrios be the single author of this article, admiring his great mathematical talent. Wheeler agreed. The Editor of PRL objected since in that two page article Fig. 2 by Wheeler and myself was still unpublished. Actually that Fig. 2 followed a discussion I previously had had with Penrose in Florence (Penrose 1969) which allowed us to present the "Penrose process" there. Some difficulties in achieving this process were obvious from the example in Fig. 2, which Roger later recognized himself (Penrose & Floyd 1971). The Editor finally agreed to our written request and the paper appeared on Sep 17, 1970 (Christodoulou, 1970). In January 1971 my article with Johnny *Introducing the Black Hole* (Ruffini & Wheeler, 1971) appeared with the new physics we were developing in Princeton, including the concept of the "ergosphere". On March 1, 1971 we submitted an article giving the mass formula for the Kerr-Newman metric, including the relation between the surface area of the horizon and the irreducible mass (Christodoulou & Ruffini, 1971) . On March 11, 1971 the same results were independently confirmed by Steven Hawking, extending further the applicability of our formula (Hawking 1971).

The thesis of Demetrios was successfully discussed by a committee including Eugene Wigner (see Fig. 1a), one of the closest collaborators of Albert Einstein and David Wilkinson (See Fig. 1b), the head of the NASA WMAP mission and Johnny and myself as supervisors. The new message was clear: black holes, far from being energy sinks, were energy sources able to emit "in principle" up to 50% of their mass energy as being extractable (Christodoulou & Ruffini, 1971).

Demetrios turned soon to the study of partial differential equations and mathematical physics, to which he dedicated for the rest of his career and results were published in four monographs: (Christodoulou and Klainerman 1994, Christodoulou 2007, Christodoulou 2009, Christodoulou 2019). In 1968, Johnny proposed to Demetrios the collapse of a "geon" composed of massless scalar field as a second

Fig. 1. Demetrios during his thesis presentation with Eugene Wigner (above) and David Wilkinson (below). Myself and Johnny were supervisors, ready to intervene in case of need, but no need of intervention was necessary! Wigner elaborated the aphorism of Niels Bohr "Interesting = wrong" in the most definite "very interesting, if true = totally wrong"

topic for his thesis. It took almost forty years for him to solve this problem, which he extended to the more difficult case of focusing gravitational waves leading to black hole formation (Christodoulou 2009).

A “long march” started on December 12, 1970 with the launch of the Uhuru satellite by Riccardo Giacconi. Early in 1971 an almost daily conversation with him and Herb Gursky at the Smithsonian Astrophysical Observatory led to the discovery of binary X-ray sources. This was soon followed by the announcement of Cygnus X1 identified as the first black hole in our galaxy (Ruffini 1973); see e.g. Gursky & Ruffini 1975 which also contained the first public announcement of the discovery of gamma ray bursts, as well as Giacconi & Ruffini 1980, 2009; see Fig. 2).

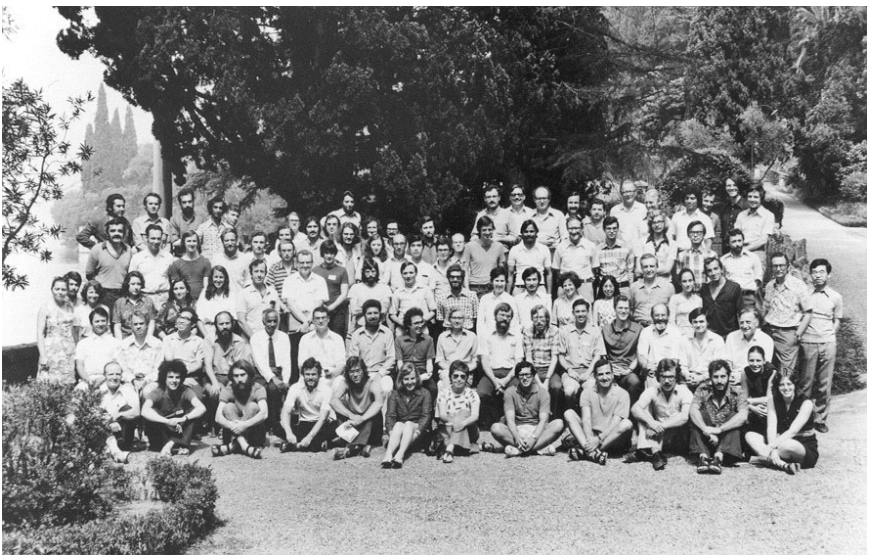

Fig. 2. In the second row, from left to right, there are, among others: E. T. Newman, S. Chandrasekhar, R. Giacconi, R. Ruffini, A. Treves, A. Hewish, D. Arnett, G. I. Taylor, J. Wilson, R. Penrose, as well as J. Bahcall, T. Damour, T. Piran et al.

Today, after fifty years this “long march” has reached a definite result: through the grandest observational multi-wavelength effort in the history of mankind, from space, ground and underground observatories, we are finally finding evidence that black holes are “alive” and their “extractable energy” in our mass formula (Christodoulou & Ruffini, 1971) is the energy source of the most energetic sources in our universe: gamma ray bursts (GRBs), active galactic nuclei (AGNs) as well as ultra-high energy cosmic rays (UHECRs) (Ruffini et al. 2021 and references therein). Their “inner engine” has three independent components: 1) a Kerr black hole which is neither in a stationary state nor in vacuum, 2) a background magnetic field aligned with the black hole rotation axis, and 3) an extremely diluted fully ionized plasma (Moradi et al. 2021). There is no role in this inner engine for ISCOs. Indeed new electrodynamical field equations describe the synchrotron radiation emitted close to the black hole horizon, and they point to a discrete and repetitive emission of “blackholic quanta” in the MeV and in the GeV. The magnitudes and the emission

time scales of these quanta, for M87 and GRB 130427A, are expressed as a function of the above three parameters (Rueda & Ruffini, 2021). A long lasting GeV emission with a luminosity decreasing as a temporal power law allows for the first time for GRBs the determination of the black hole mass and spin as well as their time evolution perfectly fulfilling our mass energy formula (Christodoulou & Ruffini, 1971): a long lasting emission process profoundly different from the traditional process of continued gravitational contraction.

2.2. *Gerard 't Hooft*

Motivation: Professor **Gerard 't Hooft** received the MG16 Individual Award *"for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon"*.

Scientific and historical background:Prof. Gerard 't Hooft has been a full Professor at the Utrecht University (the Netherlands), since 1977. Nowadays, he is an Emeritus Professor at that University. During his career, he has paid extended scientific visits to CERN (Geneva), Harvard, Stanford, Princeton and Duke University, NC. In 1999, together with M. Veltman, he received the Nobel Prize in Physics, awarded by The Royal Swedish Academy of Sciences, *"For elucidating the quantum structure of electroweak interactions in physics"*. Prof. 't Hooft main subjects of research includes:

- Gauge Theories for the sub-atomic particles and forces, various aspects and ingredients of what is now called "The Standard Model" of the sub-atomic particles: renormalizability, topological features such as magnetic monopoles and instantons, 1/N expansions,
- Theories for the quantization of the gravitational force and black holes: producing models for the quantum properties of a black hole, as derived from Standard Model and General Relativity alone; its topological features such as antipodal identification,
- Fundamental theories underlying quantum mechanics, in particular returning determinism and reality to the dynamics of the tiniest material entities in his universe, Prof. 't Hooft has been awarded the Wolf Prize of the State of Israel (1982), the Pius XI Medal (Vatican city, 1983), the Lorentz Medal (KNAW Amsterdam, 1986) as well as the Spinoza Premium (Netherlands Organization for Scientific Research NWO, 1995).

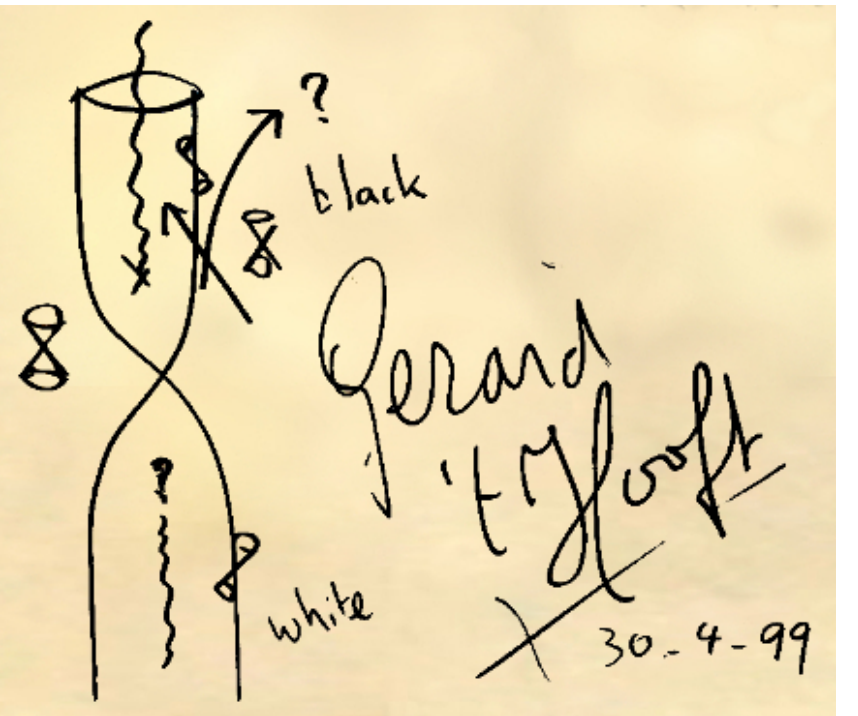

Fig. 3. The signature of Gerard 't Hooft on the wall of ICRA Room 301 (April 4, 1999).

A special event took place at ICRA on April 30, 1999. Prof. Ruffini invited Gerard 't Hooft to Rome to discuss a boundary condition for a quantum field on the black hole horizon, a topic Prof. Ruffini discussed in a previous article "Black-hole evaporation in the Klein-Sauter-Heisenberg-Euler formalism" with Thibault Damour

(Phys. Rev. D 14, 332, 1976), but which needed to be examined in more detail. Prof. Ruffini planned to direct Gerard's attention to some specific aspects of this problem. Because we have traditionally been very attentive in spending ICRA travel funds, ICRA offered Gerard to come to Rome on a reduced fare weekend ticket arriving Friday and departing Monday. He had a great relaxing weekend together with Prof. Ruffini following his seminar, which among other things allowed Gerard to sign the wall in our ICRA Room (see Fig. 3), and during this splendid Rome spring weekend he also was able to find a missing factor of 2 in a formula in Prof. Ruffini's 1971 paper with Demetri Christodoulou on the black hole mass formula. The following October, Gerard received the Nobel prize, which meant that we could no longer get away with bringing him to Rome on a cheap ticket! Ever since Gerard has been in our MG IOC helping us with the preparation of the meetings. We are very happy to announce this MG16 Award to Gerard 't Hooft with the motivating phrase "*for his persistent devotion to the study of the quantum field theory boundary conditions at the black hole horizon*".

2.3. *Tsvi Piran*

Motivation: Professor **Tsvi Piran** received the MG16 Individual Award *"for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory"*.

Scientific and historical background: Tsvi Piran is the emeritus Schwartzmann professor at the Hebrew University of Jerusalem. He obtained his PhD in

Physics, in 1976 from the Hebrew University working on the collisional Penrose process. Piran returned to the Hebrew University at 1981after being a post doc at Oxford and Texas and a long term member at the IAS at Princeton. In 1982 he initiated and directed the first ever summer school on Gravitational Waves that took place at Les Houches. Piran was a visiting professor at Harvard, Columbia and New York and a Moore scholar at Caltech. Piran's research deals with numerous aspects of relativistic astrophysics, ranging from the foundation of numerical relativity to modeling of observer relativistic phenomena and analytic work on the fate of gravitational collapse. Piran's research work focuses mostly on black holes and in particular on gamma-ray bursts. He was among the first to point out their cosmological origin and their association with merging neutron stars and heavy r-process nucleo synthesis. Piran's achievements were recognized in the 2019 EMET prize for Physics.

2.4. *Steven Weinberg*

Motivation: Professor **Steven Weinberg** received the MG16 Individual Award *"for unwavering support for the MG meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory"*.

Scientific and historical background: Steven Weinberg is a member of the Physics and Astronomy Departments at The University of Texas at Austin. His research has covered a broad range of topics in quantum field theory, elementary

particle physics and cosmology. He has been honored with numerous awards, including the Nobel Prize in Physics, the National Medal of Science, the Heinemann Prize in Mathematical Physics and in 2020, the Breakthrough Prize. He is a member of the US National Academy of Sciences, Britain's Royal Society, and other academies in the USA and abroad. The American Philosophical Society awarded him the Benjamin Franklin Medal, with a citation that said he is "considered by many to be the preeminent theoretical physicist alive in the world today." His books for physicists include *Gravitation and Cosmology*, the three-volume work *The Quantum Theory of Fields, Cosmology* and published in April of 2021, *Foundations of Modern Physics*. Educated at Cornell, Copenhagen, and Princeton, he also holds honorary degrees from sixteen other universities. He taught at Columbia, Berkeley, M.I.T., and Harvard, where he was Higgins Professor of Physics, before coming to Texas in 1982.

2.5. *Scientific and historical background for the Tsvi Piran and Steven Weinberg MG16 Awards*

The Sixteenth Marcel Grossmann Meeting (MG16) is a very special one in many respects: it will take place during a pandemic and in spite of the many difficulties, we have decided not to postpone it but to organize it as a virtual meeting. As described on the MG series webpage, these meetings started in 1975 with the first meeting at the International Centre for Theoretical Physics (ICTP) in Trieste (Italy) that I organized with Nobel Prize winner Abdus Salam. A second meeting followed in 1979, with a significantly larger participation including Nobel Laurate Cheng Ning Yang and a Chinese delegation led by Chuo Pei Yuan (see Fig. 4), including Fang Li-Zhi who had accompanied me during my entire first visit to China in 1979. The first truly international MG meeting followed in 1982 in Shanghai (China):this represented an especially important step forward both for the meeting and for China. A multi-millennia *"motto"* in China, which was then proclaimed on banners everywhere, read *"Friends from all over the world are welcomed"*.

We were soon at an impasse over the participation of scientists from Israel, since no diplomatic relations existed between China and Israel at that time and the Israeli scientists were not to be allowed to attend the meeting. A long negotiation began. The boundary conditions were clearly set by Steven Weinberg, a member of the present MG16 IOC: no MG meetings on Einstein's theory of general relativity could occur without the participation of Israeli scientists. The intervention of Yuval Ne'emann, also a member of the MG IOC then as well as the Minister of Science of Israel (see Fig. 5), proposed a compromise that would admit at least one Israeli scientist.

I went to Beijing alone, meeting every morning for a week with 12 Chinese representatives led by Chuo Pei Yuan going over all possible options. I stayed in an isolated villa not far from Tiananmen Square, accompanied by the 3 volumes of Matteo Ricci (RI MA TO) to keep me company. No solution was in sight the

Fig. 4. Chuo Pei Yuan and Cheng Ning Yang at MG2 in Trieste, Italy (1979).

entire week. At the last moment, just before my departure, an agreement was finally reached allowing two Israeli scientists into China. The historic compromise would admit Gerard Tauber and Tsvi Piran into China using a special ICRA travel document I had proposed for them to be able to participate in the meeting, accepted by the Chinese Ambassador in Rome. This modified the thousand year Chinese *"motto"* to read *"Scientists from all over the world are welcomed"*. The event was extremely beneficial for China and signaled the truly international nature of the MG meetings.

I kept on meeting Tauber in the years which followed (see Fig. 6). Soon after, Yuval Ne'emann visited China. The development of bilateral relations, including military cooperation and economical tights, grow exponentially until the establishment of normal diplomatic relations between Israel and China in 1992.

Given their key role played in the foundations of the MG meetings, I am very happy to propose on behalf of the MG16 IOC, two special Marcel Grossmann Individual Awards: one to Steven Weinberg for *"for unwavering support for the MG*

meetings since their inception, a true companion in the search for the deeper meaning of Einstein's great theory" and another one to Tsvi Piran, "*for extending Relativistic astrophysics across international frontiers, a true companion in the search for the deeper meaning of Einstein's great theory*", in the words of John A. Wheeler's photo dedication to myself (see Fig. 7).

3. MG16 Institutional Awardees

The MG16 Institutional Awards to the Spektrum-Roentgen-Gamma (SRG) mission *"for the creation of the world's best X-ray map of the entire sky, for the discovery of millions of previously unknown accreting supermassive black holes at cosmological redshifts, for the detection of X-rays from tens of thousands of galaxy clusters, filled mainly with dark matter, and for permitting the detailed investigation of the growth of the large-scale structure of the universe during the era of dark energy dominance"* went to the S.A. Lavochkin Association (presented to its Designer General Alexander Shirshakov), to the Max Planck Institute for Extraterrestrial Physics - MPE (presented to Professor Peter Predehl, Principal Investigator of eROSITA) and to the Space Research Institute (IKI) of the Russian Academy of Sciences (presented to Professor Rashid Sunyaev, Principal Investigator of SRG Observatory in Russia).

3.1. *S.A. Lavochkin Association*

The MG16 Institutional Award to the S.A. Lavochkin Association has been presented to its Designer General, **Alexander Shirshakov**.

S.A. Lavochkin Association created the Navigator space platform carrying German eRosita and Russian ART-XC X-Ray Telescopes, organized the launch of SRG Orbital X-Ray Observatory to the second Lagrangian point of the Sun-Earth system at a distance of 1.5 million km from the Earth and managed the observatory flight and the daily reception of its scientific data on Earth for 23.5 months.

Dr Alexander Shirshakov, Designer General of the S.A. Lavochkin Association, is specialized in design, manufacture, testing, launch and control of S/C for scientific purposes. Among those S/C launched, there are the *Radiostron* Astrophysical Observatory (2011) and the *Spektr-RG* space observatory (2019), while the planned S/C launches are *Luna-25* and *Exomars*.

Dr Shirshakov started his career in 1973, working as an engineer of the State Unitary Enterprise *NPO named by S.A. Lavochkin* in Khimki (Russian Federation). Starting from 1989 he has played multiple roles within the Lavochkin Association, been appointed head of the group, head of the sector, head of department, deputy head of the complex, head of the branch, director of the center, deputy head of the Design Bureau, deputy General Designer and deputy General Director.

Dr Shirshakov is an editorial board Member of the reviewed edition of *Vestnik of Lavochkin Association*. Since 2017, he is also member of the General Designer council. He has been awarded Honored Mechanical engineer of the Russian Federation as well as Agency-level award of the Russian Federal Space Agency.

3.2. *Max Planck Institute for Extraterrestrial Physics (MPE)*

The MG16 Institutional Award to the Max Planck Institute for Extraterrestrial Physics (MPE) has been presented to Professor Peter Predehl, the Principal Investigator of eROSITA.

eROSITA is the soft X-ray telescope on-board the Russian-German Spektr-RG mission which was successfully launched from Baikonur on July 13, 2019 and placed

in a halo orbit around the L2 point. 30 years after ROSAT, eROSITA performs an all-sky survey with an unprecedented sensitivity, spectral and angular resolution. Clusters of galaxies are the largest collapsed objects in the Universe. Their formation and evolution is dominated by gravity, i.e. Dark Matter, while their large scale distribution and number density depends on the geometry of the Universe, i.e. Dark Energy. X-ray observations of clusters of galaxies provide information on the rate of expansion of the Universe, the fraction of mass in visible matter, and the amplitude of primordial fluctuations which are the origin of clusters of galaxies and the whole structure of the universe. eROSITA has been designed to detect at least 100.000 clusters of galaxies and to detect systematically more than 3 Million obscured accreting Black Holes. eROSITA will also allow to study the physics of galactic X-ray source populations, like pre-main sequence stars, supernova remnants and X-ray binaries. The eROSITA telescope consists of seven identical Wolter-1 mirror modules. A novel detector system has been developed by MPE on the basis of the successful XMM-Newton pn-CCD technology. MPE is the scientific lead institute of eROSITA, responsible for the development of the instrument, the operation, the analysis software and data archive. Peter Predehl led this development as Principal Investigator of eROSITA and German lead scientist of the SRG mission for more than 15 years until the completion of the first of eight surveys in 2020. At this time eROSITA has already discovered more than 1 Million X-ray sources, more than all X-ray observatories of the last 50 years together. This demonstrates, that the design goals of the mission will easily be fulfilled.

3.3. *Space Research Institute (IKI) of the Russian Academy of Sciences*

The MG16 Institutional Award to the Space Research Institute (IKI) of the Russian Academy of Sciences has been presented to Professor Rashid Sunyaev, the Principal Investigator of SRG Observatory in Russia.

The Space Research Institute (IKI) of the Russian Academy of Sciences was responsible for developing the overall concept and scientific program of the SRG Orbital observatory and played a leading role in developing the ART-XC telescope and the entire SRG observatory as part of the Russian space science program carried out by Roskosmos Corporation in the interests of the Russian Academy of Sciences.

During the flight to the L2 point of the Sun-Earth system, SRG with German (eRosita) and Russian (ART-XC named after Mikhail Pavlinsky) X-Ray Telescopes aboard performed calibrations and long duration Performance Verification observations of a dozen of targets and deep fields. Starting in the middle of December 2019, the SRG scanned the whole sky three times. During these scans, SRG discovered two million point X-Ray sources: mainly quasars, stars with hot and bright coronae, and more than 30 thousand clusters of galaxies. There is a competition and synergy in the search for clusters of galaxies between SRG and the ground-based Atacama Cosmology and South Pole Telescopes, which are searching for clusters of galaxies in microwave spectral band using Sunyaev-Zeldovich effect.

SRG provided the X-Ray map of the whole sky in hard and soft bands, the last is now the best among existing. The huge samples of the X-ray selected quasars at the redshifts up to z=6.2 and clusters of galaxies will be used for well-known cosmological tests and detailed study of the growth of the large scale structure of the Universe during and after reionization.

SRG/eRosita is discovering every day several extragalactic objects which increased or decreased their brightness more than 10 times during half of the year after the previous scan of the same one-degree wide strip on the sky. A significant part of these objects has observational properties similar to the Events of Tidal Disruption of a star orbiting in the vicinity of the supermassive black hole. ART-XC discovered a lot of bright galactic and extragalactic transients.

Rashid Sunyaev is the Principal Investigator of SRG mission in Russia, director-emeritus of the Max-Planck Institute for Astrophysics and Maureen and John Hendricks distinguished visiting professor of the Institute for Advanced Study, Princeton.

Following the GRB 170817A prompt emission lasting a fraction of a second, 10^8 s of data in the X-rays, optical, and radio wavelengths have been acquired. We here present a model that fits the spectra, flux, and time variability of all these emissions, based on the thermal and synchrotron cooling of the expanding matter ejected in a binary white dwarf merger. The $10^{-3} M_\odot$ of ejecta, expanding at velocities of $10^9\,\mathrm{cm\,s^{-1}}$, are powered by the newborn massive, fast rotating, magnetized white dwarf with a mass of $1.3 M_\odot$, a rotation period of $\gtrsim 12$ s, and a dipole magnetic field $\sim 10^{10}$ G, born in the merger of a $1.0 + 0.8 M_\odot$ white dwarf binary. Therefore, the long-lasting mystery of the GRB 170817A nature is solved by the merger of a white dwarf binary that also explains the prompt emission energetics.

Keywords: Gamma-ray bursts; white dwarfs; white dwarf mergers.

1. Introduction

GRB 170817A is a short gamma-ray burst (GRB) whose prompt emission lasts less than a second, as was detected by the gamma-ray burst monitor (GBM) onboard

*Based on a talk presented at the Sixteenth Marcel Grossmann Meeting on Recent Developments in Theoretical and Experimental General Relativity, Astrophysics and Relativistic Field Theories, online, July 2021.

the NASA Fermi Gamma-ray Space Satellite,[1,2] and confirmed by *INTEGRAL*.[3] It was subsequently associated with GW170817, a gravitational wave signal reported by the LIGO/Virgo Collaboration about 40 min after the Fermi-GBM circular.[4] These initial data were then associated with the optical-infrared-ultraviolet source AT 2017gfo, which started to be observed about 12 h ($\approx 4 \times 10^4$ s) after the GRB trigger.[5–8] Further data of GRB 170817A have been in the mean time acquired in the X-rays and in the radio from 10^6 s after the GRB trigger, and still ongoing.

It has been well established that short GRBs are produced by neutron star binary (NS-NS) mergers.[9–11] Therefore, it is not surprising that GRB 170817A was labeled as such from the very beginning,[1,4,12] despite the fact that it had been soon recognized that GRB 170817A was observationally very different from typical short GRBs.[2] Indeed, a comparison of GRB 170817A in the gamma-rays, X-rays and in the optical with typical short GRBs led[13] to suggest that GRB 170817A looks more like a white dwarf binary (WD-WD) merger rather than an abnormal, special or unique NS-NS merger.[14] Identified additional sources similar to GRB 170817A and have proposed an alternative interpretation of them as WD-WD mergers.

In the mean time, 10^8 s of data of GRB 170817A have been acquired in the X-rays, in the optical, and in the radio wavelengths, besides just the MeV radiation of the prompt emission. These observations have indeed led to alternative explanations. In fact

- The NS-NS merger interprets the associated optical counterpart AT 2017gfo as a nuclear *kilonova* produced by the decay of r-process, which yields in the matter ejected in the merger.[5–8]
- The experimental confirmation of the nuclear *kilonova* needs a univocal spectroscopic identification of the atomic species present in the ejecta.[15–19] This has not been achievable in view of lack of available accurate models of atomic spectra, the nuclear reaction network, density profile, and details of the radiative transport (opacity). Other mechanisms can also explain the photometric properties of AT 2017gfo, for instance the cooling of the expanding ejecta of a WD-WD merger.[13,20] We will further elaborate this scenario in this paper.
- The NS-NS merger leading to a jet propagating throughout the ejected matter appears in conflict with recent data by the *Chandra* X-ray Telescope at 10^7–10^8 s after the GRB trigger.[21,22]

In view of all the above, we here explore further and extend the suggestion by Ref. 13 of GRB 170817A being the product of a WD-WD merger, adding new observations all the way up to 10^8 s.

- The possibly observed re-brightening in the X-ray afterglow of GRB 170817A at 1000 days agrees with the predicted appearance of the pulsar-like activity of the newborn WD from a WD-WD merger.[13,20]

- The rate of GRB 170817A-like events is well explained by the rate of WD-WD mergers.[13,20]
- Interestingly, the host galaxy of GRB 170817, NGC 4993 distant at about 40 Mpc, is an old elliptical galaxy.[1] Elliptical old galaxies are amply recognized as preferred sites of type Ia supernovae produced by the so-called double-degenerate scenario, namely, by WD-WD mergers.[23,24]

The aim of this paper is to extend the treatment of Ref. 20 on WD-WD mergers, and exploit the analogy with the synchrotron emission in the X-rays, optical and radio bands in the afterglow of long GRBs[25–28] to determine the emission of WD-WD mergers across the electromagnetic spectrum. Then, we apply the above considerations to the luminosity in the X-rays, optical and radio wavelengths observed in the afterglow of GRB 170817A.

We here show the prominent role of rotation and its effect on the synchrotron emission from the interaction of the newborn rotating object with the ejected matter in the merger. This process is energetically predominant and has been neglected in traditional simulations of these merging systems. The ejected matter expands in the magnetic field of the newborn fast rotating WD, which injects rotational and accretion energy into the expanding ejecta. While expanding, the ejecta radiate energy across the electromagnetic spectrum due to thermal cooling and synchrotron emission. We evidence that the newborn WD becomes observable as a pulsar when the synchrotron radiation fades off. The amount of mass ejected, the mass, rotation period, and strength of the magnetic field of the newborn WD are the most important features that determine the electromagnetic emission of the system.

We show that the above process leads to a hard-to-soft evolution of the emitted radiation with specific decreasing luminosities that approach a distinct power-law behavior. The late-time luminosity is dominated by the pulsar activity of the newborn object, therefore the asymptotic power-law gives information on the parameters of the newborn central object. The total energy radiated during the whole evolution is dominated by the energy injected and radiated from the central WD, so it is covered by its rotational energy.[29] Energy and angular momentum conservation allow to infer, for instance, the spin and magnetic field of the newborn WD directly from the light-curve of the source, prior to any detailed fit of the observational data with the theoretical model (see Refs. 26–28, for the case of long GRBs).

We apply the above considerations to GRB 170817A and show the agreement of the WD-WD merger scenario with all the available observational multiwavelength data from the gamma-rays all the way down to the radio wavelengths. This paper is organized as follows. In Sec. 2, we formulate the general physical conditions of the WD-WD coalescence that constrain the parameters of the newborn WD formed at merger. Section 3 presents an estimate of a possible mechanism leading to a gamma-ray prompt emission in these mergers, and how it compares with GRB

1780817A. Section 4 is devoted to the analysis of the WD-WD post-merger early optical-infrared-ultraviolet emission by thermal cooling, and how it compares with AT 2017gfo. In Sec. 5, we present the theoretical model of the synchrotron emission powered by the newborn WD, and how it leads to a multiwavelength emission (from the radio to the gamma-rays). A comparison with the emission of GRB 170817A $t \gtrsim 10^6\,\mathrm{s}$ is presented. We outline our conclusions in Sec. 6. We use cgs units throughout.

2. Merging Binary and Post-Merger Remnant

The fate of the central remnant of a WD-WD merger with a total mass near (below or above) the Chandrasekhar mass limit can be one of the three possibilities: (i) a stable newborn WD, (ii) a type Ia supernova, or (iii) a newborn neutron star. Sub-Chandrasekhar remnants can lead either to (i) and (ii), while super-Chandrasekhar remnants produce either (ii) or (iii). Super-Chandrasekhar remnants are supported by angular momentum, so they are less dense and metastable objects whose final fate is delayed until the excess of angular momentum is loss, e.g. via magnetic braking, inducing its compression.[30,31]

We are here interested in WD-WD mergers leading to stable, massive, sub-Chandrasekhar newborn WDs with a mass $\gtrsim 1.0 M_\odot$. These WDs can have rotation periods as short as $\sim 0.5\,\mathrm{s}$ (see Ref. 32) and can also avoid the trigger of unstable burning leading to type Ia supernova providing its central density is kept under some critical value of a few $10^9\,\mathrm{g\,cm^{-3}}$.[31]

Numerical simulations of WD-WD mergers show that the merged configuration has in general three distinct regions:[31,33–39] a rigidly rotating, central WD, on top of which there is a hot, convective corona with differential rotation, surrounded by a rapidly rotating Keplerian disk. Roughly, half of the mass of the secondary star, which is totally disrupted, goes to the corona while the other half goes to the disk. The above implies that little mass is ejected in the merger. Numerical simulations show that the amount of expelled mass is approximated by Ref. 39

$$m_{\rm ej} \approx h(q)\, M, \quad h(q) = \frac{0.0001807}{-0.01672 + 0.2463q - 0.6982q^2 + q^3}, \tag{1}$$

where

$$M = m_1 + m_2 = \left(\frac{1+q}{q}\right) m_2, \tag{2}$$

is the total binary mass, and $q \equiv m_2/m_1 \leq 1$ is the binary mass ratio. Equation (1) tells us that for a fixed total binary mass, the larger the mass symmetry, the smaller the mass that is ejected. Thus, for a fully symmetric mass ratio, $q = 1$, the amount of expelled matter becomes $m_{\rm ej} \approx 3.4 \times 10^{-4} M$.

WD-WD merger simulations show two important ingredients for our model. First, the central remnant (the newborn WD) is degenerate, namely, massive

($\gtrsim 1.0 M_\odot$), fast rotating, and magnetized.[31] Second, although the amount of expelled matter is negligible with respect to the total mass of the system, the ejecta are crucial for the electromagnetic emission in the post-merger evolution.

We start with a double WD with components of mass m_1 and m_2, with corresponding radii R_1 and R_2. We shall make use of the analytic mass-radius relation[40]

$$\frac{R_i}{R_\odot} = \frac{0.0225}{\bar{\mu}} \frac{\sqrt{1-(m_i/M_{\rm crit})^{4/3}}}{(m_i/M_{\rm crit})^{1/3}}, \tag{3}$$

where $\bar{\mu} \approx 2$ is the molecular weight, and

$$M_{\rm crit} \approx \frac{5.816 M_\odot}{\bar{\mu}^2} \approx 1.4\ M_\odot, \tag{4}$$

is the critical mass of (carbon) WDs, $M_\odot$ and $R_\odot$ are the solar mass and radius. Since little mass is expelled, we estimate the newborn WD mass as

$$m_{\rm wd} \approx M - m_d = m_1 + m_2 - m_d \approx \left(\frac{2+q}{2\,q}\right) m_2, \tag{5}$$

where we have approximated the disk mass by $m_d \approx m_2/2$, according to numerical simulations. Combining Eqs. (2) and (5), we obtain

$$M \approx 2 \left(\frac{1+q}{2+q}\right) m_{\rm wd}, \tag{6}$$

and using Eqs. (1) and (6), we obtain

$$m_{\rm wd} \approx \left(\frac{2+q}{1+q}\right) \frac{m_{\rm ej}}{2\,h(q)}. \tag{7}$$

As we shall see in Sec. 6, the above equations allow us to infer, from the inferred mass of the ejecta from the fit of the multiwavelength data of GRB 170817A, the parameters of the merging components and of the newborn WD.

3. The Prompt γ-Ray Emission

GRB 170817 was first detected by the GBM on board the *Fermi* satellite.[2] The gamma-ray emission was confirmed by *INTEGRAL*.[3]

GRB 170817A is as a short burst with a duration (T_{90}) of 2.048 s, as reported in the NASA/HEASARC database.[a] We performed a Bayesian spectral analysis of the *Fermi*-GBM data by using the Multi-Mission Maximum Likelihood Framework (3ML, see Ref. 41), and the best model is selected by comparing the deviance information criterion (DIC, see Refs. 42, 43). We first fit the data with a single power-law function, and obtained a DIC value of 3138. We then compare this model to the blackbody (Planck) spectrum over the same time interval, and obtained a DIC value of 3146. We also fit the data with a Comptonized (i.e. a cutoff power-law,

[a] https://heasarc.gsfc.nasa.gov/W3Browse/fermi/fermigbrst.html.

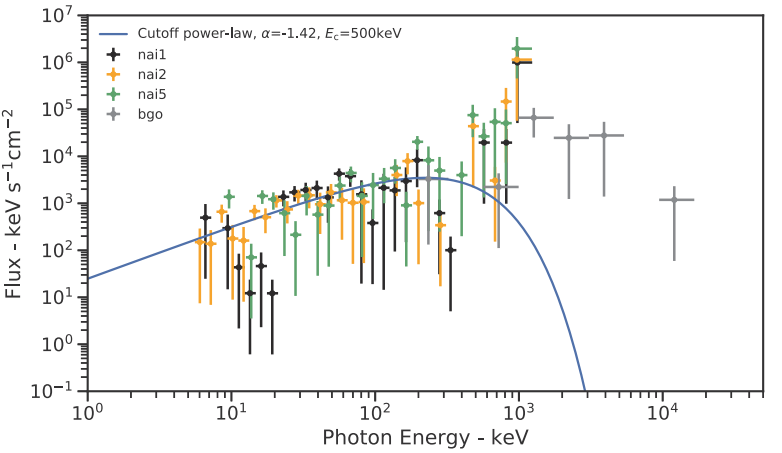

Fig. 1. Spectral fits of νF_ν spectrum for the entire pulse (-0.320 to $1.984\,$s) of the *Fermi*-GBM observation of GRB 170817A. This time interval is the best fit with a Comptonized function, with a cutoff energy $E_c = 500 \pm 317\,$keV, $\alpha = -1.42 \pm 0.18$, and time-averaged flux is $(1.84 \pm 0.82) \times 10^{-7}\,\mathrm{erg\,s^{-1}\,cm^{-2}}$ (see Sec. 3 for details of the data analysis).

hereafter CPL) function, and obtained a DIC value of 3128. The CPL model leads to a DIC improvement of 10 with respect to the power-law model, and of 18 with respect to the blackbody model, which suggests the CPL as the model that best fits the data. We refer to Refs. 44–48 for a detailed Bayesian analysis of the data and the reduction procedure applied to GRBs.

As discussed above, the entire pulse (-0.320 to $1.984\,$s) is best fitted by a CPL with a cutoff energy $E_c = 500 \pm 317\,$keV and power-law index $\alpha = -1.42 \pm 0.18$ (see Fig. 1). The time-averaged flux is $(1.84 \pm 0.82) \times 10^{-7}\,\mathrm{erg\,s^{-1}\,cm^{-2}}$. With the measured cosmological redshift of $z = 0.009783$, corresponding to a source distance of $\approx 43\,$Mpc, the isotropic energy released in this time interval is estimated to be $(4.16^{+3.15}_{-1.84}) \times 10^{46}\,$erg. The nonthermal energy released at energies above 1 MeV corresponds to only 2.82% of the emission corresponding to $\approx 1.17 \times 10^{45}\,$erg. Therefore, most of the energy is released below MeV energies, which corresponds to $\approx 4.04 \times 10^{46}\,$erg.

We here advance the possibility that the γ-ray prompt emission of GRB 170817A occurs from activity in the merged magnetosphere. We could think of the WD pulsar magnetosphere in an analogous way as the NS pulsar magnetosphere, therefore the presence of the strong magnetic field and rotation produces the presence of a electric field by Faraday (unipolar) induction.[49] Numerical simulations show that the merger forms a transient hot corona with temperatures 10^8–$10^9\,$K that cools down rapidly mainly by neutrino emission.[31] Therefore, thermal production of e^+e^- pairs can occur for short time before it cools below the pair formation energy threshold. The charged particles are accelerated by the electric field to then follow the magnetic field lines generating both curvature and synchrotron photons. Since the magnetic

field lines are curved, photon–photon collisions occur roughly in all directions, so the majority of the photons with energy in excess of $m_e c^2$ can decay into pairs again and generate a thermal plasma. A minority of photons escape along the rotation axis (see below), leading to the observed nonthermal emission above 1 MeV.

The cross-section of the $\gamma\gamma \to e^- e^+$ process is given by

$$\sigma_{\gamma\gamma} = \frac{3\sigma_T}{16}(1-\bar{\beta}^2)\left[2\bar{\beta}(\bar{\beta}^2-2) + (3-\bar{\beta}^4)\ln\left(\frac{1+\bar{\beta}}{1-\bar{\beta}}\right)\right], \tag{8}$$

where $\sigma_T \approx 6.65 \times 10^{-25}\,\mathrm{cm}^2$ is the Thomson cross-section, and $\bar{\beta}$ is the e^- (or e^+) velocity (in units of c) in the center of momentum frame

$$\bar{\beta} \equiv \sqrt{1 - \frac{2}{\bar{\epsilon}_{\rm inc}\bar{\epsilon}_{\rm tgt}(1-\cos\theta)}}, \tag{9}$$

being $\bar{\epsilon}_{\rm inc,tgt} \equiv \epsilon_{\rm inc,tgt}/(m_e c^2)$ the normalized energy of the incident and target photons which collide making an angle θ measured in laboratory frame.

Photons emitted along the curved magnetic field lines are expected to be absorbed since they will be radiated nearly isotropically. In this case, $\langle\cos\theta\rangle \sim 0$ and the cross-section becomes maximal at $\bar{\epsilon}_{\rm inc}\bar{\epsilon}_{\rm tgt} \approx 4$, and $\sigma_{\gamma\gamma} \approx \sigma_T/4$. Under these conditions, the $\gamma\gamma$ optical depth is

$$\tau_{\gamma\gamma} \approx n_{\rm tgt}\sigma_{\gamma\gamma} r \approx \frac{L_{\rm tgt}\sigma_{\gamma\gamma}}{4\pi\, r\, c\, \epsilon_{\rm tgt}} \approx \frac{L_{\rm tgt}\,\bar{\epsilon}_{\rm inc}\,\sigma_T}{64\pi\, r\, m_e c^3}, \tag{10}$$

where r is the source size and $n_{\rm tgt}$ is the density of target photons, which we have estimated as $n_{\rm tgt} \approx L_{\rm tgt}/(4\pi\, r^2\, c\, \epsilon_{\rm tgt})$, where $L_{\rm tgt}$ is the luminosity emitted at energies larger than the target photon energy.

For a transient hot corona, most photons are emitted at energies around the peak of the Planck spectrum, which for a temperature of a few 10^9 K implies $\epsilon_{\rm inc} \sim \epsilon_{\rm tgt} \sim 3{\rm kT} \sim 1\,{\rm MeV}$. Assuming a source size $r \sim R_{\rm wd} \sim 10^9\,{\rm cm}$, and a target luminosity $L_{\rm tgt} \sim 4\pi R_{\rm wd}^2 \sigma T^4 \sim 10^{51}\,{\rm erg\,s^{-1}}$, the optical depth (10) $\tau_{\gamma\gamma} \sim 10^{10}$.

The above conditions imply that most photons interact generating an optically thick pair plasma which explains the dominant blackbody component observed by *Fermi*-GBM. The observed nonthermal component is explained if $\approx 1\%$ of the photons escape from the system, which can occur near the rotation axis of the WD. There, the interaction angle could approach values as small as $\cos\theta \sim 1$, thereby reducing drastically the photon–photon cross-section.

4. Thermal Cooling of the Ejecta as Origin of the Kilonova

The second observed emission associated with GRB 170817A is the optical counterpart at about 0.5 d after the *Fermi*-GBM trigger, i.e. AT 2017gfo.[7,8,50,51] For the modeling of this thermal emission of the expanding ejecta, we must take into account that in a nonhomogeneous distribution of matter, the layers reach transparency at

different times. For simplicity, we consider the ejected matter as a spherically symmetric distribution extending at radii $r_i \in [R_*, R_{\rm max}]$, with corresponding velocities $v_i \in [v_*, v_{\rm max}]$, in self-similar expansion

$$r_i(t) = r_{i,0}\hat{t}^n, \quad v_i(t) = n\frac{r_i(t)}{t} = v_{i,0}\hat{t}^{n-1}, \tag{11}$$

where $\hat{t} \equiv t/t_*$, being $t_* \equiv nR_{*,0}/v_{*,0}$ the characteristic expansion timescale, which is the same for all layers in view of the condition of self-similarity. Here, $r_{i,0}$ and $v_{i,0}$ are the initial radius and velocity of the layer (so at times $t \ll t_*$ close to the beginning of the expansion. The case $n = 1$ corresponds to a uniform expansion.

The density at the position $r = r_i$ is given by

$$\rho(r_i) = \frac{(3-m)}{4\pi}\frac{m_{\rm ej}}{R_{*,0}^3}\left[\left(\frac{R_{\rm max}}{R_*}\right)^{3-m} - 1\right]^{-1}\left(\frac{r_i}{R_*}\right)^{-m}\hat{t}^{-3n}, \tag{12}$$

where $m_{\rm ej}$ is the total mass of the ejecta, and m is a positive constant. The distribution and time evolution given by Eq. (12) ensure that at any time the total mass of the ejecta, i.e. the volume integral of the density, is always equal to $m_{\rm ej}$.

We divide the ejecta into N shells defined by the $N + 1$ radii

$$r_{i,0} = R_{*,0} + i\frac{(R_{\rm max,0} - R_{*,0})}{N}, \quad i = 0, 1, ..., N, \tag{13}$$

so the width and mass of each shell are, respectively, $\Delta r = (R_{\rm max,0} - R_{*,0})/N$, and

$$m_i = \int_{r_i}^{r_{i+1}} 4\pi r^2\rho(r)dr \approx \frac{4\pi}{m-3}r_i^2\rho(r_i)\Delta r, \tag{14}$$

so in view of the decreasing density with distance, the inner layers are more massive than the outer layers. The number of shells to be used must be chosen to satisfy the constraint that the sum of the shells mass gives the total ejecta mass, i.e.

$$\sum_{j=1}^{N} m_j = m_{\rm ej}, \tag{15}$$

where we have introduced the discrete index $j = i+1$ to differentiate the counting of the shells from the counting of radii given by Eq. (13). In this work, we use $N = 100$ shells which ensures that Eq. (15) is satisfied with 99% of accuracy.

Under the assumption that the shells do not interact with each other, we can estimate the evolution of the ith shell from the energy conservation equation

$$\dot{E}_i = -P_i\,\dot{V}_i - L_{{\rm cool},i} + H_{{\rm inj},i}, \tag{16}$$

where $V_i = (4\pi/3)r_i^3$, E_i, and P_i are the volume, energy, and pressure of the shell, while $H_{{\rm inj},i}$ is the power injected into the shell, and

$$L_{{\rm cool},i} \approx \frac{cE_i}{r_i(1+\tau_{{\rm opt},i})}, \tag{17}$$

is the bolometric luminosity radiated by the shell, being $\tau_{\rm opt,i}$ the optical depth.

Assuming a spatially constant, gray opacity throughout the ejecta, the optical depth of the radiation emitted by the ith layer is given by

$$\tau_{\rm opt,\it i} = \int_{\infty}^{r_i} \kappa\rho(r)dr = \int_{R_{\rm max}}^{r_i} \kappa\rho(r)dr = \tau_{i,0}\hat{t}^{-2n}, \tag{18}$$

$$\tau_{i,0} \equiv \frac{m-3}{m-1}\frac{\kappa m_{\rm ej}}{4\pi R_{*,0}^2}\frac{\left[\left(\frac{R_*}{r_i}\right)^{m-1} - \left(\frac{R_*}{R_{\rm max}}\right)^{m-1}\right]}{\left[1-\left(\frac{R_*}{R_{\rm max}}\right)^{m-3}\right]}, \tag{19}$$

where we have used Eq. (12), and κ is the opacity.

We adopt a radiation-dominated equation of state for the ejecta and, improving with respect to Ref. 20, accounting for the radiation pressure, i.e.

$$E_i = 3P_i\,V_i + L^{\rm abs}_{{\rm cool},i}\frac{r_i}{c}. \tag{20}$$

The power injected into the ejecta originates from the newborn central WD.[20] This energy is absorbed and thermalized becoming a heating source for the expanding matter. The power-law decreasing density (12) suggests that the inner the layer the more radiation it should absorb. In order to account for this effect, we weigh the heating source for each shell using the mass fraction, i.e.

$$H_{{\rm inj},i} = \frac{m_i}{m_{\rm ej}}H_{\rm inj}, \tag{21}$$

where m_i is the shell's mass, and adopts the following form for the heating source:

$$H_{\rm inj} = H_0\left(1+\frac{t}{t_c}\right)^{-\delta}, \tag{22}$$

where H_0 and δ are model parameters. According to Ref. 20, power from fallback accretion with $H_0 \sim 10^{45}\,{\rm erg\,s^{-1}}$, $\delta \sim 1.3$, and $t_c \sim t_*$ (see Table 1), dominates the energy release from the newborn WD at these early-times.

The photospheric radius at a time t is given by the position of the shell that reaches transparency at that time. Namely, it is given by the position of the shell whose optical depth fulfills $\tau_{{\rm opt},i}[r_i(t)] = 1$. Using Eq. (18), we obtain

$$R_{\rm ph} = \frac{R_{{\rm max},0}\hat{t}^n}{\left[1+\frac{m-1}{m-3}\frac{4\pi R_{*,0}^2\left[1-\left(\frac{R_*}{R_{\rm max}}\right)^{m-3}\right]}{\kappa m_{\rm ej}}\left(\frac{R_{\rm max}}{R_*}\right)^{m-1}\hat{t}^{2n}\right]^{\frac{1}{m-1}}}. \tag{23}$$

Equation (23) shows that when the entire ejecta is optically thick, $R_{\rm ph} = R_{\rm max}$. Then, the transparency reaches the inner shells all the way to the instant over which

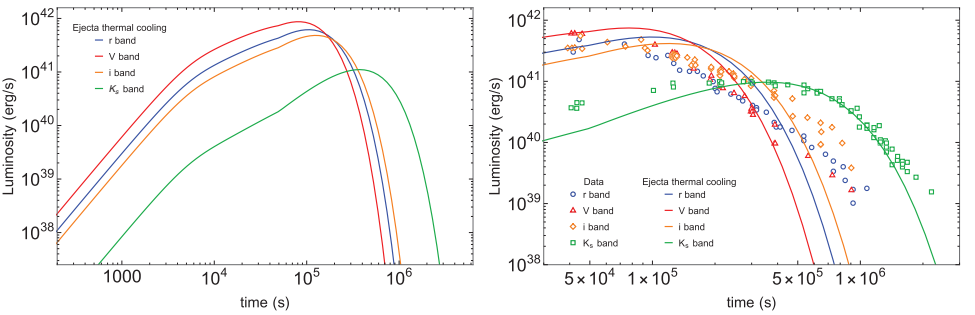

Fig. 2. Left: emission from the expanding, cooling ejecta at early-times in the visible (r and V) and in the infrared (i and K_s) bands, following the theoretical treatment of Sec. 6. Right: zoomed view of the left panel figure at the times relevant for the comparison with the observational data of AT 2017gfo.[7, 8, 50, 51]

$R_{\rm ph} = R_*$, reached at $t = t_{{\rm tr},*}$, when the entire ejecta is transparent. The time $t_{{\rm tr},*}$ is found from the condition $\tau_{{\rm opt},*}[R_*(t_{{\rm tr},*})] = 1$, and is given by

$$\hat{t}_{{\rm tr},*} = \left\{ \frac{m-3}{m-1} \frac{\kappa m_{\rm ej}}{4\pi R_{*,0}^2} \left(\frac{R_*}{R_{\rm max}}\right)^{m-1} \frac{\left[\left(\frac{R_{\rm max}}{R_*}\right)^{m-1} - 1\right]}{\left[1 - \left(\frac{R_*}{R_{\rm max}}\right)^{m-3}\right]} \right\}^{\frac{1}{2n}} . \tag{24}$$

At $t < t_{{\rm tr},*}$, the photospheric radius evolves as $R_{\rm ph} \propto t^{\frac{n(m-3)}{m-1}}$, while at later times, $R_{\rm ph} \propto t^n$. For the parameters of our system, $t_{{\rm tr},*} \sim 10^5$ s (see Fig. 2).

The bolometric luminosity is given by the sum of the luminosity of the shells

$$L_{\rm bol} = \sum_{j=1}^{N} L_{{\rm cool},j}, \tag{25}$$

so the effective temperature of the thermal blackbody radiation, T_s, can be obtained from the Stefan–Boltzmann law, i.e.

$$T_s = \left(\frac{L_{\rm bol}}{4\pi R_{\rm ph}^2 \sigma}\right)^{1/4} , \tag{26}$$

where σ is the Stefan–Boltzmann constant. The power per unit frequency, per unit area, is given by Planck's spectrum

$$B_\nu(\nu, t) = \frac{2\pi h\nu^3}{c^2} [e^{\frac{h\nu}{k_b T_s(t)}} - 1]^{-1}, \tag{27}$$

where ν is the radiation frequency, h and k_b are the Planck and Boltzmann constants. Most of the thermal cooling is radiated in the visible, infrared and ultraviolet wavelengths, which we refer to as optical. Therefore, the spectral density

Table 1. Numerical values of the theoretical model parameters that determine the thermal cooling of the expanding ejecta which fits the data of AT 2017gfo shown in Fig. 2.

Parameter	Value
n	1.22
m	9.00
$m_{\rm ej}$ ($10^{-3} M_\odot$)	1.00
$R_{*,0}$ (10^{11} cm)	4.00
$v_{*,0}$ (10^{9} cm s^{-1})	1.00
κ (cm^2 g^{-1})	0.20
H_0 (10^{45} erg s^{-1})	8.16
δ	1.30
t_c/t_*	1.00

(power per unit frequency) given by the thermal cooling at a frequency ν is

$$J_{\rm cool}(\nu, t) = 4\pi R_{\rm ph}^2(t) B_\nu(\nu, t), \tag{28}$$

and the luminosity radiated in the frequency range $[\nu_1, \nu_2]$ can be then obtained as

$$L_{\rm cool}(\nu_1, \nu_2; t) = \int_{\nu_1}^{\nu_2} J_{\rm cool}(\nu, t) d\nu. \tag{29}$$

Figure 2 shows the luminosity in the r, V, i, and K_s energy bands obtained from Eq. (29), and compares them with the corresponding observations of AT 2017gfo. For the fit of these data, we have set the parameters, as shown in Table 1.

The value of the parameter $v_{\rm max,0}$ does not have any appreciable effect in the evolution, so it cannot be constrained from the data. This happens because most of the mass is concentrated in the innermost layers, so they dominate the thermal evolution. For self-consistency of the model, we have set $v_{\rm max,0} = 2v_{*,0}$, a value that keeps the outermost shell velocity well below the speed of light at any time in the evolution. As for the initial value of the internal energy of the shells, $E_i(t_0)$, we have set them to the initial kinetic energy of each layer, $E_i = (1/2) m_i v_i(t_0)^2$.

There is a general agreement of the model with the observations, although it cannot catch any detailed observational feature. There are some extensions to the present model that can increase its accuracy. For instance, we can abandon the assumption of spherical expansion allowing the layers to have a latitude-dependent velocity. Such a detailed treatment goes beyond our present scope that is to show the broad agreement of a WD-WD merger model with the multiwavelength data but not a dedicated model of AT 2017gfo.

5. Synchrotron and WD Pulsar Radiation

We have shown above that the expanding matter reaches full transparency at about 10^5 s. After this time, the emission originated from the newborn WD as well as the one originated in the ejecta itself, become observable. We here follow the treatment

in Ref. 28 for the explanation of the X-ray afterglow of long GRBs as originating from a newborn spinning NS powering the expanding SN. Here, we simulate the emission generated in the X-rays, in the optical, and in the radio by the synchrotron emission of electrons accelerated in the expanding magnetized ejecta, together with the emission of the newborn spinning WD pulsar.

We show below that synchrotron radiation originating in the merger ejecta dominates the emission up to nearly 10^8 s. We find evidence of the newborn WD pulsar emission, owing to magnetic dipole braking, in the X-ray luminosity at approximately 10^6 s, when the synchrotron radiation was not fully overwhelming yet, and then at times 10^8 s, when the synchrotron luminosity sufficiently decreased for the WD pulsar emission to be fully observed (see Fig. 4 for details).

5.1. *Synchrotron emission by the expanding ejecta*

In this model, a fraction of the kinetic energy of the merger ejecta is used to accelerate electrons that, owing to the presence of the magnetized medium provided by the newborn WD, convert their kinetic energy into synchrotron radiation. The electrons are continuously injected from the newborn WD into the ejecta. The magnetic field threading every ejecta layer evolves as

$$B_i(t) = B_{i,0}\left[\frac{r_{i,0}}{r_i(t)}\right]^{\mu} = \frac{B_{i,0}}{\hat{t}^{\mu n}}, \tag{30}$$

where $B_i^{(0)}$ is the magnetic field strength at $r = r_{i,0}$, and μ gives the spatial dependence of the field at large distance from the newborn WD.

Because the electrons lose their energy very efficiently by synchrotron radiation (see details below), we can simplify our calculation by adopting that the radiation originates from the innermost layer of the ejecta, which we will denote to as R_*. The evolution of this layer, following Eq. (11), is given by $R_*(t) = R_{*,0}\hat{t}^n$, $v_*(t) = v_{*,0}\hat{t}^{n-1}$, $t_* = nR_{*,0}/v_{*,0}$, and the magnetic field at its varying position decreases with time as $B_*(t) = B_{*,0}\hat{t}^{-n}$.

The evolution of the distribution of radiating electrons is determined by the kinetic equation accounting for the particle energy losses[52]

$$\frac{\partial N(E,t)}{\partial t} = -\frac{\partial}{\partial E}[\dot{E}\,N(E,t)] + Q(E,t), \tag{31}$$

where $Q(E,t)$ is the number of injected electrons per unit time, per unit energy, and $\dot{E}$ is the electron energy loss rate.

In our case, we assume electrons are subjected to adiabatic losses by expansion and synchrotron radiation losses, i.e.

$$-\dot{E} = \frac{E}{\tau_{\rm exp}} + \beta B_*(t)^2 E^2, \tag{32}$$

where $\beta = 2e^4/(3m_e^4c^7)$, $B(t)$ is the magnetic field, and

$$\tau_{\rm exp} \equiv \frac{R_*}{v_*} = \frac{t}{n} = \frac{t_*}{n}\hat{t}, \tag{33}$$

is the characteristic timescale of expansion.

In order to find the solution to the kinetic equation (31), we follow the treatment of Ref. 53, adapted to our specific physical situation. We consider a distribution of the injected particles following a power-law behavior, i.e.

$$Q(E,t) = Q_0(t)E^{-\gamma}, \quad 0 \leq E \leq E_{\rm max}, \tag{34}$$

where γ and $E_{\rm max}$ are parameters to be determined from the observational data, and $Q_0(t)$ can be related to the power released by the newborn WD and injected into the ejecta. We assume that the injected power has the form

$$L_{\rm inj}(t) = L_0 \left(1 + \frac{t}{t_q}\right)^{-k}, \tag{35}$$

where L_0, t_q, and k are model parameters. We have not chosen arbitrarily the functional form of Eq. (35), actually, both the powers released by magnetic dipole braking and by fallback accretion (see Eq. (22)) obey this sort of time evolution.

Therefore, the function $Q_0(t)$ can be found from

$$L_{\rm inj}(t) = \int_0^{E_{\rm max}} E\, Q(E,t) dE = \int_0^{E_{\rm max}} Q_0(t) E^{1-\gamma} dE = Q_0(t) \frac{E_{\rm max}^{2-\gamma}}{2-\gamma}, \tag{36}$$

which using Eq. (35) leads to

$$Q_0(t) = q_0 \left(1 + \frac{t}{t_q}\right)^{-k}, \tag{37}$$

where $q_0 \equiv (2-\gamma)L_0/E_{\rm max}^{2-\gamma}$.

Having specified the evolution of the ejecta by Eq. (11) and the magnetic field by Eq. (30), as well as the rate of particle injection given by Eqs. (34) and (37), we can now proceed to the integration of the kinetic equation (31).

First, we find the evolution of a generic electron injected at time $t = t_i$ with energy E_i. Integration of Eq. (32) leads to the energy evolution

$$E = \frac{E_i\,(t_i/t)^n}{1 + \mathcal{M} E_i t_i^n [\frac{1}{\hat{t}_i^{n(1+2\mu)-1}} - \frac{1}{\hat{t}^{n(1+2\mu)-1}}]}, \tag{38}$$

where we have introduced the constant

$$\mathcal{M} \equiv \frac{\beta B_{*,0}^2 t_*^{1-n}}{n(1+2\mu)-1}, \tag{39}$$

which have units of $1/(\text{energy} \times \text{time}^n)$. In the limit $t/t_* \gg 1$ and $n = 1$, Eq. (38) reduces to Eq. (3.3) of Ref. 53, and in the limit $t_* \to \infty$, reduces to the solution presented in Sec. 3 of Ref. 52 for synchrotron losses in a constant magnetic field.

The solution of Eq. (31) is given by

$$N(E,t) = \int_E^\infty Q[E_i, t_i(t, E_i, E)] \frac{\partial t_i}{\partial E} dE_i, \tag{40}$$

where the relation $t_i(t, E_i, E)$ is obtained from Eq. (38).

We can write $N(E,t)$ as a piecewise function of time, separating it into different time intervals that allow simplifications and approximations depending upon the physical situation at work, and on the behavior of the energy injection given by Eq. (37). All the observational data of GRB 170817A are contained in the time interval $t < t_b$ and at electron energies int he range $E_b < E < E_{\max}$ (see definition of t_b and E_b below) where synchrotron losses are dominant. Under these conditions, the solution of Eq. (40) is well approximated by

$$N(E,t) \approx \begin{cases} \dfrac{q_0}{\beta B_{*,0}^2(\gamma-1)} \hat{t}^{2\mu n} E^{-(\gamma+1)}, & t < t_q, \\ \dfrac{q_0}{\beta B_{*,0}^2(\gamma-1)} \left(\dfrac{t_q}{t_*}\right)^k \hat{t}^{2\mu n-k} E^{-(\gamma+1)}, & t_q < t < t_b, \end{cases} \tag{41}$$

and we have defined

$$E_b = \frac{\hat{t}^{2\mu n-1}}{\mathcal{M} t_*^n}, \quad t_b = t_* (\mathcal{M} t_*^n E_{\max})^{\frac{1}{2\mu n-1}}. \tag{42}$$

With the knowledge of $N(E,t)$, we can proceed to estimate the synchrotron spectral density (energy per unit time, per unit frequency) from $J_{\rm syn}(\nu,t)d\nu = P_{\rm syn}(\nu,E)N(E,t)dE$, where $P_{\rm syn}(\nu,E)$ is the synchrotron power per unit frequency ν, radiated by a single electron of energy E. Most of the synchrotron radiation is emitted in a narrow range of frequencies around the so-called photon critical frequency, $\nu_{\rm crit}$. Thus, we can assume electrons emit the synchrotron radiation at

$$\nu \approx \nu_{\rm crit} \approx \alpha B_* E^2, \tag{43}$$

where $\alpha = 3e/(4\pi m_e^3 c^5)$. This gives a relation between the electron energy and the radiation frequency, and $P_{\rm syn}(\nu,E)$ can be approximated to the bolometric power

$$P_{\rm syn}(\nu,E) \approx P_{\rm syn}(\nu) = \beta B_*^2 E^2(\nu) = \frac{\beta}{\alpha} B_* \nu. \tag{44}$$

Within this approximation, the spectral density is

$$J_{\rm syn}(\nu,t) \approx P_{\rm syn}(\nu) N(E,t) \frac{dE}{d\nu}. \tag{45}$$

It can be seen from Eq. (41) that in each time and frequency interval we can write

$$N(E,t) = \eta\, \hat{t}^l E^{-p}, \tag{46}$$

where η and the power-law indexes l and p are known constants from Eq. (41). With this, the spectral density (45) becomes

$$J_{\rm syn}(\nu,t) = \frac{\beta}{2} \alpha^{\frac{p-3}{2}} \eta B_{*,0}^{\frac{p+1}{2}} \hat{t}^{\frac{2l-\mu n(p+1)}{2}} \nu^{\frac{1-p}{2}}. \tag{47}$$

The synchrotron luminosity in the frequencies $[\nu_1, \nu_2]$ can be then obtained as

$$L_{\rm syn}(\nu_1, \nu_2; t) = \int_{\nu_1}^{\nu_2} J_{\rm syn}(\nu, t) d\nu, \tag{48}$$

which in a narrow frequency band from $\nu_1 = \nu$ to $\nu_2 = \nu + \Delta\nu$ where $\Delta\nu/\nu \ll 1$, can be well approximated as

$$L_{\rm syn}(\nu, t) \approx \nu J_{\rm syn}(\nu, t) = \frac{\beta}{2} \alpha^{\frac{p-3}{2}} \eta B_{*,0}^{\frac{p+1}{2}} \hat{t}^{\frac{2l-\mu n(p+1)}{2}} \nu^{\frac{3-p}{2}}, \tag{49}$$

where we have used Eq. (47).

5.2. *WD evolution and pulsar emission*

The central WD emits also pulsar-like radiation. We adopt a dipole + quadrupole magnetic field model.[54] In this model, the total luminosity of spindown is

$$\begin{aligned} L_{\rm sd} &= L_{\rm dip} + L_{\rm quad} \\ &= \frac{2}{3c^3} \Omega^4 B_{\rm dip}^2 R_{\rm wd}^6 \sin^2 \chi_1 \left(1 + \xi^2 \frac{16}{45} \frac{R_{\rm wd}^2 \Omega^2}{c^2} \right), \end{aligned} \tag{50}$$

where the parameter ξ defines the quadrupole to dipole strength ratio as

$$\xi \equiv \sqrt{\cos^2 \chi_2 + 10 \sin^2 \chi_2} \frac{B_{\rm quad}}{B_{\rm dip}}, \tag{51}$$

and the modes can be separated: $\chi_1 = 0$ and any value of χ_2 for the $m = 0$ mode, $(\chi_1, \chi_2) = (90°, 0°)$ for the $m = 1$ mode, and $(\chi_1, \chi_2) = (90°, 90°)$ for the $m = 2$ mode.

The WD evolution is obtained from the energy balance equation

$$-(\dot{W} + \dot{T}) = L_{\rm tot} = L_{\rm inj} + L_{\rm sd}, \tag{52}$$

where W and T are, respectively, the gravitational and rotational energies of the newborn WD. We can obtain an analytic, sufficiently accurate solution of Eq. (52) by noticing the following. The power injected in electrons $L_{\rm inj}$ is larger than $L_{\rm sd}$ and has a shorter timescale with respect to the spindown timescale (see Eq. (35) and Fig. 5), so at $t < t_q$, we have $L_{\rm tot} \approx L_{\rm inj}$. At later times, $L_{\rm tot} \approx L_{\rm sd}$, so the luminosity should approach the spindown luminosity

$$L_{\rm sd} = L_{\rm sd,0} \left(1 + \frac{t}{\tau_{\rm sd}} \right)^{-s}, \tag{53}$$

where $s = (n_b + 1)/(n_b - 1)$, being n_b the so-called braking index ($n_b = 3$ for a pure dipole and $n_b = 5$ for a pure quadrupole), and $\tau_{\rm sd}$ is the spindown timescale

$$\tau_{\rm sd} = \frac{1}{2\mathcal{A}\Omega_0^2}, \tag{54}$$

being $\mathcal{A} = (2/3)(B_{\rm dip}^2 R_{\rm wd}^6)/(c^3 I)$, and Ω_0 the initial angular velocity of the WD.

With the above, Eq. (52) is integrated analytically accounting for changes in the WD structure. We describe the WD as an effective Maclaurin spheroid,[55] so the angular velocity, Ω, is related to the spheroid eccentricity, e, by

$$\Omega^2 = 2\pi G\rho g(e), \quad g(e) = \frac{\left(3-2e^2\right)\left(1-e^2\right)^{1/2}\arcsin(e)}{e^3} - \frac{3\left(1-e^2\right)}{e^2}, \tag{55}$$

where $\rho = 3m_{\rm wd}/(4\pi R_{\rm wd}^3)$ is the density of the sphere with the same volume of the spheroid, being $m_{\rm wd}$ and $R_{\rm wd}$ the corresponding values of the mass and radius of the WD. The total energy of the spheroid is also a function of the eccentricity as

$$E = T + W = \pi G\rho I_0 \mathcal{F}(e), \tag{56}$$

where $I_0 = (2/5)m_{\rm wd}R_{\rm wd}^2$, and

$$\mathcal{F}(e) = -2 + \frac{3(1-e^2)^{2/3}}{e^2} + \frac{(4e^2-3)(1-e^2)^{1/6}}{e^3}\arcsin(e) \approx -\frac{4e^2}{15}, \tag{57}$$

being the last line a series expansion of the function $\mathcal{F}$ which is accurate enough for low values of the eccentricity and which allows to give an analytic solution for the eccentricity as a function of time.

Then, integrating Eq. (52) and using Eqs. (56) and (57), we obtain

$$e(t) \approx \sqrt{\frac{15\Theta(t)}{4}}, \quad \Omega \approx \sqrt{2\pi G\rho\Theta(t)}, \tag{58}$$

where

$$\Theta(t) = -\mathcal{F}(e_0) + \mathcal{G}(t), \tag{59}$$

$$\mathcal{G}(t) = \frac{L_0 t_q}{\pi G\rho I_0(k-1)}\left[\left(1+\frac{t}{t_q}\right)^{1-k} - 1\right] + \frac{L_{\rm sd,0}\tau_{\rm sd}}{\pi G\rho I_0(s-1)}\left[\left(1+\frac{t}{\tau_{\rm sd}}\right)^{1-s} - 1\right], \tag{60}$$

where e_0 is the initial value of the spheroid eccentricity, and we have used that the function $g(e)$ in Eq. (55) satisfies $g(e) = -\mathcal{F}(e)$, at the order of our approximation. We recall that the moment of inertia changes with the eccentricity as $I = I_0(1-e^2)^{-1/3} \approx I_0(1+e^2/3)$. The corresponding parameters of the model that explains the afterglow emission at different wavelengths are presented in the next section.

6. Model Parameters from the Multiwavelength Data

We proceed to determine the model parameters that best fit the GRB 170817A afterglow. We list in Table 2 the value adopted for each parameter of the present model to fit the multiwavelength data of GRB 170817A shown in Fig. 3. We did not consider here data at MeV energies because it is only present in the prompt emission that we have already discussed in Sec. 3 and is explained by a different mechanism from the synchrotron radiation. There are observations in the 30 MeV-10 GeV energy band by AGILE[67] which give upper limits $\sim 10^{44}$–$10^{45}\,{\rm erg\,s^{-1}}$ in

Table 2. Numerical values of the theoretical model of synchrotron radiation of Sec. 5 that fit the multiwavelength observational data of GRB 170817A as shown in Fig. 3.

Parameter	Value
γ	1.13
k	2.70
μ	1.50
L_0 (10^{39} erg s^{-1})	1.80
$B_{*,0}$ (10^9 G)	1.00
$E_{\rm max}$ (10^6 $m_e c^2$)	1.00
t_q (10^7 s)	1.22
ξ	0.00
$B_{\rm dip}$ (10^{10} G)	1.30
P (s)	12.21

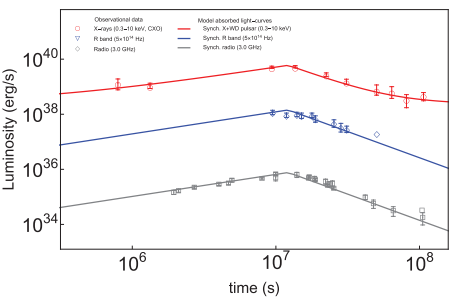

Fig. 3. Comparison of the theoretical (solid curves) light-curves with the observational data (points) of GRB 170817A, in selected energy bands from the radio to the gamma-rays. The radio data at 3 GHz have been taken from Refs. 56–63; the infrared (F606W HST band) data points are retrieved from Refs. 63–64; the X-ray (0.3–10 keV) data from CXO are taken from Ref. 66.

the time interval $\sim 10^3$–10^6 s. For the parameters of Table 2, no emission is indeed expected at these energies because the maximum synchrotron radiation frequency obtained from Eq. (43) falls below 10 GeV before $\sim 10^4$ s. The synchrotron luminosity vanishes at these energies at longer times.

Having discussed the gamma-rays, we turn now to the X-rays, optical and radio emission. Figure 3 compares the absorbed luminosity predicted by the model (see Sec. 4), as a function of time, in selected energy bands, with the corresponding observational data of GRB 170817A. We have here included the X-ray data the 0.3–10 keV energy band from the *Chandra* X-ray Observatory (CXO) including the latest observations,[66] the infrared data from the HST at $\approx 5 \times 10^{14}$ Hz,[63–65] and the radio data at 3 GHz.[56–63, 66]

The model shows a satisfactory fit of the data in the X-rays, optical and radio data, both where the luminosity rises, at times $t \sim 10^6$–10^7 s, and where it fades off, at $t \gtrsim 10^7$ s. We show a closer view in Fig. 4 of the X-rays, optical, and radio luminosities around the time of the peak luminosity. The synchrotron luminosity

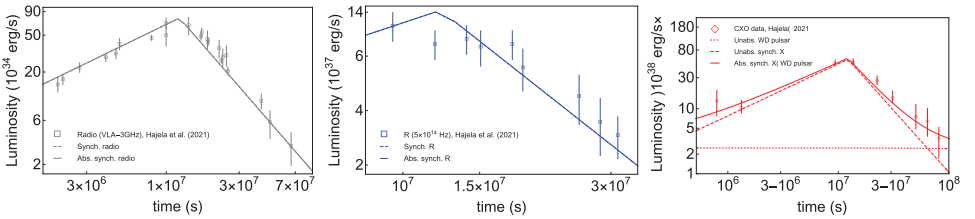

Fig. 4. Zoomed views of the radio (left), optical (center), and X-ray (right) luminosities around transparency. The dashed curves represent the unabsorbed luminosities. The dotted curve in the right panel shows the contribution from the newborn WD pulsar which causes the deviation from the pure synchrotron power-law luminosity at times $\gtrsim 3 \times 10^7$ s.

rises as a power-law while the energy injection is constant, i.e. up to $t \approx t_q = 1.2 \times 10^7$ s, while it decreases as a power-law at later times. Probably the most interesting feature that can be seen from these zoomed views appears in the X-ray emission, where we can see in addition to the synchrotron luminosity, evidence of the WD pulsar emission owing to the magnetic dipole braking. The contribution from the pulsar emission is seen first at $t \sim 10^6$ s when the synchrotron radiation is rising but is still comparable with the pulsar spindown luminosity. Then, the synchrotron luminosity takes over, reaches a peak at approximately 10^7 s, and then decreases. While the optical and radio counterparts continue to fade with time as dictated by the synchrotron radiation, the accuracy of the X-ray data of the CXO presented in Ref. 66 allows to identify a clear deviation in the X-rays at a few 10^7 s from such a power-law behavior. This is again the signature of the emergence of the WD pulsar emission.

We have used the entity of this deviation to constrain the WD pulsar parameters. Since the pulsar emission depends on the WD radius (see Sec. 5.2), we first estimated the mass of the newborn WD. To accomplish this task, we must apply the considerations of Sec. 2. From the inferred mass of the ejecta, $m_{\rm ej} = 10^{-3} M_\odot$ (see Table 1), we obtain an upper limit to the binary mass ratio via Eq. (7), by requesting that the newborn object be a stable, sub-Chandrasekhar WD, i.e. $m_{\rm wd} \lesssim 1.4 M_\odot$, which leads to $q \lesssim 0.87$. According to this maximum mass ratio and the ejecta mass value, Eq. (5) constraints the secondary mass to the range $m_2 \lesssim 0.85 M_\odot$. With the knowledge of q and m_2, Eq. (2) constrains the total binary mass to $M \lesssim 1.82 M_\odot$. Thus, the primary component must satisfy $m_1 \lesssim 0.97 M_\odot$.

We assume that the newborn WD is stable, therefore it might have a mass close but not equal to the Chandrasekhar mass, since some mass will be accreted via matter fallback. Hereafter, we shall adopt in our estimates $m_{\rm wd} \approx 1.3 M_\odot$, so a radius $R_{\rm wd} \approx 3.4 \times 10^8$ cm. With these WD structure parameters, we can proceed to constrain the magnetic field strength and rotation period.

The X-ray emission data show that deviation from the pure synchrotron emission behavior starts at $\approx 3 \times 10^7$ s, and extends up to when we have data, namely, up to $\approx 10^8$ s (see Fig. 4). This would suggest to chose this time for the spindown timescale

$\tau_{\rm sd}$, but at the moment it is only a lower limit to $\tau_{\rm sd}$ because the luminosity did not reach yet the power-law given by the pulsar luminosity.

Hereafter, we assume a pure dipole (i.e. $\xi = 0$) because the fit of the X-ray emission does not require at the moment the quadrupole component (see Fig. 4). By eliminating the rotation angular velocity between the pulsar luminosity (50) and the spindown timescale (54), we can express the magnetic field strength as

$$B_{\rm dip} = \frac{3^{1/2} c^{3/2} I}{2^{3/2} L_{\rm sd}^{1/2} R_{\rm wd}^3 \tau_{\rm sd}}, \tag{61}$$

where I is the moment of inertia. We can use Eq. (61) to give an upper limit to $B_{\rm dip}$ by setting as values of $L_{\rm sd}$ and $\tau_{\rm sd}$, the values of the latest value of the X-ray luminosity data, i.e. $L_{\rm sd} = L_X \approx 4.87 \times 10^{38}\,{\rm erg\,s^{-1}}$, and $\tau_{\rm sd} \approx 10^8\,{\rm s}$. With this, we obtain an upper value $B_{\rm dip,max} \approx 7.46 \times 10^{11}$ G. To this upper value of $B_{\rm dip}$, it corresponds an upper value of the initial rotation period which can be obtained by calculating $P_0 = 2\pi/\Omega_0$ from Eq. (50), i.e.

$$P_0 = 2\pi \left(\frac{2 B_{\rm dip}^2 R_{\rm wd}^6}{c^3 L_{\rm sd}} \right)^{1/4}, \tag{62}$$

from which we obtain $P_{0,\rm max} \approx 75.25\,{\rm s}$. We can further constrain the rotation period by seeking for values of the magnetic field strength and rotation period in agreement with the model presented in Sec. 3 for the prompt emission. Such a mechanism is expected to release magnetic energy stored in the magnetosphere, i.e.

$$E_B \approx \frac{1}{6} B_{\rm dip}^2 R_{\rm wd}^3, \tag{63}$$

so we need a dipole magnetic field strength

$$B_{\rm dip} = \left(\frac{6 E_B}{R_{\rm wd}^3} \right)^{1/2} \approx \left(\frac{6 E_{\rm prompt}}{R_{\rm wd}^3} \right)^{1/2}. \tag{64}$$

If we assume that the entire energy of the prompt emission, $E_{\rm prompt} \approx 4.16 \times 10^{46}\,{\rm erg}$ (see Sec. 3) is paid by the magnetosphere energy, we obtain a magnetic field $B_{\rm dip} = 9.61 \times 10^{10}$ G. If we require the magnetic field energy to cover only the nonthermal component of the prompt, i.e. $1.17 \times 10^{45}\,{\rm erg}$ (see Sec. 3), then the dipole magnetic field becomes 1.30×10^{10} G. For the above magnetic field values, Eq. (62) gives, respectively, $P_0 \approx 30\,{\rm s}$, and $P_0 \approx 12\,{\rm s}$. The WD pulsar luminosity shown in Figs. 3 and 5 corresponds to the latter case.

The energy released (and injected into the ejecta) by the fallback accretion phase is $E_{\rm fb} = H_0 t_*/(\delta - 1) \approx 3.34 \times 10^{48}\,{\rm erg}$. Energy and angular momentum are transferred to the newborn WD during this phase, and since the rotational to gravitational energy ratio of a uniformly rotating WD is of the order of 10^{-2},[32] the newborn WD has gained about a few $10^{46}\,{\rm erg}$ of rotational energy during this phase. This might produce at a rotation period decrease of the order of a second, which confirms that the WD must be already fast rotating at birth.

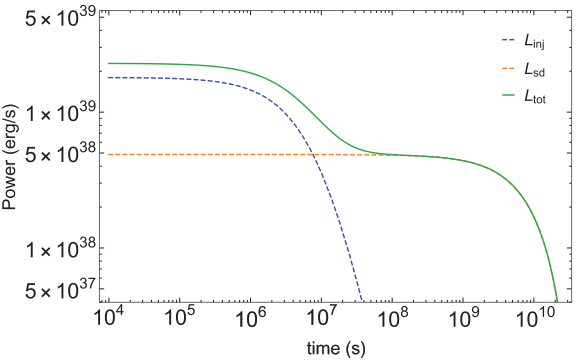

Fig. 5. Power injected into the ejecta by the newborn WD and the pulsar emission as given, respectively, by Eqs. (35) and (50). See the main text for further details.

In Fig. 5, we plot the power injected in energetic electrons from the WD, $L_{\rm inj}$, and the luminosity due to magnetic dipole braking, $L_{\rm sd}$. Both components release an energy of the order of 10^{46} erg. From the inferred rotation period of 12.21 s, the initial eccentricity turns out to be $e_0 \approx 0.39$, so the moment of inertia is about 5% bigger than the one of the equivalent spherical configuration. Using the evolution equations (58), we obtain that the moment of inertia, for instance from 10^4 s to 10^8 s, changes in about 0.03%. This small change in the structure of the WD, and the associated change in the rotational and gravitational energy, are sufficient to pay for the energy released by the ongoing magnetospheric phenomena responsible for the injection of particles into the ejecta and for the pulsar emission; see Sec. 5.2.

7. Conclusions

We have here addressed a self-consistent explanation of GRB 170817A, including its associated optical emission AT 2017gfo, based on a WD-WD merger. The most recent data of *Chandra* of the X-ray emission of GRB 170817A at $\sim 10^8$ s (~ 1000 d) after the GRB trigger,[21,22] indicate an X-ray re-brightening. This is explained by the emergence of the pulsar-like activity of the newborn WD (see Figs. 3 and 4), as predicted in Refs. 13, 20. We have here inferred that the newborn object is consistent with a massive ($\sim 1.3\,M_\odot$), fast rotating ($P \gtrsim 12$ s), highly magnetized ($B \sim 10^{10}$ G) WD, formed in a $1.0 + 0.8$ WD-WD merger (see Secs. 2 and 6).

The post-merger emission at different wavelengths is explained as follows. The prompt gamma-ray emission detected by the *Fermi*-GBM, with a luminosity of $\sim 10^{47}\,{\rm erg\,s^{-1}}$ and observed duration of $\lesssim 1$ s, can be explained by the transient hot corona produce at the merger. The high temperature produces photons that undergo $e^- e^+$ pair creation, the pairs are accelerated by the electric field induced by the 10^{10} G magnetic field an the WD rotation, thereby producing photons. The system is highly opaque to these photons (see Sec. 3) to the $\gamma\gamma$ pair production process. Only a small percentage of photons is expected to be able to escape from

the system along the polar axis, leading to the small amount of nonthermal emission observed above 1 MeV, while the rest is expected to form a nearly thermal plasma.

The ejecta expand with velocities $\sim 10^9\,\mathrm{cm\,s^{-1}}$, and release energy by thermal cooling (see Sec. 4) and synchrotron radiation (see Sec. 5), powered by the newborn WD at the merger (see Sec. 5.2). Fallback accretion onto the newborn WD injects energy into the ejecta at early-times, heating up the ejecta. The ejecta is optically thick up to nearly 10^5, so the ejecta cool by diffusion while it expands. The thermal radiation is in agreement with the data of the early optical counterpart AT 2017gfo (see Fig. 2). This explanation is markedly different from the *nuclear kilonova* from decay of r-process synthesized heavy nuclei in an NS-NS merger ejecta.

The signature of the synchrotron radiation is identified from nearly 10^6 s, which explains the rising and decreasing luminosities with the same power-law slopes in the X-ray, optical and radio emissions (see Fig. 3 for details).

The X-ray data are essential for identifying the emergence of the newborn WD as a pulsar. We have shown evidence of the pulsar emission around 10^6 s and at late-times 10^8 s, causing the X-ray luminosity to deviate from the power-law emission of a pure synchrotron emission (see Figs. 3 and 4). These data reveal a rotation period $\gtrsim 12$ s, and magnetic field of $\sim 10^{10}$ G. The follow-up of the GRB 170817A X-ray emission in the next months/years to come is crucial to confirm this prediction.

Summarizing, GRB 170817A/AT 2017gfo are explained by a WD-WD merger. The $10^{-3} M_\odot$ expelled in the merger expand and radiates via thermal and synchrotron cooling. The former explains AT 2017gfo and the latter the late-time X-rays, optical and radio emission. In this line, the association of GW170417A with GRB 170817A[1] is not confirmed in our treatment based on the new data in the X-rays, optical, and in the radio up to 10^8 s. Therefore, we indicate the necessity to further inquire on the spacetime sequence of the early part of these events.

Indeed, WDs of parameters approaching the present ones have been already identified, e.g. the WD in V1460 Her with $P \approx 39$ s,[68] and the most recent observation of the WD in LAMOST J024048.51+195226.9 with $P \approx 25$ s.[69] WDs of similar properties have been proposed as a model of SGRs and AXPs.[70–73] Therefore, the newborn WD pulsar in GRB 170817A could show itself in the near future as an SGR/AXP in the GRB 170817A sky position.

National Research University "Higher School of Economics", Staraya Basmannaya st., 21/4 s. 5, Moscow, Russia, 105066

Astrophysical problems such as modelling of core-collapse supernovae, collapse of protostellar clouds as well as other processes, involving collapsing matter, deal with regions (e.g. protostars, protoneutron stars), where a speed of sound has much larger values, than in remaining parts of a computational domain. A time-step in explicit numerical schemes, thus, has to be bounded by acoustic Courant-Friedrichs-Lewy condition, due to high speed of sound in these compact regions. In some cases, this condition can be very restrictive, and (semi-) implicit numerical schemes may outperform the explicit ones. We propose a semi-implicit solver on a collocated mesh for self-gravitating gas dynamical flows, in which only acoustic waves are treated implicitly. We use an operator-difference approach to construct difference analogues of vector differential operators on unstructured meshes in two and three dimensions, which allows us to save the conjugacy properties of the operators. A Rusanov-type dissipation was used to get monotonic flow profiles and usual linear flux reconstruction to improve an order of spatial approximation. Results of test calculations are presented.

Keywords: Gas dynamics; semi-implicit schemes; self-gravity.

1. Introduction

Numerical simulations of astrophysical fluid flows is one of the key instruments, which allow us to explain a wide range of astronomical phenomena on the qualitative level, as well as to compare the theoretical predictions to observational data quantitatively. An astrophysics is rich for different types of gas and plasma flows in the case, when one can use ideal compressible fluid approximation without dissipation (e.g. Euler equations). The ideal flow is described in terms of hyperbolic systems of partial differential equations, for which the explicit schemes, such as Godunov-type finite volume,[1] can be successfully applied (see also textbooks[2,3]). Explicit SPH solvers are broadly used by astrophysical community as well.[4] But there are the problems, such as, for example, star formation from protostellar clouds, collapses of stars' iron cores and supernovae explosions, where the implicit or semi-implicit schemes may possibly outperform the explicit solvers. It is a common situation in astrophysical modelling, when the compact high-density regions of a collapsed matter with high speed of sound (such as protostars, protoneutron stars) appear in a computational domain, where the velocity of the flow is very low compared

to the acoustic speed, so that we deal with low Mach number flows. At the same time, in other parts of the domain, the flow can be considered as compressible, strong shocks and other different flow discontinuities may form. The latter situation is common for e.g. a post-bounce evolution of core-collapse supernovae.[5] It also stands for magnetorotational supernove simulations, when we have small acoustic timescale and large magnetic field evolution timescale.[6,7] The mesh size during such astrophysical simulations is usually refined in the regions of collapsed objects up to several orders of magnitude, compared to the cell size on the outer boundary. The explicit solvers are restricted by Courant-Friedrichs-Lewy (CFL) condition. In the mentioned types of astrophysical flows, the global CFL condition comes mostly from the high sound speed from resolved collapsed objects and may be very restrictive, which makes such kind of simulations computationally expensive and challenging. Thus, the implicit treatment of acoustic waves in hydrodynamical schemes allows to increase timestep significantly, and hence, to reduce the computational cost of such astrophysical simulations.

Implicit evaluation of the pressure field is a common approach in incompressible flow simulations.[8] The idea to extend the semi-implicit to compressible flows was proposed in mid-80's by Casulli and Greenspan,[9] but only quite recently this approach was used to construct the so-called *All-Mach number solvers* for gas dynamics (see e.g. works[10–13] on structured and[14,15] on unstructured grids, and references therein) and for MHD equations,[16,17] written in conservative form. They are the pressure-based solvers by its nature, but they can work as high resolution shock-capturing methods as well in presence of discontinuities. The usage of semi-implicit solvers results to the solution of an elliptic equation with a Laplace-type operator for the pressure on each time-step, and it is very important to construct a consistent difference analogue of the solving differential problem, which provides the cheaply solvable linearized systems. To obtain a symmetric sign-definite matrices for the linear elliptic problems, we use a Support (basic) Operators Method (operator-difference approach)[19] to construct the difference analogues of differential operators in three dimensions. The support operators method has also many common features with mimetic finite difference[18] approach.

The idea of the support operators method is that the difference operators should be derived in the way to fulfil the same properties as the continuous operators. Thus, the constructed operators should satisfy the difference analogues of integral relations such as Green formula. This approach allows to obtain the so-called completely conservative fully implicit finite-difference schemes for gas dynamics and MHD equations[19] on unstructured grids. For 2D simulations of magnetorotational supernova explosion this method was used e.g. in[20] with a cell-nodal approximation[21,22] in the framework of Newtonian MHD with self-gravity.

The paper is organized as follows. In the next subsection we derive the nodal difference operators of gradient and divergence in three dimensions. In the 3-rd subsection we provide the description of the solving gravitational gas-dynamics

system and derive a semi-implicit numerical scheme for these equations, and in the last subsections we present and discuss the results of numerical simulations of several benchmark problems in low and high Mach number regimes.

2. Difference analogues of differential operators

In the Support operators method the difference analogues of differential operators are built in pairs. Further we are going to consider only the nodal gradient and divergence operators, while the other difference analogues can be obtained in a similar way. To introduce difference GRAD and DIV operators one should define finite dimensional linear grid spaces and scalar products of grid functions in them. The first operator can be obtained using any numerical differencing technique, while the second one has to satisfy the grid analogue of the Green formula in corresponding grid space. Thus, the resulting operators are conjugated to each other. The GRAD operator can be derived in two different ways: either using the finite element approach with linear basis functions inside the tetrahedra (for 2D case see e.g.[23]) or with a finite volume approach using piecewise-constant basis functions on the nodal edge-based (median-dual) cells, as in Godunov-type methods on unstructured grids (see e.g.[24]). The grid gradient operator reads (for 3D case):

$$(\nabla_\times p)_j = -\frac{1}{12W_j}\sum_{i\in G_j}\sum_{k=1}^{4}\left(S_k\mathbf{n}_k p_k\right)_i, \tag{1}$$

where p is a nodal scalar function, G_j is a set of tetrahedral cells adjoined to sought j-th node, i is a cell index, k is a node index inside the i-th cell, $\mathbf{n}_k$ and S_k are unit normal and area to the tetrahedron's triangular face, which does not contain the node k in its vertexes, and $W_j = \frac{1}{4}\sum_{i\in G_j} V_i$ is a "node" volume (the volume of a median-dual cell), V_i is a volume of i-th tetrahedron.

To obtain the consistent approximation of the divergence operator, the Green formula and its difference analogue should be used:

$$\begin{gathered}\int_V p\nabla\cdot\mathbf{v}dV + \int_V(\nabla p)\cdot\mathbf{v}dV = \oint_{\partial V} p\mathbf{v}\cdot\mathbf{dS},\\ \sum_{l=1}^{N_n}(\nabla_\times p)_l\cdot\mathbf{v}_l W_l + \sum_{k=1}^{N_n} p_k(\nabla_\times\cdot\mathbf{v})_k W_k = (\Phi\cdot\mathbf{v}, p),\end{gathered} \tag{2}$$

where ∇ and $\nabla\cdot$ are the gradient and the divergence operators correspondingly, $\mathbf{v}$ is a vector function, N_n is a total number of the nodes, and V is a volume of the computational domain. The surface integral in the right hand side of the formulae (2) correspond to the so-called *Boundary operator* Φ in a formalism of the support operators method. Its evaluation can be found in.[21,22,25] The boundary operator is used to formulate the boundary-value problems in the operator-difference form.

We do not consider it here, because in the solver we use ordinary finite volume boundary conditions via ghost cells approach.

To derive the DIV operator in the interior nodes of the computational domain, the Green formula in (2) is written without the integral in the right hand side. By substituting the grid gradient operator (1) in the analogue of the Green formula (2) and rearranging the terms, the following approximation for the divergence operator can be obtained

$$(\nabla_\times \cdot \mathbf{v})_j = -\frac{1}{12W_j} \sum_{i \in G_j} \sum_{k=1}^{4} \left(S_k \mathbf{n}_k \cdot \mathbf{v}_k\right)_i. \tag{3}$$

We note, that the latter operator has the same form, as the initially derived gradient one (1) due to the usage of purely nodal approximation, while its form and stencil is different from the cell-nodal DIV operator. The divergence operator (3) is conjugated to (1), and thus, the grid Laplacian transforms into the symmetric and sign-definite matrix. The usage of the support operators technique allows to derive the full set of vector calculus operators in any geometry, which satisfy the conjugacy properties.

Finally, the difference analogues of differential operators can be written in a finite-volume form[26]

$$(\nabla_\times^{fw} p)_j = \frac{1}{W_j} \sum_{n \in H_j} \left(\frac{S_{nj} \mathbf{n}_{nj} (p_n + p_j)}{2} \right), \tag{4}$$

where H_j is a set of neighbouring nodes to the sought node with index j, S_{nj} and $\mathbf{n}_{nj}$ are the area and the unit normal to the n-th face of the node-centred median-dual control volume. This approximation leads to exactly the same expression as (1).[26]

3. Semi-implicit numerical scheme for the equations of gas dynamics with gravitation

3.1. *Euler equations with self-gravity*

Gas dynamical equations with self-gravity can be written in the following conservative formulation:

$$\begin{gathered} \frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \\ \frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v}) + \nabla P = -\rho \nabla \Psi, \\ \frac{\partial \rho E}{\partial t} + \nabla \cdot \left(\rho \mathbf{v} \big(E + \frac{P}{\rho}\big) \right) = -\rho \mathbf{v} \cdot \nabla \Psi, \\ \nabla \cdot \nabla \Psi = 4\pi G \rho. \end{gathered} \tag{5}$$

In the system above, the first three equations without source terms in right hand sides correspond to ideal Euler equations, while the last one is the Poisson equation for a gravitational potential Ψ. The source terms correspond to presence of an acceleration by gravity, G is a gravitational constant. In ideal Euler equations (5) ρ is a mass density, $\mathbf{v}$ is a flow velocity; P is a pressure, $E = \frac{\mathbf{v}^2}{2} + E_{th}$ is a total energy density, E_{th} is an internal energy density. A thermodynamic equation of state is needed to close the system of equations (5). In this paper we consider only a perfect gas equation of state with an adiabatic index γ:

$$P = (\gamma - 1)\rho E_{th}. \tag{6}$$

Extension of a semi-implicit solver (see next subsection) to an arbitrary equation of state is straightforward and can be found in e.g.[11,12]

3.2. *Poisson solver*

The Poisson equation should be solved on each time-step to calculate the value of the gravitational potential, and hence, a gravitational force. The support operators method allows to construct a discrete Laplace operator in the form of a symmetric and sign-definite matrix. Purely nodal approximation requires the stencil, which consists of the second-order neighbours for each node. The boundary conditions are projected to the boundary nodes and included in the operator-difference form of the solving problem. For example, the Dirichlet boundary-value problem reads[21,22]

$$(I - \delta)\nabla_\times \cdot \nabla_\times (I - \delta)\Psi + (I - \delta)\nabla_\times \cdot \nabla_\times \delta\Psi_\gamma = 4\pi G(I - \delta)\rho, \tag{7}$$

where Ψ_γ is a boundary value of the gravitational potential, I is a unit operator, δ is an operator, which is equal to unity in the boundary nodes, and zero - in the interior ones.[22] For other types of boundary conditions (e.g. an absence of the force on the boundary) we solve the Poisson using the ghost cells approach. The resulting linear system can be solved with a matrix-free conjugate gradient method. The gravitational acceleration then can be calculated as a nodal gradient of the potential.

In Fig. 1 the solution of the Poisson equation is shown for the spherically-symmetric Gaussian-law solution $\Psi = \exp\big(-\frac{x^2+y^2+z^2}{2}\big)$ given by the function $f = \exp\big(-\frac{x^2+y^2+z^2}{2}\big)(x^2 + y^2 + z^2 - 3)$ in the right-hand side of the equation.

The cell-node approximation can also be used for the solution of the Poisson equation procedure. It allows to use a smaller stencil for the matrix, while the gradient of the potential still can be found with a purely nodal operator (4).

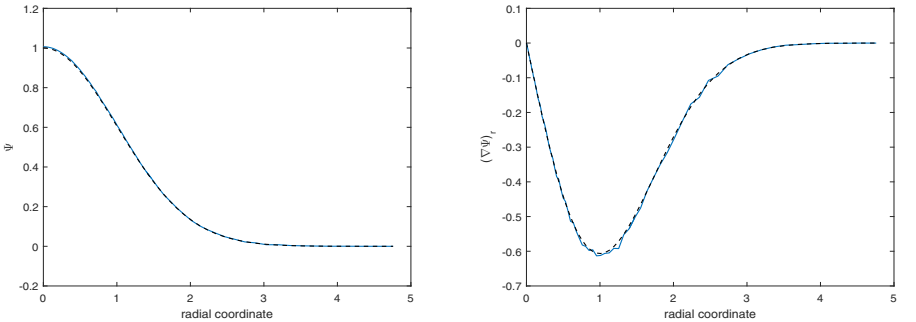

Fig. 1. The solution of the Poisson equation (blue lines, 1D plots are given for the X-axis) for the potential (left) and its gradient (right) together with an analytical solution (black lines). The computational domain is cube ($0 < x, y, z < 5$) with no force conditions on the symmetry boundaries and Dirichlet conditions on outer ones.

3.3. *Hydro-solver*

The difference gas dynamical system of equations can be written in the following form on a collocated mesh

$$\begin{gathered}
\frac{\rho^{n+1}-\rho^n}{\tau} + \widetilde{\nabla}_\times \cdot (\rho^n \mathbf{v}^n) = 0, \\
\frac{\rho^{n+1}\mathbf{v}^{n+1}-\rho^n\mathbf{v}^n}{\tau} + \widetilde{\nabla}_\times \cdot (\rho^n \mathbf{v}^n \otimes \mathbf{v}^n) + \nabla_\times P^{n+1} = \mathbf{S}_v, \\
\frac{\rho^{n+1}E^{n+1}-\rho^n E^n}{\tau} + \widetilde{\nabla}_\times \cdot \left(\rho^n \mathbf{v}^n \frac{(\mathbf{v}^2)^n}{2}\right) + \nabla_\times \cdot \left(h^{n+1}\rho^{n+1}\mathbf{v}^{n+1}\right) = \mathrm{S}_e,
\end{gathered} \tag{8}$$

where $h = E_{th} + \frac{P}{\rho} = \frac{\gamma P}{(\gamma-1)\rho}$ is a thermodynamic enthalpy. This system describes the flow evolution from time $t = t^n$ to $t = t^{n+1} = t^n + \tau$. The last terms in the left parts of the second and third equations in (8) should be evaluated implicitly according to,[9,11] which allows to treat implicitly only the acoustic waves in the gas dynamical system (5). The source terms are given by the formulae $\mathbf{S}_v = -\rho^{n+1}\nabla_\times\Psi$, $S_e = -\rho^{n+1}\mathbf{v}^n \cdot \nabla_\times\Psi$. The gravitational potential is solved for the density distribution on the $(n+1)$-th time-step. Note, that such separate treatment of acoustic waves is equivalent to the Toro-Vazquez flux splitting approach.[27]

The difference operator with tilde $\widetilde{\nabla}_\times\cdot$ in explicitly evaluated advective fluxes corresponds to an upwind monotonic scheme for advection. It is written together with a Rusanov-type numerical dissipation:

$$(\widetilde{\nabla}_\times \cdot \mathbf{F})_j = (\nabla_\times \cdot \mathbf{F})_j - \frac{1}{2W_j}\sum_{i\in H_j}\left(\left|\frac{\partial \mathbf{F}}{\partial \mathbf{u}}\right||\mathbf{n}_{ij}|S_{ij}(u_i - u_j)\right), \tag{9}$$

where dissipation is written in a finite-volume form (4), in which $\mathbf{u}$ and $\mathbf{F}$ are the vector of conservative variables and the flux vector correspondingly:

$$\begin{aligned} \mathbf{u} &= (\rho, \rho\mathbf{v}, \rho E) \\ \mathbf{F} &= (\rho\mathbf{v}, \rho\mathbf{v} \otimes \mathbf{v}, \rho\mathbf{v}E). \end{aligned} \tag{10}$$

We use $|\frac{\partial \mathbf{F}}{\partial \mathbf{u}}| = \max(|\mathbf{v}|_i, |\mathbf{v}|_j)$, thus, dissipation coefficient is independent on the speed of sound.[11] The explicit advective scheme is implemented in the same manner, as the edge-based Godunov-type finite volume solvers on median-dual grids,[28] so that the advective fluxes $\mathbf{F}$ in (9) are calculated at the centres of the edges between the nodes.

The numerical scheme is conditionally stable with a milder CFL condition, which depend only on the flow velocity and not on the speed of sound:

$$\tau < \tau_{adv} = \min \frac{\Delta X}{2 \mid \mathbf{v} \mid}, \tag{11}$$

where ΔX is a characteristic local mesh size.

By substituting the momentum from the momentum equation in (8) to the energy equation, we can obtain the following nonlinear equation:

$$\begin{aligned} &\frac{P^{n+1}}{\gamma - 1} - \tau^2 \nabla_\times \cdot \left(h^{n+1} \nabla_\times P^{n+1} \right) \\ &= \rho^n E^n - \rho^{n+1} \frac{(\mathbf{v}^2)^{n+1}}{2} - \tau \widetilde{\nabla}_\times \cdot \left(\rho^n \mathbf{v}^n \frac{(\mathbf{v}^2)^n}{2} \right) + \tau S_e \\ &-\tau \nabla_\times \cdot \left(h^{n+1} (\rho^n \mathbf{v}^n - \tau \widetilde{\nabla}_\times \cdot (\rho^n \mathbf{v}^n \otimes \mathbf{v}^n) + \tau \mathbf{S}_v) \right), \end{aligned} \tag{12}$$

The latter system is nonlinear, and the usual approach to solve it is a usage of nested Newton-type iterations (r-iterations, Picard iterations),[11,12] which converge rapidly (usually 2-3 iterations are enough). The resulting linearised system reads:

$$\begin{aligned} &\frac{P^{n+1,r+1}}{\gamma - 1} - \tau^2 \nabla_\times \cdot \left(h^{n+1,r} \nabla_\times P^{n+1,r+1} \right) \\ &= \rho^n E^n - \rho^{n+1} \frac{(\mathbf{v}^2)^{n+1,r}}{2} - \tau \widetilde{\nabla}_\times \cdot \left(\rho^n \mathbf{v}^n \frac{(\mathbf{v}^2)^n}{2} \right) + \tau S_e \\ &-\tau \nabla_\times \cdot \left(h^{n+1,r} (\rho^n \mathbf{v}^n - \tau \widetilde{\nabla}_\times \cdot (\rho^n \mathbf{v}^n \otimes \mathbf{v}^n) + \tau \mathbf{S}_v) \right), \end{aligned} \tag{13}$$

$$h^{n+1,r} = \frac{\gamma P^{n+1,r}}{(\gamma - 1)\rho^{n+1}}.$$

To obtain the solution from n-th time level to $n+1$-th, the following procedures should be done:

(I) solving the mass conservation equation in (8) with the explicit scheme and obtaining ρ^{n+1}

(II) solving the Poisson equation (7) with the density ρ^{n+1} for the gravitational potential and calculating the forces in the source terms of gas-dynamical system (8)
(III) defining $P^{n+1,1} = P^n$, $h^{n+1,1} = h^n$ and $\mathbf{v}^{n+1,1} = \mathbf{v}^n$
(IV) r-iterations, $r = \overline{1, r_p}$

  (a) Solving (13) and obtaining $P^{n+1,r+1}$
  (b) recalculating $h^{n+1,r+1}$ and calculating $\mathbf{v}^{n+1,r+1}$ from the momentum equation (8) using $P^{n+1,r+1}$

(V) defining $P^{n+1} = P^{n+1,r_p}$, $h^{n+1} = h^{n+1,r_p}$ and $\mathbf{v}^{n+1} = \mathbf{v}^{n+1,r_p}$
(VI) calculating the energy using a semi-implicit equation from the system (8).

This procedures allow to obtain a numerical solution of the gas-dynamical system (5) with a first order in space and time. In this study we use $r_p = 3$ Picard iterations.

To extend this scheme to higher order in space, we use the same approach as in explicit finite volume Godunov-type schemes on unstructured meshes, as it is done in e.g.[28] (see also[29] for a different approach). We apply a piecewise-linear reconstruction of conservative gas-dynamical variables in advection upwind fluxes (9) with Barth-Jespersen slope limiters,[24] thus, the explicit advective part of the solver is calculated with the second order in space. For this reason, the resulting order of spatial approximation of the scheme is higher, than one. Note, that the difference operators like (4) provide the second order in space on the mesh, consisting on equilateral tetrahedra (or equilateral triangles in 2D), because these operators are analogous to the usual central differences on the uniform grid, so that on such kind of meshes the solver has the second approximation order in space. High order in time approximation can be achieved either by employing explicit high order methods for the advective parts of the solving system, as was done in e.g.,[15] or by using the implicit-explicit Runge-Kutta methods.[13]

The linearised problem (13) has a matrix of a Laplace-type second order difference operator and, in addition, a diagonal, filled with the positive elements. The conjugated difference operators allow to obtain an easily reversible symmetric and positive definite matrix. We use a matrix-free conjugate gradient method to solve the system (13), which is very efficient.

It is also possible to make a discretization of the system (5) in time, substitute the expression for $\rho^{n+1}\mathbf{v}^{n+1}$ in the energy equation, and further discretize the energy equation in space.[13] The cell-node approximation and the Support operators method can be applied for the Laplace-type operator in (13), thus, making the matrix stencil more compact. Preliminary calculations show, that this approach is slightly more effective, as well as it provides a collocated pressure system, which is similar in properties to the staggered grid approach.[13]

4. Test computations

The code was developed in two variants: 2D and 3D Cartesian versions. We have tested our code in several benchmark problems in high and low Mach number regimes as well as simulated a test problem of a dust collapse to check the code's ability to simulate the flows with self-gravity.

In Fig. 2 the Sod shock tube problem solution is shown for the 3D (the first three pictures) and 2D versions of our code at the time $T = 0.45$ for the mesh with $N_x = 200$ nodes in X-direction and $N_y = N_z = 10$ ones in Y- and Z-directions. The initial conditions are as usual: $\rho(x < 1) = 0.125, P(x < 1) = 0.1$ and $\rho(x \geq 1) = 1, P(x \geq 1) = 1$, while the velocity is zero everywhere. The shock profile is about 4-5 cells thick. The solution is obtained by the conservative scheme, thus, the discontinuities have physically correct amplitudes and velocities.

In Fig. 3 the density profile of a slowly moving contact discontinuity is presented. The initial conditions are the following: $\mathbf{v} = (0.01, 0, 0), P = 3$ everywhere, while the density $\rho(x < 0.25) = 50, \rho(x \geq 0.25) = 1$. The problem is solved until the final time $T = 50$, which corresponds to the contact discontinuity located at $x = 0.75$.

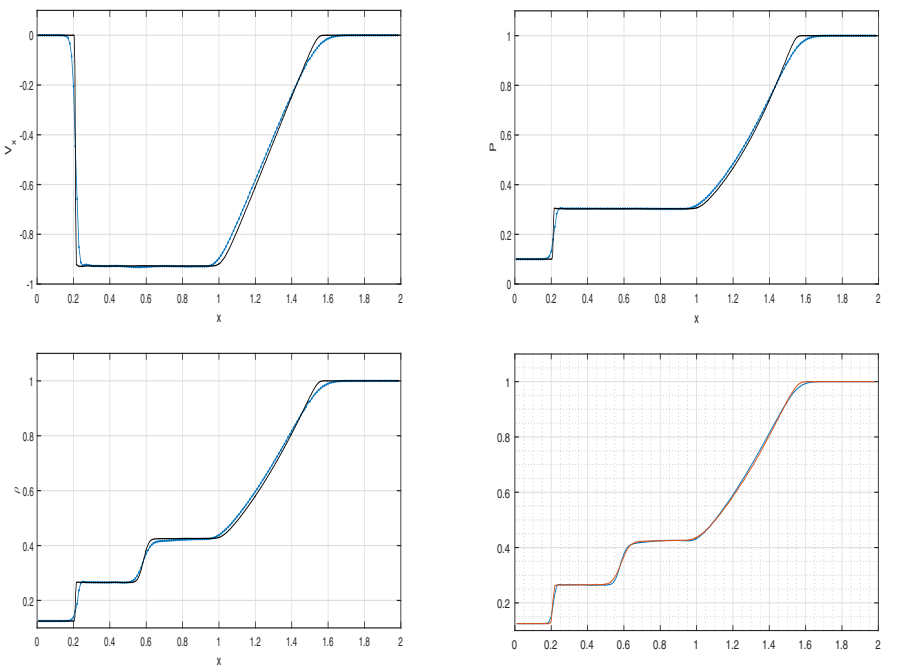

Fig. 2. Velocity, pressure and density fields (the first three figures, blue lines) of the gas in the Sod shock tube at time $T = 0.45$, compared to the reference solution given by a second-order explicit second-order local Lax-Friedrichs solver with Barth-Jespersen slope limiters (black lines) on a finer mesh with $N_x = 500$ nodes. On the last picture the density plot is shown for 2D explicit (red line) and 2D semi-implicit (blue line) solvers with the same mesh resolution.

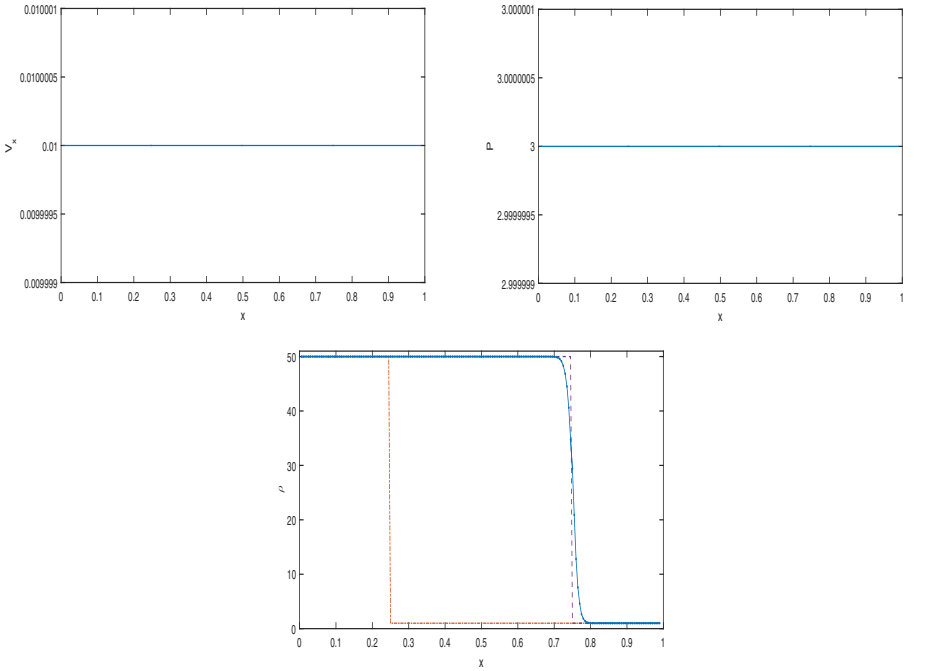

Fig. 3. Velocity, pressure and density fields of the gas in a slowly moving contact discontinuity problem at time $T = 50$. The blue lines correspond to our numerical solution, while the red dash-dotted line and dashed purple line are initial and final location of the contact discontinuity correspondingly.

The profile is smeared over ~ 10 grid points. On this problem, the semi-implicit scheme greatly outperforms the explicit solver by a factor of ~ 40. The time step τ_{adv} (11) is equal to $\sim 200\tau_{CFL}$.

The next test is the Sedov-Taylor planar blast wave solution, which was performed in a 2D cylindrical geometry. The shock front location is $R \approx \sqrt{T}$. Fig. 4 shows the density and pressure profiles at $T = 0.2$. The 2D mesh, used in the simulations, is refined at the centre of explosion by a factor of 10. It has 8756 nodes. The numerical solution shows a good agreement with analytics. In the refined central part ($r = \sqrt{x^2 + y^2} \ll 1$) of the computational domain, the sound speed is greatly exceeds the velocity, while at $r \lesssim 1$ the strong high Mach number shock wave is pronounced. At the end of the simulation, the advective time-step was about 50 times higher, than the CFL time-step τ_{CFL}. In real astrophysical conditions this ratio of time-steps could be even higher.

The latter situation is more pronounced in 3D Sedov-Taylor blast wave problem, where the semi-implicit calculation (see Fig. 5) was at least 10 times faster, than the explicit solver, due to restrictive acoustic time-step in the centre of computational domain.

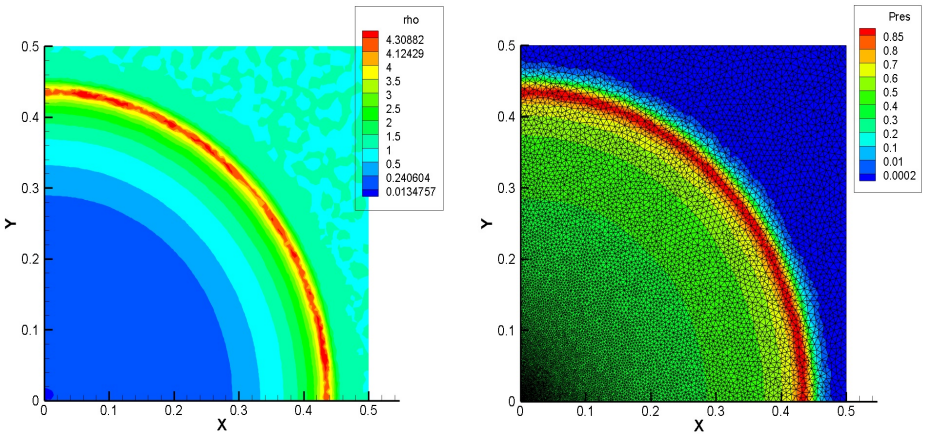

Fig. 4. Density (left) and pressure (right, together with the 2D mesh) of the gas in a planar Sedov-Taylor blast wave problem at time $T = 0.2$.

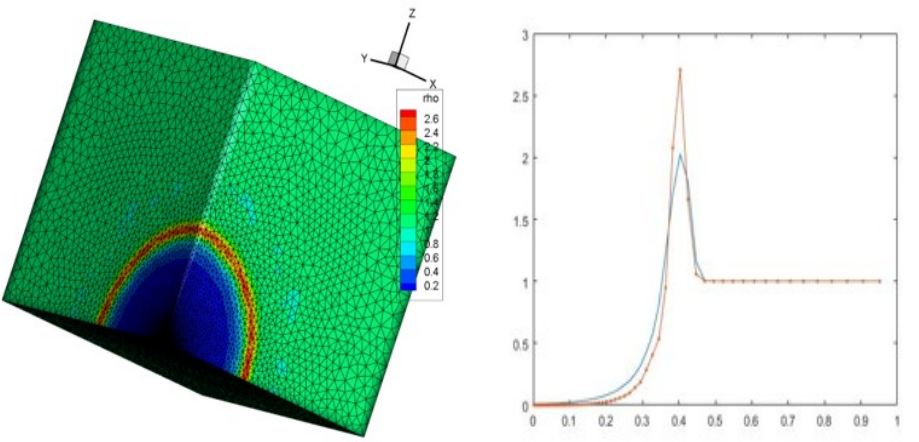

Fig. 5. Density (left) and its 1D slice (right, red line, together with the explicit solver calculation) of the gas in a 3D Sedov-Taylor blast wave problem at time $T = 0.1$.

We have tested our code including the self-gravity module and simulated a well-known problem on the spherical collapse of a pressureless star (dust collapse), which was originally considered in the paper by Colgate and White.[30] The octant-symmetric 3D results for the density at dimensionless time $T = 1.791$ are presented in Fig. 6. We use the system of units, which removes the multiplier $4\pi G$ in the Poisson equation for the gravitational potential (7). In these units the free-fall time $t_{ff} = \sqrt{\frac{3}{2}}\frac{\pi}{2} \approx 1.9238$. The initial cloud radius and density are equal to unity. We use the mesh, which is refined to the centre of the computational domain. The snapshot

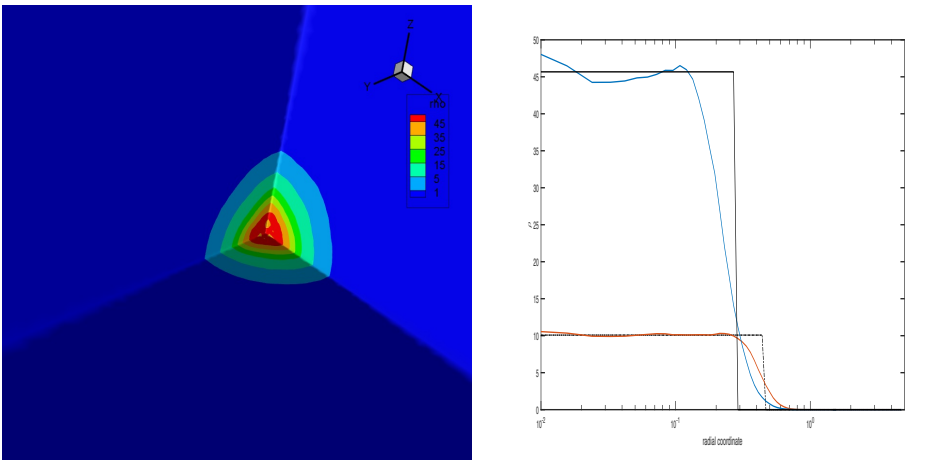

Fig. 6. Density of the gas in the dust collapse problem at time $T = 1.791$. Left panel correspond to 3D solution, while the right panel corresponds to 1D spherical plot (blue line - numerical solution, black dashed line - analytics) together with the solution at the time $T = 1.618$ (red line - numerical solution, black dotted line - analytics).

of our simulation in Fig. 6 shows a physically correct evolution of collapsing matter, although at the developed stage of the collapse the density field has a discrepancy from the analytical solution (blue line in Fig. 6, right) due to the high spatial and temporal steps. The initial spherically-symmetric conditions are also disturbed by unstructured mesh, and these disturbances tend to slight deviation from spherical symmetry.

5. Conclusion

In this paper we have constructed the semi-implicit nodal (edge-based) pressure-based solver for gravitational gas dynamics on unstructured tetrahedral meshes. The usage of the Support operators technique results to linear systems with symmetric and sign-definite matrices for the pressure system in semi-implicit gas-dynamical solver as well as for the Poisson equation for the gravitational potential. The code works efficiently both in low and high Mach number regimes, and its spatial accuracy is close to the second order. In future, we plan to apply this code to simulation of the post-bounce evolution of core-collapse supernovae. Further development of the code will be devoted to improvement of temporal accuracy, massive parallelization and inclusion of magnetic fields.

Many neutron stars propagate through the interstellar medium with supersonic velocities, and their magnetospheres interact with the interstellar medium (ISM), forming bow shocks and magnetotails. Using numerical MHD simulations, we investigated the propagation of a magnetized neutron stars through a non-uniform ISM, the interaction of the magnetospheres with the ISM and the influence of ISM density on the shape of the magnetosphere tail. We consider the interaction of magnetized neutron stars with small-scale and large-scale inhomogeneities in the ISM. We conclude that the inhomogeneities in the ISM can change the shapes of the bow shocks and magnetotails at different values of the magnetization.

Keywords: Neutron stars; magnetic field; PWN; ISM; MHD.

1. Introduction

The most dramatic bow shock nebulae are associated with the neutron stars. Pulsars emit winds of relativistic particles and magnetic fields, and are frequently surrounded by the pulsar wind nebulae. Most pulsars propagate supersonically through the interstellar medium, and their PWNs interact with the ISM, forming bow shocks and magnetotails. The bow shocks are often observed in the H_α spectral line.[2] Many interesting structures (bow shocks, very long tails, and jet-like features) are observed in the X-ray[5] and radio wavebands. A remarkable example of PWN is the Guitar Nebula discovered in 1992. It's powered by an ordinary NS, PSR B2224+65. This pulsar travels at an extraordinarily high velocity, about 1600 km/sec. It leaves behind a "tail" in the ISM, that looks like a guitar. The high-resolution observations in the H_α line show that the shape of the Nebula's head becomes wider with time. The variation in shape may be connected with the variation in the density of the ISM.[4]

Many of the PWN show irregularities in their shapes in the X-ray band, as well as very long tails (see review by Kargaltsev et al.[7]). Longer tails are observed in the radio band.[8] Two examples of PWN, observed in the X-ray and radio bands are presented on the Figure 1: the PWN associated with the pulsar PSR J1509-5850

and the Mouse Nebula, powered by the pulsar PSR J1747-2958.[6] These PWNs have extended tails in the X-ray band (red lines), and longer tails in the radio-band (blue lines). One can see that both the heads of the PWN and their tails have different unevenness in shapes.

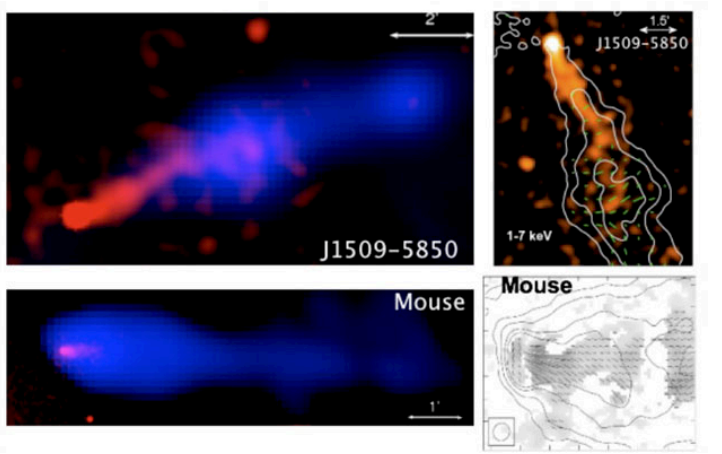

Fig. 1. X-ray and radio images of the very long pulsar tails, by Kargaltsev and Pavlov.[6] Right panels show the radio contours and the direction of the magnetic field. The red and blue colours in the left panels correspond to X-ray and radio, respectively.

When a pulsar or an isolated neutron star propagates supersonically through the ISM, then the PWN or magnetosphere of isolated star interacts with the ISM, forming a bow shock and magnetotails. In the bow shock, the energy of accelerated particles may dominate over magnetic energy. However, in the magnetotails, the magnetic energy may be comparable to or larger than the energy of the particles. Long and magnetically dominated magnetotails can to form in the PWN. They may be visible, if the accelerated particles propagate into the magnetotails, or invisible. In the simulation of the supersonic PWN, it is important to take into account both, the matter and the magnetic field components of the PWN.

Supersonic propagation of pulsars and isolated neutron stars through the ISM has been studied in a number of axisymmetric non-relativistic and relativistic hydrodynamic simulations (e.g., Bucciantini,[3] Barkov[1]). Most of the these simulations of the bow shocks propagating through an inhomogeneous ISM medium were performed in hydrodynamic approximation. Early we performed MHD simulation of supersonic propagation of magnetized isolated neutron stars in the homogeneous ISM.[9,10] Then we started MHD simulation of the bow shock PWN propagating through a non-uniform ISM.[12] Our aim is to consider this problem in axisymmetric MHD simulations at different magnetization values of the pulsar wind.

2. Model

We performed MHD simulations to investigated the supersonic propagation of magnetized isolated neutron star and PWNs through the non-uniform ISM. We used an axisymmetric, resistive MHD code, that incorporates the methods of local iterations and flux-corrected-transport.[13] The flow is described by the resistive MHD equations:

$$\frac{\partial \rho}{\partial t} + \nabla\cdot(\rho\ \mathbf{v}) = 0\ ,$$

$$\rho\frac{\partial \mathbf{v}}{\partial t} + \rho(\mathbf{v}\cdot\nabla)\mathbf{v} = -\nabla p + \frac{1}{c}\mathbf{J}\times\mathbf{B} + \mathbf{F}^g\ ,$$

$$\frac{\partial \mathbf{B}}{\partial t} = \nabla\times(\mathbf{v}\times\mathbf{B}) + \frac{c^2}{4\pi\sigma}\nabla^2\mathbf{B}\ ,$$

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \nabla\cdot(\rho\varepsilon\mathbf{v}) = -p\nabla\cdot\mathbf{v} + \frac{\mathbf{J}^2}{\sigma}\ . \tag{1}$$

We assume axisymmetry ($\partial/\partial\phi = 0$), but calculate all three components of $\mathbf{v}$ and $\mathbf{B}$. The equation of state for an ideal gas, $p = (\gamma-1)\rho\varepsilon$, where $\gamma = 5/3$ is the specific heat ratio and ε is the specific internal energy of the gas. The equations incorporate Ohm's law $\mathbf{J} = \sigma(\mathbf{E}+\mathbf{v}\times\mathbf{B}/c)$, where σ is the electric conductivity. The associated magnetic diffusivity, $\eta_{\rm m} \equiv c^2/(4\pi\sigma)$, is assumed to be a constant. The gravitational force, $\mathbf{F}^g = -GM\rho\mathbf{R}/R^3$, is due to the star because the self-gravity of the accreting gas is negligible.

We use a cylindrical, inertial coordinate system (r, ϕ, z) with the $z-$axis parallel to the star's dipole moment μ and rotation axis $\mathbf{\Omega}$. The vector potential $\mathbf{A}$ is calculated so that automatically $\nabla\cdot\mathbf{B} = 0$ at all times. The intrinsic magnetic field of the star is taken to be an aligned dipole, with vector potential $\mathbf{A} = \mu\times\mathbf{R}/R^3$. A description of numerical model in detail can be found in.[11,12]

We measure length in units of the Bondi radius $R_B \equiv GM/c_s^2$, with c_s the sound speed at infinity, density in units of the density of the interstellar medium ρ, and magnetic field strength in units of B_0 which is the field at the pole of the numerical star. We measure time in units of $t_0 = (Z_{max} - Z_{min})/v_\infty$, which is the crossing time of the computational region with the star's velocity, v_∞.

3. Propagation of magnetized isolated neutron stars through non-uniform ISM

First, we consider a supersonic propagation of magnetized, isolated old neutron stars (IONS) through the non-uniform ISM, in particular through the a dense and cold cloud. Simulations were done for a number of values of the star's magnetic moments μ, the velocity of the star v and the density of the ISM cloud ρ. We received pictures

of the flow of matter for different parameters μ, v and ρ. For all used parameters a magnetospheric radius of the star is much larger than accretion radius $R_m >> R_{acc}$, so that matter cannot accretes onto neutron star surface. This case corresponds to the georotator regime for isolated neutron stars.

When a neutron star moving through an uniform medium with the density ρ_0, incoming matter forms a conical shock wave around the star. The magnetic field lines stretches in the direction of flow of matter out of the magnetospheric radius R_m and form a long tail of the magnetosphere. A picture of the matter flow one can see on top panel of the Figure 2. We observed a reconnection of magnetic field lines in the tail. Then a star passes through the non-uniform medium which is a cold and dense cloud, and the shape of the bow shock and the tail of the magnetosphere varies depending on the density and temperature of the ISM. The shape of the bow shock changes its width and the shape of the magnetotail gets multiple "bumps".

A typical example of the matter flow is represented on Figure 2. In this case Mach numbers $\mathcal{M} = v/c_s = 6$ and density of the cloud $\rho/\rho_0 = 6$. A central region of calculation at moments $t_1 = 0$, $t_2 = 0.33t_0$, $t_3 = 0.66t_0$ and $t_4 = 1.0t_0$ is shown, when t_0 is the crossing time of the computational region. On the left panel the background represents the logarithm of the density and solid lines are magnetic field lines. The length of the arrows is proportional to the poloidal velocity of the matter. We can see that with increasing density of the cloud the width of the bow shock and width of the tail decreases. Then with decreasing density of of the cloud the magnetosphere recovers its shape. Magnetic field lines are compressed by the dense incoming flow and form new reconnections in the tail. On the right panel the background represents the logarithm of the temperature. We can see that with decreasing temperature of the cloud the width of the bow shock and width of the tail decreases. Then with increasing temperature of of the cloud the magnetosphere recovers its shape.

Left panel on Figure 3 shows a density distribution across the magnetotail on the distance $z = 0.5$ and at the same time $t = 0.33t_0$, A solid line represents an uniform medium with constant density ρ_0. A maximum of the density correspond to the distance $r = 0.37$ approximately. A dotted line represents the cloud density $\rho/\rho_0 = 3$. A maximum of the density correspond to $r = 0.26$. A dashed line represents the cloud density $\rho/\rho_0 = 6$. A maximum of the density correspond to $r = 0.20$. We can see that with an increase in the density of the ISM the tail of the magnetosphere becomes more narrow and hollow.

Right panel on Figure 3 shows a temperature distribution across the magnetotail on same distance $z = 0.5$ and at the same time $t = 0.33t_0$. The solid line represents an uniform medium with constant density ρ_0. The dotted line represents the cloud density $\rho/\rho_0 = 3$ and a dashed line represents the cloud density $\rho/\rho_0 = 6$. For all three values of the density, the temperature is maximum at the Z axis, then decreases along R axis and forms a "step", and then becomes a constant. We can see that with a decrease in the temperature of the ISM the tail of the magnetosphere becomes more narrow and hollow.

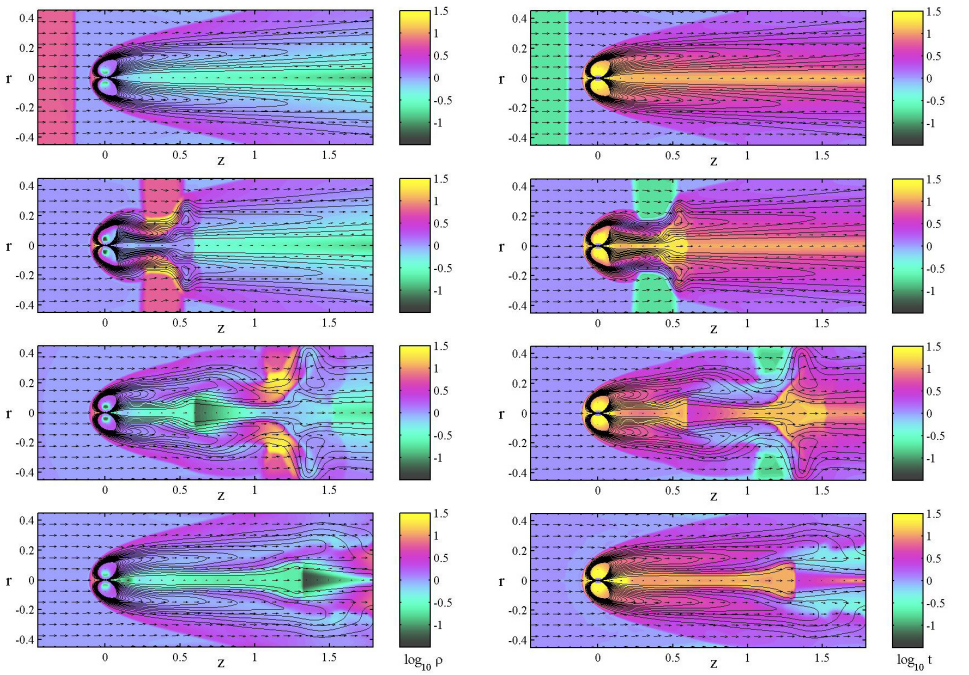

Fig. 2. The propagation of a neutron star with a magnetic field through the dense and cold cloud of interstellar medium. Mach numbers $\mathcal{M} = 6$ and dencity of the cloud $\rho/\rho_0 = 6$. Central region of matter flow at moments $t_1 = 0$, $t_2 = 0.33t_0$, $t_3 = 0.66t_0$ and $t_4 = 1.0t_0$ is shown. On the left panel the background represents the logarithm of the density the background represents the logarithm of density. Solid lines are magnetic field lines. The length of the arrows is proportional to the poloidal velocity. On the right panel the background represents the logarithm of the temperature.

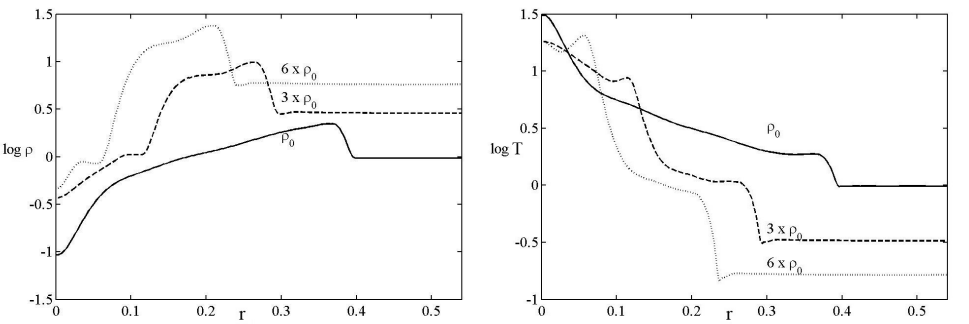

Fig. 3. Left panel: Distribution of the density across the magnetotail at the same time $t = 0.33t_0$ on the distance $z = 0.5$. Right panel: Distribution of the temperature across the magnetotail at the same time $t = 0.33t_0$ on the distance $z = 0.5$.

4. Propagation of PWN through the non-uniform ISM

We investigate the propagation of a PWN through an ISM with an inhomogeneous matter distribution. Observations point to large and small-scale inhomogeneities, and therefore we consider two types of imhomogeneities: (1) large-scale clouds, which are much larger than the size of the bow shock, (2) small-scale clouds, whose size is comparable with the width of the bow shock.

4.1. *Large-scale cloud*

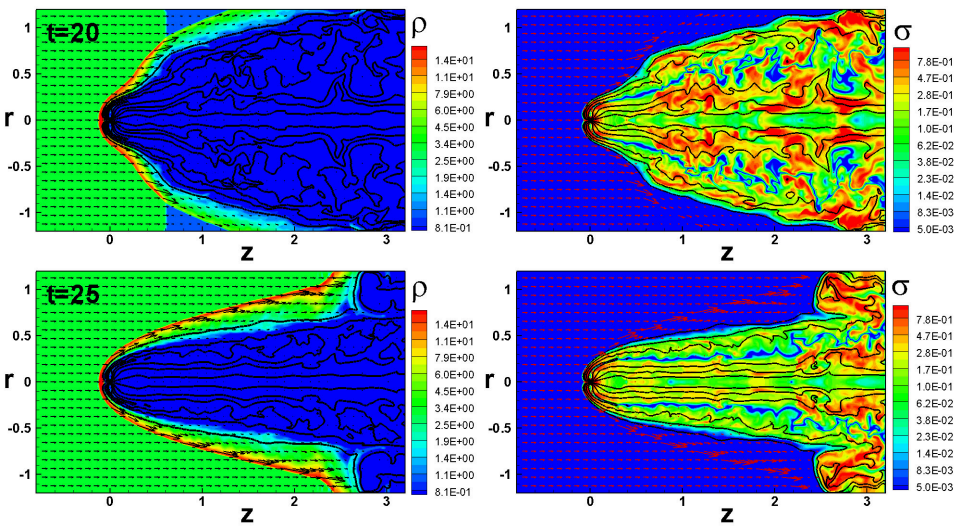

Fig. 4. *Left panels:* Propagation of a PWN of moderate magnetization through a large cloud of density $\rho_{\rm cloud} = 3\rho_0$ at two moments in time. The background represents the logarithm of density. The solid lines are magnetic field lines. *Right panels:* Same, but the background shows magnetization σ.

Fig. 4 shows an example of propagation of a large cloud of density $\rho_{\rm cloud} = 3\rho_0$ through the PWN in the model with a moderate magnetization. The left panels show that the cloud compresses the bow shock and the bow shock has a smaller opening angle (the Mach cone). The cloud is in pressure balance with the rest of the ISM, so that the sound speed in the cloud is three times lower than in the rest of the ISM. Therefore, the Mach number of the star inside the cloud is $M_{\rm new} = v_p/c_s = 3M_{\rm old} = 60$. This is why we observe a smaller opening angle of the Mach cone. The bottom left panel shows that after entering the cloud, the KH instability develops in the region of CD. This is an expected result: at larger Mach number, there is a larger difference between velocities of matter from two sides of the contact discontinuity. The right panels of Fig. 4 show that the region of high magnetization becomes more narrow after the passage of the cloud. Also, the region

of high magnetization becomes less homogeneous (more patchy) due to the action of the KH instability. These simulations demonstrate that propagation through a large-scale cloud leads to a reconstruction of the magnetic field in space and to change in the value of the magnetic field. The tangled magnetic field may reconnect and the magnetic energy can be converted to the energy of accelerated particles and radiate. This may be a possible reason for the re-brightening of PWN magnetotails observed in X-ray.[7]

4.1.1. *Small-scale inhomogeneities*

Our simulations show that the KH instability frequently forms at the CD and produces some wavy structure of the bow shock. However, a wavy structure could also result from the interaction of the bow shock with the small-scale inhomogeneities in the ISM. To model the interaction of the small-scale inhomogeneities with the bow shock, we took models where the KH instability is weak and does not modify the shape of the bow shock.

We model small-scale inhomogeneities as a set of small clouds with Gaussian density distribution, with the maximum density of $\rho_{\max}$ and half-width of $\Delta r = 0.2$. To keep the pressure balance between the clouds and the rest of the ISM, we take the temperature in the cloud to be $T_{\rm cloud} = T_{\rm ISM} * \rho_0/\rho_{\rm cloud}$. We experimented with clouds of different densities, and found that the shape of the bow shock varies significantly if the density in the cloud is $\rho_{\rm cloud} \gtrsim 2\rho_0$. At $\rho_{\rm cloud} = 2\rho_0$, a wavy structure starts to become visible, while at $\rho_{\rm cloud} = 3\rho_0$, the bow shock changes its local shape significantly.

Fig. 5 shows a wavy variation of density in the bow shocks that appears after the propagation of clouds of density $\rho_{\rm cloud} = 3\rho_0$ in the models with low and moderate magnetizations. Such an interaction with small-scale inhomogeneities may explain the wiggles in the shape of the bow shock observed in PSR J0742-2822 (see Fig. 1). In PSR J0742-2822, the estimated stand-off distance is $R_{\rm sd} \approx 4.2 \times 10^{16} d/2{\rm kpc}$ cm. The size of clouds in our model $R_{\rm cl} \approx (2-4)R_{\rm sd} \approx (0.8-1.6) \times 10^{17} d/2{\rm kpc}$ cm. It may correspond to one of scales in turbulent ISM matter. We should note that an alternative explanation of these small-scale features in bow shocks can be connected with the KH instability. Currently, we cannot distinguish between these two mechanisms.

5. Conclusions

We performed MHD simulations of the supersonic propagation of magnetized neutron star and bow shock PWN propagating through a uniform and non-uniform ISM at different levels of magnetization. Our main findings are the following:

The fluctuations in the density or temperature leads to a change in shape of bow shock and the tail of the magnetosphere structure of the neutron star. With an increase in the density of the ISM the bow shock nebulae and the tail of the

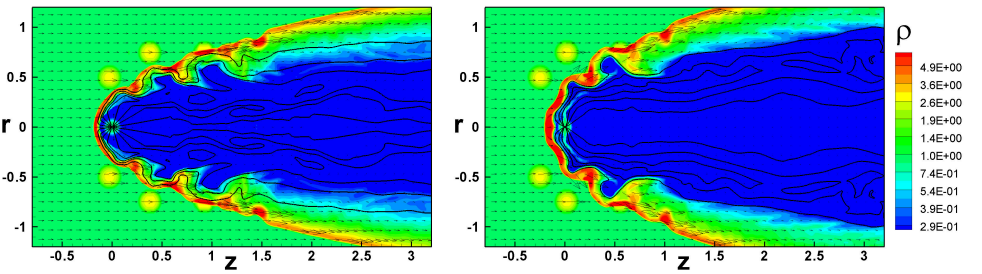

Fig. 5. Interaction of the bow shock with small-scale clouds of maximum density $\rho_{\rm cloud} = 3\rho_0$ in the model with low σ (left panel) and in the model with medium σ (right panel). The background represents the logarithm of density. The solid lines are magnetic field lines.

magnetosphere become narrow and vice versa. A temperature dependence is opposite. With an increase in the temperature of the ISM the bow shock nebulae and the tail of the magnetosphere become wider. A presence of "bubbles" or "bumps" in the shape of bow shock and the magnetotail most likely indicates on the changing density or temperature of the ISM.

The interaction of the bow shock with a large-scale, dense cloud leads to the compression of the bow shock and the formation of a new bow shock with a smaller opening angle. The level of compression (the ratio between the original and final widths of the bow shock) is approximately the same for PWN of different magnetization.

The interaction of the bow shock with the small-scale inhomogeneities in the ISM leads to a wavy structure in the bow shock. The amplitude of the "waves" increases with the ratio $\rho_{\rm cloud}/\rho_0$. For example, variation in the shape of the bow shock of pulsar PSR J0742-2822 can be explained by the propagation through a series of clouds with a density ratio of $\rho_{\rm cloud}/\rho_0 \approx 3$. Small-scale clouds produce wavy shapes of the bow shocks in PWN of different magnetization.

A solution of the Boltzmann equation is obtained for a magnetized plasma with arbitrary degenerate electrons and nondegenerate nuclei. For the arbitrary and non-degenerate electrons kinetic coefficients are obtained by solving Boltzmann equation by Chapman-Enskog method of successive approximations. The expressions have a considerably more complicated dependence on magnetic field than analogous dependences derived in previous publications on this subject.

Keywords: Neutron stars; magnetic field; kinetics.

1. Introduction

The transfer of heat and charge in a magnetized nondegenerate plasma plays an important role in describing its behavior both under laboratory conditions and in the structure and evolution of stars. Kinetic coefficients such as thermal conductivity, diffusion, thermal diffusion and diffusional thermal effect determine heat fluxes and current densities. Knowing the distribution of heat and current, one can calculate the magneto-thermal evolution, the distribution of the magnetic field and temperature over the surface of stars, or describe the behavior of plasma obtained and accelerated in laboratory conditions.

Here is presented results of solving Boltzmann equation by two methods. For arbitrary degeneracy case we used the Chapman–Enskog method of successive approximations. Tensors of thermal diffusion, diffusion and diffusional thermal effect are found by using an expansion of three polynomials.[1,2] In Lorentz approximation Boltzmann equation has an exact solution. It is shown by using Lorentzian gas as an example that the method has good convergence to the exact solution.

2. General equations

We use the Boltzmann equation for arbitrary-degenerate electrons in a magnetic field, taking into account the interaction of electrons with ions and with each other. Boltzmann equation describing the change in the electron distribution function f

over time in the presence of electric and magnetic fields, written as[3,4]

$$\frac{\partial f}{\partial t} + c_i \frac{\partial f}{\partial r_i} - \frac{e}{m_e}\left(E_i + \frac{1}{c}\varepsilon_{ikl} c_k B_l\right)\frac{\partial f}{\partial c_i} + J = 0. \quad (1)$$

Here $(-e), m_e$ — charge (negative) and electron mass, E_i, B_i — electric field strength and magnetic induction, ε_{ikl} completely antisymmetric Levi - Civita tensor, c — the speed of light. The collision integral J for nondegenerate electrons and singly charged ions, according to,[5–8] is written in the form:

$$J = J_{ee} + J_{eN} = \int [f f_1 - f' f'_1] g_{ee} b \, db \, d\varepsilon dc_{1i} + \int [f f_I - f' f'_I] g_{eI} b \, db \, d\varepsilon dc_{Ii}. \quad (2)$$

Here the impact parameter b and ε are the geometric parameters of the collision of particles with relative speeds g_{ee}, g_{eI}.

Integration in the electronic part of the collision integral in (2) is performed over the phase space incident particles (dc_{1i}) and their physical space ($b \, db \, d\varepsilon$).[5] Post-collision velocity functions are marked with strokes.

The transfer equations for the electron concentration total momentum and energy of electrons in a two-component mixture of electrons and kernels can be obtained in the usual way from Boltzmann equations in quasineutral plasma[3–5,9]

Here and in what follows, we assume the average mass velocity to be equal to the average ion velocity $c_{0i} = \langle c_{Ii} \rangle$, we also consider electric current and heat flux only from electrons.

The Boltzmann equation can be solved by using the Chapman-Enskog method of successive approximations.[5] This method is used when the distribution functions are close to their values in the state of thermodynamic equilibrium, and deviations are considered in a linear approximation. In a first approximation, we look for the distribution function f in the form $f = f_0[1 + \chi(1 - f_0)]$

The χ function allows the solution to be represented as:[1]

$$\chi = -A_i \frac{\partial \ln T}{\partial r_i} - n_e D_i d_i \frac{G_{5/2}}{G_{3/2}}, \quad (3)$$

where diffusion vector d_i:

$$d_i = \frac{\rho_N}{\rho}\frac{\partial \ln P_e}{\partial r_i} - \frac{\rho_e}{P_e}\frac{1}{\rho}\frac{\partial P_N}{\partial r_i} + \frac{e n_e}{P_e}\left(E_i + \frac{1}{c}\varepsilon_{ikl} c_{0k} B_l\right). \quad (4)$$

$G_n = \frac{1}{\Gamma(n)} \int_0^\infty \frac{x^{n-1} dx}{1 + exp(x - x_0)}$, $x_0 = \frac{\mu}{kT}$, here G_n is Fermi integral and μ is chemical potential. The functions A_i and D_i determine the heat flux and diffusion.

The collision integral similar to J_{ee} from (2) for strongly degenerate neutrons in nuclear matter is given in,[8] see also.[11] In the presence of non-degenerate heavy nuclei and highly degenerate neutrons, the contribution of collisions between them to the heat transfer and diffusion coefficients is negligible compared to neutron-nucleus

collisions. The same situation holds for highly degenerate electrons. Therefore, for strongly degenerate electrons, the Lorentz approximation, taking into account collisions between light and heavy particles, is asymptotically accurate. Therefore, we can neglect J_{ee} compared to J_{eN}, and we can equate $J = J_{eN}$ in (2). In this case Boltzmann equation is solved in Lorentz approximation as it was shown in[1,12] and the components of four tensors of kinetic coefficients are calculated.

General expressions for the heat flux q_i, and the average directional (diffusion) electron velocity $\langle v_i \rangle$ are given by

$$q_i = -\lambda_{ij} \frac{\partial T}{\partial x_j} - n_e \nu_{ij} d_j = q_i^{(A)} + q_i^{(D)}, \tag{5}$$

$$\langle v_i \rangle = -\mu_{ij} \frac{\partial T}{\partial x_j} - n_e \eta_{ij} d_j = \langle v_i^{(A)} \rangle + \langle v_i^{(D)} \rangle, \tag{6}$$

where λ_{ij} and ν_{ij} are the tensors of thermal conductivity and diffusional thermal effect, and μ_{ij} and η_{ij} — thermal diffusion and diffusional tensors, respectively.[11,13] The indices (A) and (D) determine the heat fluxes and diffusion velocities of electrons determined by the temperature gradient $\partial T/\partial x_j$, and the diffusion vector d_j, respectively.

The method for finding the coefficients of the thermal conductivity tensor λ_{ij} for arbitrary degeneracy is described in detail in the work,[1] where analytical expressions are found for them. For strongly degenerate electrons, the coefficients of thermal diffusion, diffusion and diffusion thermal effect in the Lorentz approximation are found in.[12]

3. Exact solution in Lorentz approximation

The Lorentz approximation for solving the kinetic equation is used when the mass of light particles much less than the mass of heavy particles, and electron-electron collisions can be neglected. So we can neglect J_{ee} in comparison with J_{eN}, and we can equate $J = J_{eN}$ in the (2). In this approximation, the linearized Boltzmann equation has exact solution. This approximation works well for transport in metal, where strong electron degeneracy makes it possible to neglect electron-electron collisions. The Lorentz approximation can be used to check the approximate polynomial solution, since it makes it possible to trace the convergence of the approximate solution to the exact one with increasing degree of the polynomials. Solution in Lorentz's approximation was considered in different approaches,[5,16,17] see also.[15] For thermal conductivity, the convergence of a polynomial solution to an exact one was considered in,[1] if we consider only the heat flux connected with the temperature gradient, at zero value of the diffusive vector d_i from (5), (6) than we obtain the expression

for the heat flux for the case $B = 0$ from[15] as:

$$q_i^A = -\frac{640k}{\Lambda}\frac{m_e(kT)^4}{n_N Z^2 e^4 h^3}\left(G_5 - \frac{1}{2}\frac{G_{5/2}}{G_{3/2}}G_4\right)\frac{\partial T}{\partial r_\mathrm{i}}. \tag{7}$$

In the limiting cases the coefficient in (7) is reduces to

$$\begin{aligned}\lambda_e^l &= \frac{40\sqrt{2}}{\pi^{3/2}\Lambda}k\frac{n_e}{n_N}\frac{(kT)^{5/2}}{\mathrm{e}^4 Z^2\sqrt{m_e}} = \frac{320}{3\pi}\frac{k^2 T n_e}{m_e}\tau_{nd} \quad (ND)\\ &= \frac{5}{64\Lambda}\frac{k^2 T n_\mathrm{e}^2 h^3}{m_\mathrm{e}^2 n_N Z^2 e^4} = \frac{5\pi^2}{6}\frac{k^2 T n_e}{m_e}\tau_d \quad (D).\end{aligned} \tag{8}$$

Average frequency of electron-ion collisions ν_{ei} in[14] in the limiting case of non-degenerate electrons is written as

$$\begin{aligned}\nu_{ei} &= \frac{4}{3}\sqrt{\frac{2\pi}{m_e}}\frac{Z^2\mathrm{e}^4 n_N\Lambda}{(kT)^{3/2}} \qquad (ND)\\ &= \frac{32\pi^2}{3}m_e\frac{Z^2\mathrm{e}^4\Lambda n_N}{h^3 n_\mathrm{e}} \qquad (D).\end{aligned} \tag{9}$$

Here indices (ND) and (D) determine non-degenerate and degenerate cases respectively.

Using the same approach as in,[1] we can find an exact solution in explicit form for the Lorentz approximation for the case $B = 0$:

$$\langle v_i^A\rangle = -\frac{128k}{\Lambda}\frac{m_e(kT)^3}{n_N n_e Z^2 e^4 h^3}\left(G_4 - \frac{5}{8}\frac{G_{5/2}}{G_{3/2}}G_3\right)\frac{\partial T}{\partial r_\mathrm{i}}, \tag{10}$$

$$\langle v_i^D\rangle = -n_e\frac{G_{5/2}}{G_{3/2}}\eta_{ij}d_j = \frac{32}{\Lambda}\frac{m_e(kT)^4}{n_e n_N Z^2 e^4 h^3}\frac{G_{5/2}}{G_{3/2}}G_3 d_i, \tag{11}$$

$$q_i^D = -n_e\frac{G_{5/2}}{G_{3/2}}\nu_{ij}d_j = \frac{128}{\Lambda}\frac{m_e(kT)^5}{n_N Z^2 e^4 h^3}\frac{G_{5/2}}{G_{3/2}}G_4\frac{\partial T}{\partial r_\mathrm{i}}. \tag{12}$$

In limiting cases, the coefficient in (10) reduces to

$$\mu_e^l = \frac{12k}{\pi^{3/2}\Lambda n_N}\frac{(kT)^{3/2}}{\mathrm{e}^4 Z^2\sqrt{2m_e}} = \frac{16k}{m_e\pi}\tau_{nd} \quad (ND), \tag{13}$$

and the coefficients in (11), (12) are reduced to

$$\eta_e^l = -\frac{32}{3\pi}\frac{kT}{n_e m_e\pi}\tau_{nd}, \qquad \nu_e^l = -\frac{128(kT)^2}{3\pi m_e}\tau_{nd}. \tag{14}$$

The exact formulas in the Lorentz model are used by[5] to estimate the accuracy of the polynomial approximation. The contribution of electron-electron collisions to the thermal diffusion coefficient for different Z can be estimated from the graph

of normalized three-polynomial thermal diffusion coefficients in the direction perpendicular to the magnetic field, introducing the quantity $Q_\perp^{(3l)}$, $U_\perp^{(3l)}$ and $W_\perp^{(3l)}$ defined as:

$$Q_\perp^{(3l)} = \frac{\mu_{nd}^{(13)}}{\mu_{e,nd}^{l}}, \qquad U_\perp^{(3l)} = \frac{\eta_{nd}^{(13)}}{\eta_{e}^{l}}, \qquad W_\perp^{(3l)} = \frac{\nu_{nd}^{(13)}}{\nu_{e}^{l}}. \tag{15}$$

Here $\mu_{e,nd}^{l}$ is taken from the top line in (13), $\nu_{e,nd}^{l}$ and $\eta_{e,nd}^{l}$ are taken from (14). Curves for different Z, including $Z = \infty$, related to Lorentz approximation are shown in Fig. (1a) for thermodiffusion, on Fig. (1b) for diffusional thermal effect, on Fig. (2a) for diffusion and on Fig. (2b) thermal conductivity plots[1] are presented for comparison.

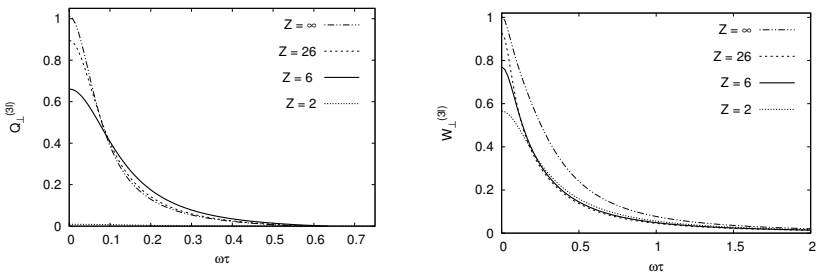

Fig. 1. On the (a) figure are presented the plots of the values of $Q_\perp^{(3l)}$ as functions of $\omega\tau$ in the three-polynomial approximation for nondegenerate plasma of helium ($Z = 2$), carbon ($Z = 6$), iron ($Z = 26$) in comparison with Lorentz plasma, formally corresponding to $Z = \infty$. The deviation from the Lorentzian plasma is due to the contribution of electron-electron collisions. On the right-side figure are plots of the values of the diffusional thermal effect $W_\perp^{(3l)}$ as a function of $\omega\tau$.

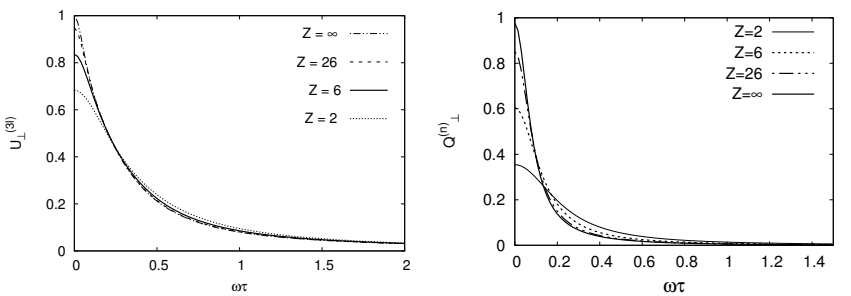

Fig. 2. On tthe (a) figure are plots of diffusion values of $U_\perp^{(3l)}$ as functions of $\omega\tau$ in the three-polynomial approximation for nondegenerate plasma of helium (Z=2), carbon (Z=6), iron (Z=26), for comparison with the Lorentz plasma, formally corresponding to $Z = \infty$. On the (b) figure are plots for heat conductivity coefficient from[1] as a function of $\omega\tau$, here: $Q_\perp^{(3l)} = \lambda_\perp^{(3)}/\lambda_\parallel^{lor}$.

4. Partially degenerate electrons

To examine the effect of degeneracy on the convergence of the polynomial approximation to the exact value, we compare the coefficients calculated by the method of successive approximations with the coefficients obtained as an exact solution in the Lorentz approximation. In a partially degenerate plasma, it is enough to simply calculate collision integral for electron-ion at $\mu = 0$ - chemical potential with the degeneracy level $DL = \epsilon_{fe}/kT = 1.011$. When compared with the exact solutions for heat conductivity and thermaldiffusion, obtained by the Lorentz method, the 3-polynomial solution for thermal conduction differs from the exact solution by about 13%, for thermal diffusion - by 7%. For non-degenerate electrons in the 3-polynomial approximation, the coefficient of thermal conductivity differs by 2.2%, and thermal diffusion by 1.3%.

For partial degeneracy, it is found that the 3-polynomial solution for diffusion differs from the exact one by 2.6%. For diffusion thermal effect: 3-polynomial by about 8%. For the nondegenerate case, the 3-polynomial approximation differs by 0.14% from the exact one for diffusion, and by 0.38% for the diffusion thermal effect. Detailed description of the calculations can be found in.[1,2] The accuracy of approximation by a series of orthogonal functions decreases with an increase in the degree of degeneracy.

5. Discussion

In this work, the tensors of the kinetic coefficients of diffusion, thermal diffusion, and diffusion thermal effect are found for nondegenerate electrons in a nonquantizing magnetic field. Tensors are obtained from the solution the kinetic Boltzmann equation by the classical Chapman–Enskog method using the expansion into Sonin polynomials and taking into account two and three terms of the expansion. Electron-ion and electron-electron collisions are taken into account. Tensors are written for an arbitrary local direction magnetic field and temperature gradient in the Cartesian coordinate system according to.[4]

Using the example of the Lorentz approximation, it was shown that the accuracy of the approximation by a series of orthogonal functions, similar to Sonin's polynomials, decreases with increasing degree of degeneracy.

For non-degenerate electrons, disregarding electron-electron collisions, the value of the thermal diffusion coefficient in the two-polynomial approximation underestimates the exact solution obtained in the Lorentz approximation at $B = 0$ by 26%, and in the three-polynomial approximation it overestimates by approximately 1%. For partially degenerate electrons, at $\mu = 0$, the two-polynomial solution underestimates the exact one by 28%, and the three-polynomial one underestimates the exact one by 7%. It should be noted that electron-electron collisions further decrease the coefficient values.

The diffusion coefficient value obtained from the two-polynomial approximation underestimates the exact solution by about 4%, and the three-polynomial solution

underestimates the exact solution by 0.14% for nondegenerate electrons. In the case of partial degeneracy, the diffusion obtained from the two-polynomial solution underestimates the exact one by 0.4%, and the one obtained from the three-polynomial solution overestimates the exact one by 3%.

The diffusion thermal effect coefficient for nondegenerate electrons in the two-polynomial approximation underestimates the exact solution by 12%, and in the three-polynomial approximation overestimates the exact solution by 0.4%. With partial degeneracy of electrons, the two-polynomial solution underestimates the exact solution by 2.5%, and the three-polynomial solution overestimates the exact solution by 8%.

The Chapman–Enskog method can be used for a sufficiently dense gas (plasma), where the time between particle collisions is the smallest value among other characteristic times. In the presence of a magnetic field, in addition to the lifetime of the system and the characteristic time of changes, in the plasma parameters rotation time in the Larmor circle is added $\tau_L = 2\pi/\omega$. This time must be much less than τ, which leads to a condition under which the Chapman–Enskog method can be used, in the form $\omega\tau \ll 2\pi$. Therefore, this work can be successfully applied for $\omega\tau \lesssim 1$, and for large $\omega\tau$ only qualitative estimates can be obtained.

The coefficients can be used for calculation of heat fluxes and electric current in white dwarfs, on the surface of magnetized neutron star, as well as in the magnetized matter accreting to the magnetized neutron star or for describing plasma obtained in laboratory conditions.

Modeling of magnetic fields of accretion discs, using no-z- and RZ-approximations

M. V. Pashentseva[1], E. A. Mikhailov[1,2]
[1] *Faculty of Physics, Lomonosov Moscow State University, Moscow, Russia*
[2] *P.N.Lebedev Physical Institute, Russia*

The evolution of the accretion discs surrounding different compact objects (such as white dwarfs, neutron stars and black holes) is closely connected with the magnetic fields and their features. It is highly likely that the magnetic field generation is connected with the dynamo action. As for the dynamo, we have a lot of specific models which have been constructed for different astrophysical objects. For accretion discs we can take the approaches that were used for galactic discs which have nearly the same shape. There are two main models. The first one is connected with no-z approximation which is based on the fact that the discs is quite thin. RZ-model describes the discs with large half-thickness and can be used for the objects where we should study the vertical structure of the magnetic field. Here we show the results obtained for the accretion discs which used both of these approaches and compare the results.

Keywords: Magnetic fields, accretion discs, dynamo theory, no-z model, RZ-model.

1. Introduction

The accretion discs surrounding different compact objects (such as black holes, neutron stars and white dwarfs), play an important role in different branches of astrophysics. Their structure and features is closely connected with the magnetic fields, which should have a strong influence on the motions in the disc.[1] Nowadays there are different approaches that describe the origin of magnetism of such objects. First of all, we should mention the transition of the field which is connected with the accreting matter.[2] Also there are some models which describe the field as a result of interaction between the central object and the accretion disc. However, observational data and theoretical models show that the field is highly likely to be generated by the dynamo mechanism.[3–5]

The dynamo mechanism is widely used to study the magnetic field evolution in different objects such as the Sun, stars, galaxies etc. The equations of the dynamo are quite difficult to be solved in explicit form. So there are different specific two-dimensional models which take into account geometrical features of the celestial body and allow us to simplify the problem. As for the galaxies, there is so-called no-z approximation,[6] which is based on the fact that the galactic disc is quite thin. So some of the partial derivatives can be changed by the algebraic expressions, and the z-component of the field can be taken from the solenoidality condition. This approach can be used to study magnetism of the accretion discs,[7,8] because their shape is quite close to the one of the galaxies. As for thick galactic discs, we can

take the RZ-model, which uses another basic assumptions.[9] In this paper we study the magnetic field using this model, too. After that we compare the given results.

2. Dynamo

The dynamo is connected with transition of the energy of turbulent motions to the energy of the magnetic field.[10] If we are speaking about the large-scale magnetic field, it is based on two main effects. First of all, it is the alpha-effect which is connected with the helicity of the turbulent motions. It is connected with the rotation of the magnetic field. The second process is associated with the differential rotation which is caused by changing angular velocity (most of celestial bodies rotate with a non-solid law). They compete with the dissipative effects which destroy the large-scale structures of the field. So, dynamo is a threshold process: the field can grow only if the alpha-effect and differential rotation are more intensive than the dissipation. Otherwise the field will decay and the dynamo won't be able to generate significant fields.

The evolution of large-scale component of the field is described by the Steenbeck – Krause – Rädler equation, which has been obtained by averaging the magnetohydrodynamics equations by scales comparable with size the turbulent cells:[11]

$$\frac{\partial \vec{B}}{\partial t} = \nabla \left(\alpha \vec{B}\right) + \nabla \left[\vec{V}, \vec{B}\right] + \eta \Delta \vec{B},$$

This equation is rather difficult to be solved. So usually the researchers use specific two-dimensional models for every type of the objects: such as Parker dynamo for stars of torus dynamo for outer rings of galaxies.

2.1. *No-z approximation for accretion discs*

While studying the magnetic fields in the accretion discs, it is quite convenient to use the models which have been developed for the objects that have nearly the same geometrical shape (of course, taking into account sufficiently different lengthscales). As for the galactic discs, so-called no-z approximation is widely used. It studies the evolution of two components of the field (which lie in the equatorial plane), which makes the problem much easier. The z-component of the field is taken using the solenoidality condition. Also it is quite convenient to assume that the field is axisymmetric (as for the accretion discs it is even more reasonable than for the galactic ones).

If we study the accretion disc, we should take the keplerian law for the rotation velocity Ω[1]:

$$\Omega = \frac{(GM)^{\frac{1}{2}}}{r^{\frac{3}{2}}},$$

where M is the mass of the black hole, neutron star or white dwarf; r is the distance from the central object.

The equations should be solved for values $r_{in} < r < R$, where r_{in} is the inner radius and R is the outer one.

It is quite convenient to use the dimensionless units: all parameters are measured in their typical values. As for the magnetic field, some dimensionless parameters characterizing the dynamo regime are introduced.

R_α shows the intensity of the alpha-effect:

$$R_\alpha = \frac{\Omega(R) l^2}{\eta},$$

where Ω is the angular velocity of the disc and l is the typical size of the turbulent cell.

R_ω is connected with the differential rotation:

$$R_\omega = \frac{\Omega(R) h^2}{\eta},$$

λ corresponds to the ration between the lengthscales of the disc (half-thickness h and radius R):

$$\lambda = \frac{h}{R} = 0.037 r^{\frac{1}{8}} \left(1 - \sqrt{\frac{r_{in}}{r}}\right)^{\frac{3}{20}}.$$

Taking these assumptions into account, the equations for the magnetic field in dimensionless form look like this:

$$\frac{\partial B_r}{\partial t} = -R_\alpha B_\varphi \left(1 - \frac{B^2}{B^{*2}}\right) - \frac{\pi^2 B_r}{4} + \lambda^2 \left(\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial}{\partial r}\left(r B_r\right)\right)\right) - \frac{V_0}{r\left(1 - \sqrt{\frac{r_{in}}{r}}\right)}\left(\frac{\partial B_r}{\partial r}\right), \tag{1}$$

$$\frac{\partial B_\varphi}{\partial t} = -\frac{3 R_\omega}{2 r^{\frac{3}{2}}} B_r - \frac{\pi^2 B_\varphi}{4} + \lambda^2 \left(\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial}{\partial r}\left(r B_\varphi\right)\right)\right) - \frac{V_0}{r\left(1 - \sqrt{\frac{r_{in}}{r}}\right)}\left(\frac{\partial B_\varphi}{\partial r}\right). \tag{2}$$

The equipartition field is assumed to be the following:[7]

$$B^* = 420 r^{\frac{-21}{16}} \left(1 - \sqrt{\frac{r_{in}}{r}}\right)^{\frac{17}{40}}.$$

It is included in the equations using the non-linearity coefficient $(1 - \frac{B^2}{B^{*2}})$.

As for the boundary conditions, we use the following ones:

$$\frac{\partial B_r}{\partial r}(R) = 0,$$

$$\frac{\partial B_\varphi}{\partial r}(R) = 0.$$

$$B_r\left(r_{in}\right) = 0,$$

$$B_\varphi\left(r_{in}\right) = 0.$$

Also we can take the zero derivative conditions on the inner boundary:[8]

$$\frac{\partial B_r}{\partial r}\left(r_{in}\right) = 0,$$

$$\frac{\partial B_\varphi}{\partial r}\left(r_{in}\right) = 0.$$

However, it has been shown that the results for the magnetic field will be nearly the same as for the model with zero field boundary condition.

The magnetic field for different inner radius is shown on figure 1. It can be seen that larger inner radius moves the field from the center. Also the time dependence is shown on figure 2.

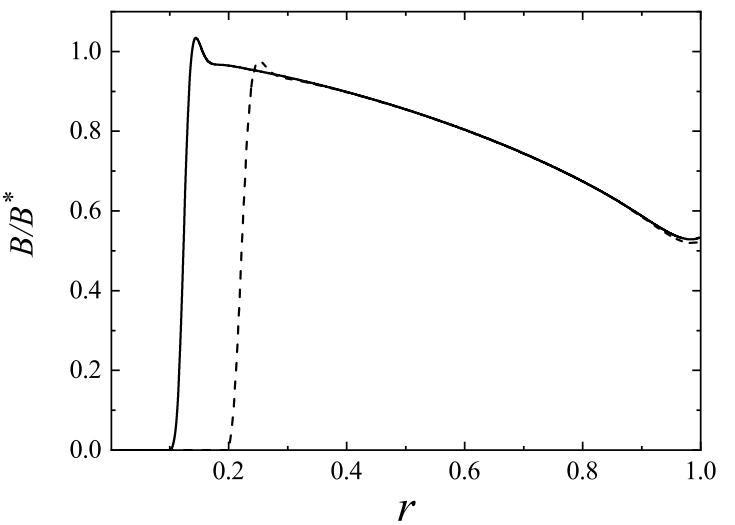

Fig. 1. The dependence of the magnetic field on the distance to the center of the accretion disk for different inner radius with zero boundary condition ($D_{eff} = 15$). Solid line shows the case, when $r_{in} = 0.1$ and the dotted line – the case $r_{in} = 0.2$.

3. RZ-model

No-z approximation has a lot of advantages for a wide spectra of objects (from galaxies to accretion discs). Unfortunately, it cannot be use for the objects where the vertical structure is more complicated than a standard law which is taken into

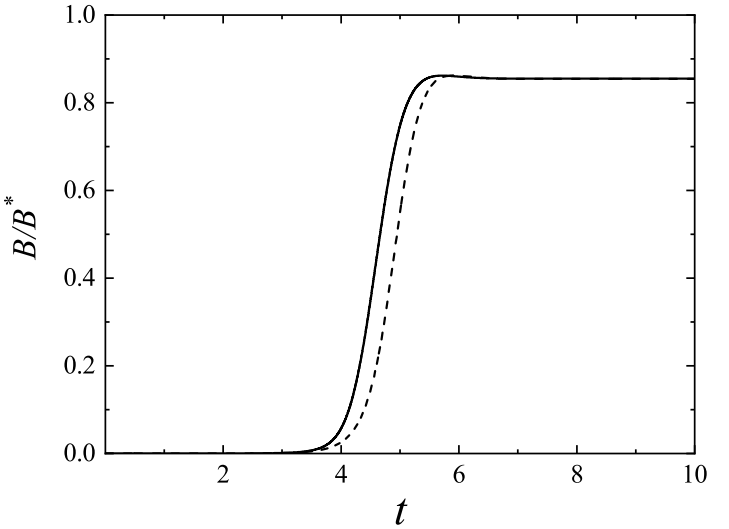

Fig. 2. Time dependence of the magnetic field for different r_{in} with zero boundary condition. Solid line shows the case, when $r_{in} = 0.1$ and the dotted line – the case $r_{in} = 0.2$.

account there. So, for thick discs we should take the RZ-approximation which describes the field using another approaches. Firstly these ideas have been used for the torus dynamo in outer rings of galaxies[12] and now there are results which can describe the whole disc.[9]

The magnetic field $\vec{B}$ can be presented as:

$$\vec{B} = B\vec{e_\varphi} + \nabla\left(A\vec{e_\varphi}\right),$$

where B is the azimuthal magnetic field and A is the azimuthal part of the vector potential of the magnetic field.

If we use this model, the Steenbeck – Krause – Rädler equation will take the following approximate form:

$$\frac{\partial A}{\partial t} = R_\alpha z B\left(1 - B^2\right) + \lambda^2 \Delta A - V\frac{\partial A}{\partial r},$$

$$\frac{\partial B}{\partial t} = R_\omega r\left(-\frac{3}{2}r^{\frac{5}{2}}\frac{\partial A}{\partial z}\right) + \lambda^2 \Delta B - V\frac{\partial B}{\partial r}.$$

All main dimensionless parameters here are the same as for the previous model. The equations are solved for $-h < z < h$, $r_{in} < r < R$, and the boundary conditions are:

$$A|_{t=0} = 0$$

$$B|_{t=0} = B_0 sin(\pi r) cos\Big(\frac{\pi z}{h}\Big)$$

$$\frac{\partial A\,(r,-h)}{\partial\ z} = 0.$$

The comparative results are shown on Fig 3. Here we can see both the field modeled using no-z approximation and the RZ-model. We can see that the field for the RZ-model reaches a bit larger values and the typical dependence is different, too.

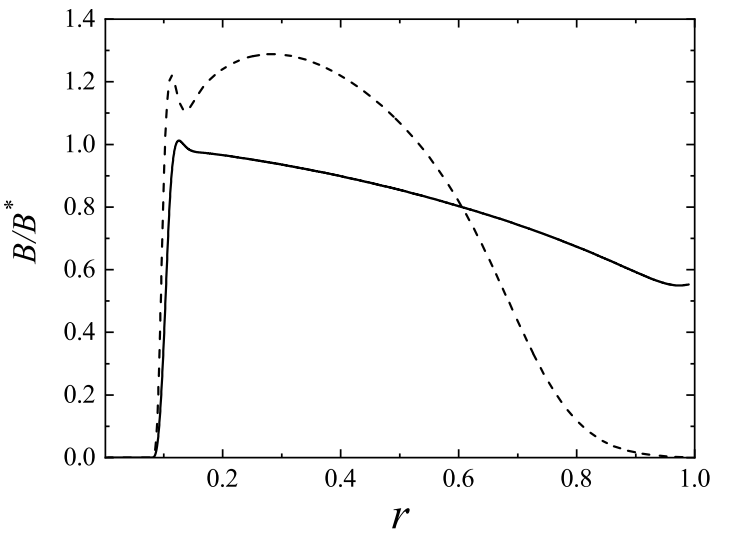

Fig. 3. Comparison of two models. Dashed line shows RZ-model and solid line shows no-z model.

Figure 4 shows the 2D-structure of the field. Here we can see the maximum of the magnetic field quite close to the inner boundary, and near the outer boundary the field decreases.

Also we have studied the connection between the dynamo number $D = R_\alpha R_\omega$ and the r-dependence of the field. It can be seen that for lower D the field is smaller, too.

4. Conclusion

In this work we have studied evolution of the magnetic field in accretion discs. We have used two different models taking into account different approaches to the dynamo. First of all, we studied the evolution of the magnetic field using the no-z approximation which has been developed for thin discs.[6] After that, we passed to

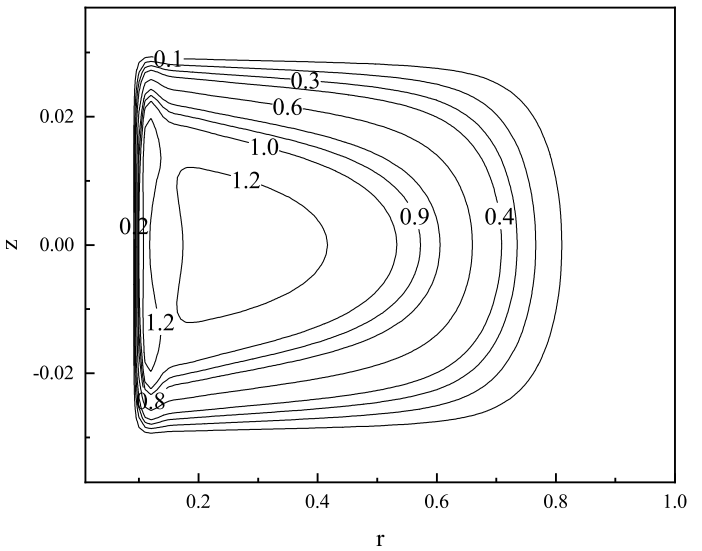

Fig. 4. The dependence of the magnetic field on r and z coordinates for RZ-model.

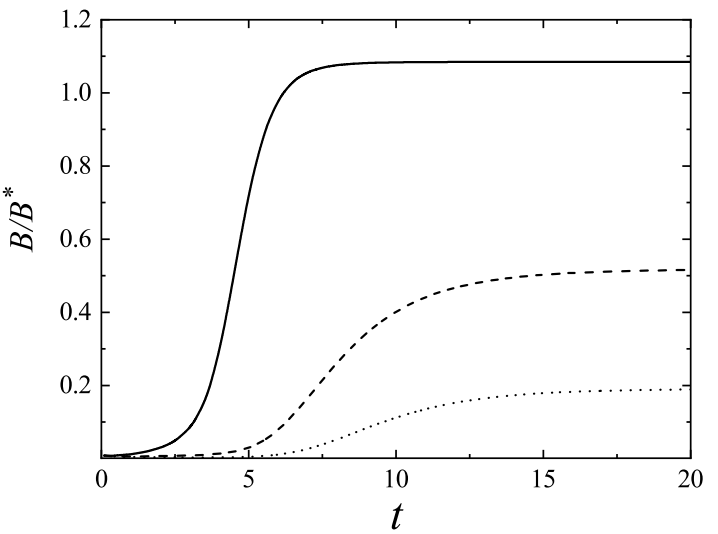

Fig. 5. Time dependence of the magnetic field for RZ-model for different D_{eff}. Solid line shows the case, when $D_{eff} = 15$, dashed line shows the case, when $D_{eff} = 9$, dotted line shows the case, when $D_{eff} = 7$.

the RZ-model, which takes into account z-dependence of the magnetic field, but it is more difficult to be solved from the numerical point of view. We can conclude that if we study thick discs, it is better to take the RZ-model, and for thin one we can take no-z approximation.

We consider agglomerates of misaligned tori orbiting a supermassive black hole. The aggregate of tilted tori is modeled as a single orbiting configuration by introducing a leading function governing the distribution of toroids (and maximum pressure points inside the disks) around the black hole attractor. The orbiting clusters are composed by geometrically thick, pressure supported, perfect fluid tori. This analysis places constraints on the existence and properties of tilted tori and more general aggregates of orbiting disks. We study the constraints on the tori collision emergence and the instability of the agglomerates of tori with general relative inclination angles, the possible effects of the tori geometrical thickness and on the oscillatory phenomena. Some notes are discussed on the orbiting ringed structure in dependence of the dimensionless parameter ξ representing the (total) BH rotational energy extracted versus the mass of the BH, associating ξ to the characteristics of the accretion processes.

Keywords: Accretion disks; Accretion– jets; Black hole physics; Hydrodynamics

1. Introduction

We study agglomerates of tori orbiting one central Kerr super-massive black hole (SMBH), in two macro-configuration models: (i) as an equatorial-**R**inged **A**ccretion **D**isk (eRAD), where the toroids equatorial and symmetry planes coincide with the central Kerr BH equatorial plane;[1–9] (ii) as **R**inged **A**ccretion **D**isk (RAD), where the agglomerate is composed by misaligned (tilted) tori.[10–12]

The eRAD tori rotation orientation is a well defined quantity, and a couple of eRAD toroids can be both corotating or counter-rotating with respect to the central spinning BH, otherwise tori can have a relative alternate rotation orientation (with an inner corotating toroid and an outer counter-rotating toroid with respect to the central attractor or *viceversa*). Tori with different relative rotation orientation constitute an interesting case from the viewpoint of the constrains posed by the eRAD or RAD model, for example in the case of double tori accretion phase or also tori collision which depends generally on the spin-mass ratio of the central BH. It is clear that an orbiting tori aggregate model could be constructed considering a different disk model for each toroidal component. However in this analysis we mostly consider a Polish doughnut (PD) model. This is a well known geometrically thick disk model, widely used in literature in a variety of different applications.[1,13] Polish doughnut shows a remarkably good fitting of main morphological characteristics of thick disks also in comparison with more refined dynamical GRHD or

GRMHD models.[13] RAD is a "constraining-models", providing initial configurations for dynamical (GRMHD) situations. In general aggregates of toroidal structures orbiting one central BH attractor can result from different accreting phases of the SMBHs growing, where the infalling materials, having diverse angular momentum, may trace back the BH story.[2,5,14–23]

This paper is structured in two parts: In the first part, Sec. (2), we discuss the eRAD model, focusing on the model parameters and distribution of pressure and density critical points. We introduce the concept of leading function for the agglomeration describing the tori distribution around the central attractor.

The second part, Sec. (3), focuses on aggregates of misaligned tori (RAD), discussing explicit solutions of its inner structure and an adapted parametrization for the toroidal components.

2. The Equatorial Ringed Accretion Disks

2.1. *Leading function and geodesic structure*

A key step in the modelization of the orbiting agglomerate is to individuate an adapted "leading function", representing the tori location around the central attractor. For large part of this analysis, we can identify the leading function with the definition of fluid specific angular momentum ℓ. Different choices are the agglomerate leading functions also possibles as we see some examples in Sec. (2.4) and Sec. (3.1). In the Kerr spacetime there is

$$\begin{aligned} \ell &\equiv \frac{L}{E} = -\frac{U_\phi}{U_t} = -\frac{g_{\phi\phi}U^\phi + g_{\phi t}U^t}{g_{tt}U^t + g_{\phi t}U^\phi} = -\frac{g_{t\phi} + g_{\phi\phi}\Omega}{g_{tt} + g_{t\phi}\Omega}, \\ \Omega &\equiv \frac{U^\phi}{U^t} = -\frac{Eg_{\phi t} + g_{tt}L}{Eg_{\phi\phi} + g_{\phi t}L} = -\frac{g_{t\phi} + g_{tt}\ell}{g_{\phi\phi} + g_{t\phi}\ell}, \end{aligned} \tag{1}$$

where $g_{\alpha\beta}$ are metric components in the Boyer-Lindquist coordinates, U^α is the fluid four velocity, Ω is the fluid relativistic angular velocity and (E, L) are constants of motions–see for example.[1,2] In general, we may interpret E, for timelike geodesics, as representing the total energy of the test particle coming from radial infinity, as measured by a static observer at infinity, and L as the axial component of the angular momentum of the particle. (For the PD tori orbiting in a Kerr spacetime the set of results known as Von Zeipel theorem holds, therefore the fluid is barotropic and the surfaces of constant pressure coincide with the surfaces of constant density. In these spacetimes, the family of von Zeipel's surfaces does not depend on the particular rotation law of the fluid, $\Omega = \Omega(\ell)$, but on the background spacetime only.[24–28])

The leading function provides the distribution of the possible maximum points of pressure and density in the fluids surrounding the BH, which are identified as the RAD-"rings seeds" , coincident with torus centers r_{center}, and eventually the minimum points of pressure of the fluids orbiting around the central attractor. The

minimum points of pressure are associated to the cusps $r_\times$ of the PD torus Roche lobe and are regulated by the geodesic structure of the background, composed by the marginally stable circular orbit (r_{mso}), the marginally bounded circular orbit (r_{mbo}) and the marginally circular orbit (r_γ) which is also a photon orbit. (The cusp location in the PD model, located in the range $]r_{mbo}, r_{mso}[$, could be related to the inner edge of an accreting torus.) In the RAD and eRAD models, the location of the maximum points of the pressure around the attractor are interpreted as "rings seeds", and are regulated by a set of radii, associated to the geodesics structure, located in the "stability region" at $r > r_{mso}$ and defined by

$$
\begin{aligned}
& r^\pm_{(\mathrm{mbo})} : \ \ell^\pm(r^\pm_{\mathrm{mbo}}) = \ell^\pm(r^\pm_{(\mathrm{mbo})}) \equiv \ell^\pm_{\mathrm{mbo}}, \quad \text{with} \quad r^\pm_{(\gamma)} : \ell^\pm(r^\pm_{\gamma}) = \ell^\pm(r^\pm_{(\gamma)}) \equiv \ell^\pm_{\gamma}, \\
& \text{where} \quad r^\pm_{\gamma} < r^\pm_{\mathrm{mbo}} < r^\pm_{\mathrm{mso}} < r^\pm_{(\mathrm{mbo})} < r^\pm_{(\gamma)} \\
& \text{and} \quad r^\pm_{\mathcal{M}} : \partial_r \partial_r \ell^\pm = 0, \quad \text{with} \quad r^\pm_{(\mathcal{M})} : \ \ell^\pm(r^\pm_{(\mathcal{M})}) = \ell^\pm(r^\pm_{\mathcal{M}})) \equiv \ell^\pm_{\mathcal{M}}.
\end{aligned} \tag{2}
$$

In here and in the following with $\mathcal{Q}^\pm$ we indicate quantities $\mathcal{Q}$ associated to counter-rotating ($\ell a < 0$) or corotating ($\ell a > 0$) structures respectively, with respect to the central BH spin a/M. In the following, for any quantity $\mathbf{Q}$ and radius $r_\bullet$ we adopt the notation $\mathbf{Q}_\bullet \equiv \mathbf{Q}(r_\bullet)$. Where more conveniently, we use dimensionless quantities where $r \to r/M$ and $a \to a/M$.

The leading function, solution of $\partial_r^2 \ell^\pm(r, \theta; a) = 0$ (where (r, θ, ϕ, t) are the Boyer-Lindquist coordinates of the Kerr metric), provides the point of maximum density of the rings seeds distribution around the BH.

The corotating and counter-rotating tori cusps orbital regions are shown in the Figs 1 for different BH attractors. In the Figs 1 the orbital regions for the ring seeds locations (tori centers) are also shown. The union of these regions provides the maximum rage of the location of the rings seeds and the maximum extension of the disks inner part (the region $[r_{inner}, r_{center}]$ where $r_\times \leq r_{inner}$ is the torus cusp and r_{inner} is the inner edge of the quiescent (i.e. not cusped torus)). The orbital strips in Figs 1 relative to the corotating and counter-rotating fluids, cross in different points depending on the BH spin–mass ratio and particularly for slower spinning attractors.

2.2. *Ideal GRMHD and GRHD*

Polish doughnuts have been realized in different ideal GRMHD and GRHD setups, where for the ideal GRMHD (infinitely conductive plasma) case there is

$$
\begin{aligned}
& U_\alpha \nabla^\alpha \rho + (p + \rho) \nabla^\alpha U_\alpha = 0, \\
& (p + \rho) U^\alpha \nabla_\alpha U^\gamma - \epsilon h^{\beta\gamma} \nabla_\beta p - \epsilon (\nabla^\alpha F_{\alpha\delta}) F_\beta{}^\delta h^{\beta\gamma} = 0, \\
& U^\alpha \nabla_\alpha s = 0.
\end{aligned}
$$

(F^β_α is the Faraday tensor and ϵ is a quantity related to the metric signature[29,30]). The electric field does not affect the continuity equation or the equation for the

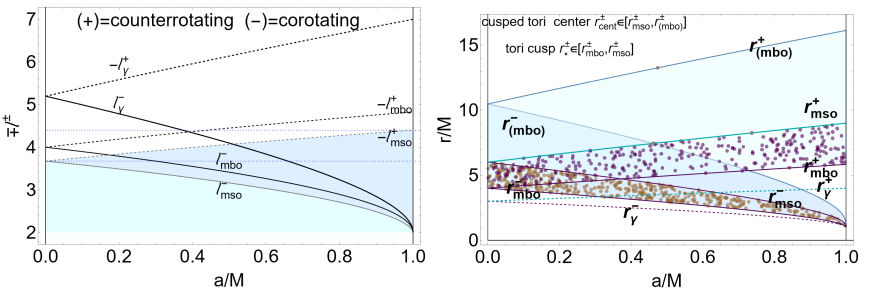

Fig. 1. Left: Fluid specific angular momentum $\ell^{\pm}$ of the eRAD tori, for corotating $(-)$, and counterrotating $(+)$, fluids, versus SMBH dimensionless spin a/M. Tori can form for $\mp\ell^{\pm} > \mp\ell^{\pm}_{mso}$ respectively. There is $\ell_{\bullet} \equiv \ell(r_{\bullet})$ for $r_{\bullet} = \{r_{mso}, r_{mbo}, r_{\gamma}\}$, r_{mso} is the marginally stable circular orbit, r_{mbo} is the marginally bounded orbit and r_{γ} the last circular (photon) orbit. Right: radii r_{mbo} and r_{mso} and the pair $r_{(mbo)}$ and $r_{(mso)}$ as functions of the dimensionless spin of the BH–see Eqs (2).

entropy. The entropy per particles s is conserved along the flow U^{α}, defined for *each* torus of the aggregate, and h^{β}_{α} is the metric on the 3-sheet orthogonal to flow direction U^{α}, defining the projector tensor (there is $\nabla_{\alpha} g_{\beta\gamma} = 0$). The inner ringed structure is defined by the boundary conditions determining the tori (edges)—see for more details.[9,29,31]

To simplify our discussion we consider in this analysis the GRHD scenario (see for example[1,13]). With the barotropic equation of state, $p = p(\rho)$, the set of GRHD equations for the PD model, reduces to the only constrain equation for the pressure (Euler equation):

$$\frac{\nabla_{\mu} p}{p+\rho} = -\nabla_{\mu} W + \frac{\Omega \nabla_{\mu} \ell}{1 - \Omega \ell};$$

where $W = W(a; \ell; r, \theta)$ is an effective potential, function of (r, θ) for the Kerr metric (in the Boyer-Lindquist coordinates). The equation for the pressure critical points can be further simplified by considering ℓ as a model parameter, constant in each torus of the aggregate. In this setup the extreme points of pressure are the extremes of the potential W, and the leading function is given by the radial derivative of the effective potential. More precisely the tori parameters are the couple (ℓ, K) with $\ell = constant$ and $V_{eff} = K = constant$ for each torus, where $W = \ln V_{eff}$.

In this context, the eRAD leading function is $\ell(r) : \partial_r V_{eff} = 0$. The tori (Boyer) surfaces are equipressure surfaces (also surfaces of constant (p, ρ, ℓ, Ω)) and the fluids fill every equipressure surfaces.[32]

2.2.1. *The energy function and tori energetics*

The "energy function" $K(r) = V_{eff}(\ell(r))$ regulates, with the leading function $\ell(r)$, the RAD aggregate, where $K : K(r)$ =constant for each torus. More precisely,

function $K(r,\theta;a) \equiv V_{eff}(\ell,r,\theta;a)|_{\ell(r,\theta;a)}$ determines the flow (and the torus) geometrical thickness, the tori extension on the equatorial plane, and it is uniquely identified by $\ell(r)$ in the case of cusped tori. The relation between the geometrical maxima (defined by K) and the density maxima (fixed by ℓ) is provided by the extreme of the leading function $\ell(r,\theta;a)$.[12] We can relate $K(r)$ to certain features of the tori energetics, evaluating some characteristics related to the flow thickness, as mass accretion rate or cusp luminosity as listed in Table (1). It is clear that these quantities depends on the details of the different tori models, but this analysis can provide an estimation of these quantities with respect to the flow co-rotation or counter-rotation, the dimensionless BH rotational energy (or dimensionless spin) and the tori location in the aggregate.[33]

Table 1. There is $\varpi = n+1$, with $\gamma = 1/n+1$ being the polytropic index, κ is the polytropic constant. Ω is the relativistic angular velocity. $W = \ln V_{eff}$ is the value of the equipotential surface, which is taken with respect to the asymptotic value, $W_\times = \ln K_\times$ is W at the cusp $r_\times$, while $W_s \geq W_\times$ and r_s is related to the accreiting flow thickness. $\mathcal{L}$ representing the total luminosity, $\dot{M}$ the total accretion rate where, for a stationary flow, $\dot{M} = \dot{M}_\times$, $\eta \equiv \mathcal{L}/\dot{M}c^2$ the efficiency, $\mathcal{D}(n,\kappa), \mathcal{C}(n,\kappa), \mathcal{A}(n,\kappa), \mathcal{B}(n,\kappa)$ are functions of the polytropic index and the polytropic constant. $\mathcal{L}_\times/\mathcal{L}$ is the fraction of energy produced inside the flow and not radiated through the surface but swallowed by central BH–see Figs 2

Quantities $\mathcal{O}(r_\times, r_s, n) \equiv q(n,\kappa)(W_s - W_\times)^{d(n)}$	**Quantities** $\mathcal{P} \equiv \frac{\mathcal{O}(r_\times, r_s, n) r_\times}{\Omega(r_\times)}$
$\mathcal{R}$**-quantities:** $\mathcal{R}_\times \equiv (W(r_s) - W_\times)^{\varpi}$	$\mathcal{N}$**-quantities:** $\mathcal{N}_\times \equiv \frac{r_\times (W(r_s) - W_\times)^{\varpi}}{\Omega(r_\times)}$
Enthalpy-flux: $\mathcal{D}(n,\kappa)(W_s - W_\times)^{n+3/2}$, **Mass-Flux:** $\mathcal{C}(n,\kappa)(W_s - W_\times)^{n+1/2}$ $\frac{\mathcal{L}_\times}{\mathcal{L}} = \frac{\mathcal{B}(n,\kappa)}{\mathcal{A}(n,\kappa)} \frac{W_s - W_\times}{\eta c^2}$	**torus-accretion-rate:** $\dot{m} = \frac{\dot{M}}{\dot{M}_{Edd}}$ **Mass-accretion-rates:** $\dot{M}_\times = \mathcal{A}(n,\kappa) r_\times \frac{(W_s - W_\times)^{n+1}}{\Omega(r_\times)}$ **Cusp-luminosity:** $\mathcal{L}_\times = \mathcal{B}(n,\kappa) r_\times \frac{(W_s - W_\times)^{n+2}}{\Omega(r_\times)}$

Evaluation of these quantities defined in Table (1) are in Figs 2 as functions of the BH dimensionless rotational energy for different models, fixed according to selected values of the fluid specific angular momentum ℓ (fixing the cusp location and the center of maximum density) and the $K_s \in]K_\times, 1[$, fixing the flow thickness at the cusp.[34]

2.3. *The BH rotational energy*

The BH rotational energy is related to the BH geometrical features through its irreducible mass M_{irr}. From the definition of irreducible mass $M_{irr}^2 = \left(M^2 + \sqrt{M^4 - J^2}\right)/2$, where M is the BH total (ADM) mass and the $J = aM$,

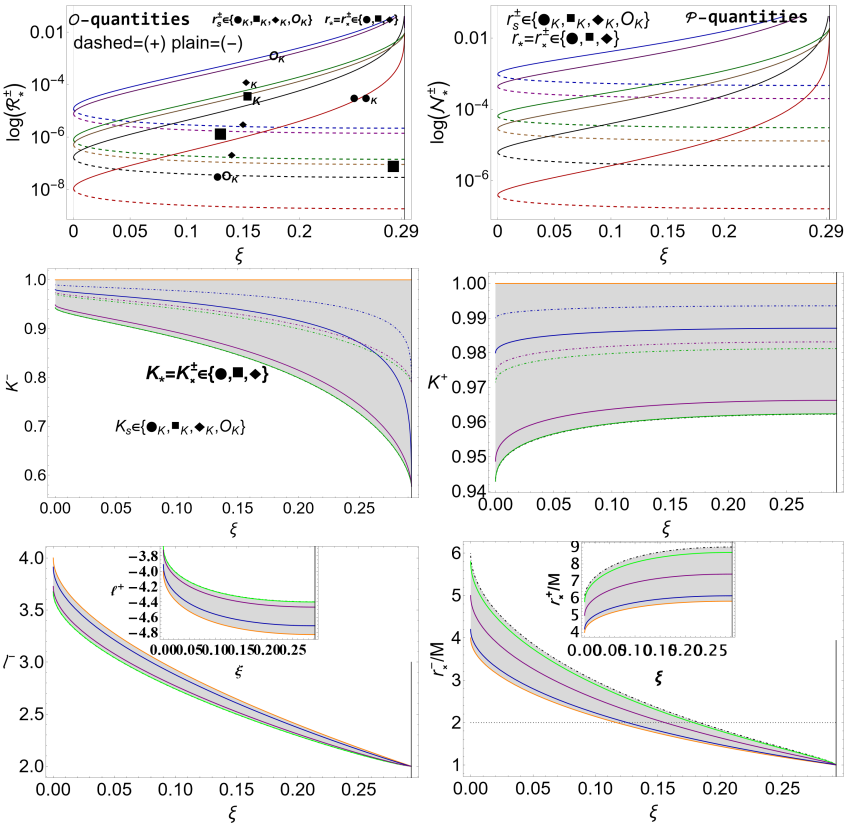

Fig. 2. Plots of $\mathcal{N}_\times^\pm \equiv r_\times(W^\pm(r_s) - W_\times^\pm)^\kappa(\Omega(r_\times^\pm))^{-1}$ for $\mathcal{P}$-quantities analysis and $\mathcal{R}_\times^\pm \equiv (W^\pm(r_s) - W_\times^\pm)^\kappa$ for $\mathcal{O}$-quantities analysis defined in Table (1) for corotating ((-)–continuum curves) and counterrotating ((+)–dashed curves) tori for different values of the cusps $r_* = r_\times^\pm \in \{\bullet, \blacksquare, \blacklozenge\}$ and radii $r_s \in \{\bullet_K, \blacksquare_K, \blacklozenge_K, \mathrm{O_K}\}$, related to thickness of the accreting matter flow, where $\varpi = n+1$, with $\gamma = 1/n+1$ is the polytropic index, κ is the polytropic constant. Radii $(r_\times, r_s)$ and the associated angular momentum ℓ and K parameters are shown with $\{\bullet, \blacksquare, \blacklozenge, \bullet_K, \blacksquare_K, \blacklozenge_K, \mathrm{O_K}\}$. Ω is the relativistic angular velocity. ξ is the dimensionless BH rotational energy.

the dimensionless rotational energy ξ is:

$$\xi \equiv \frac{M_{rot}}{M(0)} = 1 - \frac{\sqrt{1+\sqrt{1-\frac{J(0)^2}{M(0)^4}}}}{\sqrt{2}}, \qquad (3)$$
$$\xi_\pm^\mp = 1 \pm \sqrt{\frac{r_\mp}{2}}, \quad \frac{\delta M_{irr}}{M_{irr}} = \frac{\delta M - \delta J \omega_H^+}{\sqrt{M(0)^2 - \frac{J(0)^2}{M(0)^2}}},$$

where $\xi \equiv \xi_-^+$, M_{rot} is the rotational mass, $r_\pm$ are the outer and inner BH horizons, ω_H^+ is the BH relativistic frequency (light-like limiting circular frequency evaluated at the BH outer horizon r_+). Thee BH dimensionless spin is $a(\xi) = \mathcal{A} \equiv 2\sqrt{-(\xi-2)(\xi-1)^2\xi}$. The rotational energy ξ is governed by the constraint

$\delta M_{irr} \geq 0$ thus $(\delta M - \delta J \omega_H^+) \geq 0$, where $\xi = 1 - M_{irr}/M$, with quantities evaluated at an initial state (0). It is $\xi \in [0, \xi_\ell]$ where $\xi_\ell \equiv \frac{1}{2}\left(2 - \sqrt{2}\right)$, limiting the total rotational energy extracted to a $\approx 29\%$ of the total mass M for a process leading an extreme Kerr BH to the static Schwarzschild BH.

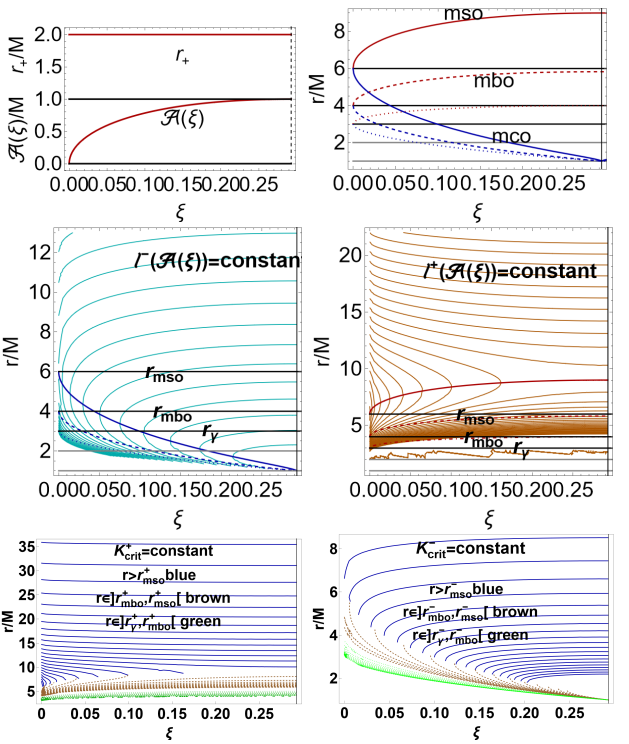

Fig. 3. Upper left panel: the BH outer horizon r_+ and the dimenionless BH spin function $\mathcal{A}(\xi)$, as functions of the dimensionless BH rotational energy ξ. Extreme Kerr BH corresponds to $\xi \approx 0.29$. Upper right panel: marginally bounded orbit *mbo* (dashed curves), marginally stable orbit *mso* (plain curves), marginally circular orbit *mco* (dotted curves) for corotating motion (blue curves) and counter-rotating motion (red curves) as functions of the parameter ξ. Center Bottom panels: the tori specific fluid angular momenta $\ell^{\mp}$ =constant for corotating (center left panel) and counter-rotating (center right panel) tori, the RAD energy function $K^{\pm}(r)$ =constant for the counter-rotating (bottom left panel) and corotating fluids (bottom right panel) as functions of ξ, where $r_\gamma^{\pm}$ is the last circular circular orbit (photon orbit) for counter-rotating (+) and corotating orbits (-).

In Figs 2 and Figs 3 the tori aggregates energetic characteristics at the state 0, prior a possible process involving the BH and its environment, are related to the BH rotational energy. The energetic parameter ξ and the angular relativistic velocity of the BH determine the BH state prior the transition-.[34–36] This analysis turns particularly relevant for the RAD model which, because of its inner discrete

structure, can be characterized by phases of enhanced accretion rates. Furthermore, as each torus of the aggregate is a geometrically thick disk, each component can contribute with super-Eddington accretion rates, with the possibility of further effects as runaway instability,[37,38] or in the case of RAD composed by misaligned tori, the Bardeen-Petterson effect.[39]

2.4. *Magnetized tori: alternative leading function*

As mentioned in Sec. (2.1), the leading function is not necessary the fluid specific angular momentum. An example providing a different aggregate leading function is the case of orbiting agglomerates composed by magnetized tori with a "Komissarov" toroidal magnetic field.[40] In this case the eRAD aggregate leading function is a function $\mathcal{S}$, defined by the magnetic field parameters and proving the rings seeds locations, the minima of pressure (according to the conditions for the cusp formation), the maximum values of the $\mathcal{S}$-parameter for the formation of a tori couple and constrains on the eRAD inner structure in dependence on the tori relative rotation orientation. More precisely, let us consider the toroidal magnetic field: $B^{\phi}=\sqrt{2p_B/A}$, where $A\equiv \ell^2 g_{tt}+2\ell g_{t\phi}+g_{\phi\phi}$, and $p_B=\mathcal{M}\left(g_{t\phi}g_{t\phi}-g_{tt}g_{\phi\phi}\right)^{q-1}\hat{\omega}^q$ is the magnetic pressure, $\hat{\omega}$ is the fluid enthalpy, q and $\mathcal{M}$ are constant; The Euler equation can be written as

$$\frac{\partial_* p}{\rho+p}=G^{(f)}_*+G^{(em)}_*,\quad G^{\natural}_*=-\frac{\partial}{\partial *}W^{\natural}_*;\quad *=\{r,\theta\},\quad \natural=\{(em),(f)\},\tag{4}$$

$$\partial_\mu(W^{(f)}+W^{(em)})=\partial_\mu\left[\ln V_{eff}+\mathcal{G}\right],\ \mathcal{G}(r,\theta)=\mathcal{S}\left(\mathcal{A}V^2_{eff}\right)^{q-1},\ \mathcal{S}\equiv\frac{q\mathcal{M}\hat{\omega}^{q-1}}{q-1}.$$

The RAD leading $\mathcal{S}$–function is

$$\mathcal{S}_{crit}\equiv-\frac{\Delta^{-\mathcal{Q}}}{\mathcal{Q}}f(a,\ell;r)\quad(\mathcal{Q}\equiv q-1),$$

where $f(a,\ell;r)$ is a function of the BH spin and fluid angular momentum[9,31] (there is $\Delta\equiv r^2-2Mr+a^2$).

3. Misaligned Tori

In this section we discuss the tori aggregates containing misaligned tori. To simply our discussion we consider misaligned tori orbiting a central static BH. In this case we can use different leading functions for the description of the aggregate introduced in Sec. (3.1). Tori geometrical thickness is discussed in Sec. (3.2). Frequency models in tori aggregates are considered in Sec. (3.2.1) and tori geometrical characteristics are deepened in Sec. (3.3) for quiescent (not cusped) tori in Sec. (3.3.1) and for cusped tori analyzed in Sec. (3.3.2).

3.1. *Leading functions*

In this section we introduce three definitions of leading functions for the tori aggregates–see.[11]

The critical $\bar{r}(r_i)$ and $r^{\varepsilon}_{\times}$ functions:

$$\bar{r}(r_i) = \frac{2r_i\left[\sqrt{2r_i - r_\gamma} + r_i - 1\right]}{(r_i - r_+)^2}, \quad r^{\varepsilon}_{\times} \equiv \frac{r_{center}\left(\sqrt{2r_{center} - r_\gamma} + 1\right)^2}{(r_{center} - r_+)^2}, \quad (5)$$

(solutions of $\ell(r) = \ell(r_p)$ for two orbits (r, r_p)). In this case the leading function is a relation between the extremes of pressure inside the tori $\bar{r}(r_i)$, or the cusp $r^{\varepsilon}_{\times}$ as function of the center of maximum pressure. The distance $r_{center} - r_\times$ increases with the tori distance in the aggregates from the central BH attractor.

Leading function $\ell^o_{crit}(K)$:

There is

$$\ell^o_{crit}(K) \equiv \sqrt{\frac{27K^4 - K\left(9K^2 - 8\right)^{3/2} - 36K^2 + 8}{2K^2\left(K^2 - 1\right)}}, \quad (6)$$

$$\ell^i_{crit}(K) \equiv \sqrt{\frac{27K^4 + K\left(9K^2 - 8\right)^{3/2} - 36K^2 + 8}{2K^2\left(K^2 - 1\right)}}, \quad (7)$$

$$\text{where} \quad \ell^o_{crit}(K) > \ell^i_{crit}(K) > \ell_{mso}, \quad \ell^i_{crit}(K) \in [\ell_{mso}, \ell_\gamma[.$$

In this case, notably the leading function, relating the two tori parameters ℓ and K, bas been split in function $\ell^o_{crit}(K)$, the leading function providing parameters (ℓ, K) at the tori centers (rings seeds), and function $\ell^i_{crit}(K)$ for the tori cusps.

Similarly we introduce the following alternative functions.

Tori critical radius $r^o_{crit}(K)$: There is

$$r^o_{crit}(K) \equiv -\frac{8}{K\left(\sqrt{9K^2 - 8} + 3K\right) - 4}, \; r^i_{crit}(K) \equiv \frac{8}{K\left(\sqrt{9K^2 - 8} - 3K\right) + 4},$$
$$r^i_{crit}(K_\times) = r_\times, \; r^o_{crit}(K_{center}) = r_{center} \quad (8)$$

similarly to $\ell^o_{crit}(K)$, the leading function is $r^o_{crit}(K)$, relating the center of maximum pressure (ring seed) and the K parameter at the torus center.

3.2. *Geometrical thickness*

Disk geometrical thickness is an important characteristic for the RAD tori. The eRAD is a geometrical thin disk composed by geometrical thick tori with an inner articulated ringed structure, combining some features of geometrical thick disks, inherited by its components and features typical of the geometrical thin disks in its global structure. Geometrical thickness is a relevant parameter in the comparison with other disks model, in the assessment of the torus vertical structure and the influence of a possible poloidal magnetic field, for the accretion mechanism and the study of tori oscillations. The definition of geometrical thickness adopted here coincides with the thickness **S** of the outer Roche lobe section of the PD torus. For large part of the (ℓ, K) range, cusped tori can be considered geometrically thin i.e. $\mathbf{S} < 1$. There are classes of toroidal components with equal thickness. For example, in the "reference" case $\mathbf{S} = 1$, distinguishing geometrically thin and geometrically

thick disks, where there are couples of toroids with equal energy parameter K, regulating also the flow thickness.[10,11]

A further parameter for the evaluation of tori geometrical thickness is the dimensionless β_{crit}

$$\beta_{crit} = \frac{(r_{center}-2)^2(r_{center}-r_\times)\sqrt{r_{center}r_\times - 2(r_{center}+2r_\times)}}{r_{center}\sqrt{r_{center}-3}r_\times\sqrt{r_\times-2}},$$

emerging from the analysis of cusped tori oscillation.[41–43] Similarly to the leading function $\bar{r}(r_i)$ of Eq. (5), β_{crit} depends on the distance between the maximum and minimum point of pressure in the tori, which increases with the distance from the central attractor. For small β_{crit} ($\beta_{crit} \geq 0$), tori may be considered geometrically thin for radial and vertical oscillation, and can be described by the radial and vertical epicyclical frequencies from the hypothesis of thin (slender) tori, coincident therefore with the respective circular orbit frequencies.[42,44,45] The conditions for geometrical thin components according to definition $\mathbf{S} < 1$ and conditions for geometrical thin tori according to β_{crit} coincide only for special conditions on ℓ and K parameters (therefore depending on the tori location in the agglomerate and their dimension), having tori with combined characteristics typical of geometrical thin and thick disks.[10]

3.2.1. *Frequency models in tori aggregates*

In the conditions where $\beta_{crit} \geq 0$, we can consider the circular orbit approximation for the oscillation frequencies. In[10] different frequency models are applied to the RAD structure, interpreted as a frame for the high–frequency (HF) Quasi-Periodic Oscillations (QPOs), assuming the geodesic (nearly circular geodesic motion) frequencies

$$\nu_r(r) = \nu_K(r)\sqrt{1-\frac{r_{mso}}{r}}, \quad \nu_\theta(r) = \nu_K(r) \equiv \frac{1}{r^{3/2}}, \tag{9}$$

determined by the tori constraints. The frequencies (9) are combined for the fitting of resonance ratios, identifying the upper ν_U and lower ν_L frequencies from different oscillation models and assuming $(\nu_r(r), \nu_K(r))$ evaluated at different points r of the tori surfaces. Therefore in[10] we used the frequency models (**TD**,**RP**,**RE**,**WD**) listed Table (2), evaluated in different tori models. The twin peak quasi-periodic oscillations with resonant frequency ratios $\nu_U/\nu_L = \{3:2, 4:3, 5:4, 2:1, 3:1\}$ have been analyzed.[10]

Different components of the aggregates fit different frequency models, according to tori location in the aggregate with respect to the central attractor distinguishing therefore the toroidal components and the different torus active parts.[10] In the models of Table (2), the torus inner edge has been considered the active part of the emission process, the frequencies being evaluated at $r_{inner} > r_\times$ (for quiescent tori) or $r_{inner} = r_\times$ for cusped tori, and as ($\beta_{crit} \gtrapprox 0, \mathbf{S} \ll 1$), the maximum of

Table 2. Frequency models and related tori models for the analysis of Sec. (3.2.1). Frequencies (ν_θ, ν_r) are in Eq. (9), the relativistic frequency $\nu_K = \Omega$, coincident with ν_θ in the static spacetime is in Eq. (1). The fluid specific angular momentum is ℓ and K is the energy parameter, r_{center} is the center of maximum density and pressure in the torus, r_{out} is the torus outer edge. The relativistic-precession model coincides in static BH also with the total precession models **TP**. Radius $r^{\times}_{\rm max}$ is the cusped torus geometrical maximum of Eq. (13), where $r^{o}_{\rm max}(r) \equiv r^{\times}_{\rm max}$ as functions of ℓ. Radii $\bar{r}(r_i)$ and $r^{\epsilon}_{\times}$ are the aggregate leading functions of Eqs (5); function $\bar{r}(r_i)$ relates the critical points of pressure in each toroidal component of the aggregate, and function $r^{\epsilon}_{\times}$ provides the torus cusp as function of the torus center–see Eq. (5).

Frequency models	**Tori models**
(RP): $\nu_U = \nu_K$, $\nu_L = \nu_{per} \equiv \nu_K - \nu_r$;	[**(a)-model**]: function of r/M
(relativistic-precession model)	[**(b)-model**]: $r = r_{center}(\ell)$ function of $\ell \in [\ell_{mso}, \ell_{mbo}]$
(RE): $\nu_U = \nu_\theta$, $\nu_L = \nu_r$;	[**(c)-model**]: for $r = r_{out}(\ell)$ functions of ℓ
(resonance epicyclic models)	[**(d)-model**]: in $r = r^{\times}_{\rm max}(\ell)$ function of ℓ
(**TD**): $\nu_L = \nu_K$, $\nu_U = (\nu_K + \nu_r)$;	[**(e)-model**]: for $r = r^{\epsilon}_{\times}$ function of r/M torus cusp or center
(tidal distortion model)	[**(f)-model**]: function of $\bar{r}(r_i)$
(**WD**): $\nu_L = 2(\nu_K - \nu_r)$, $\nu_U = (2\nu_K - \nu_r)$;	[**(g)-model**]: for $r = r_{center}(K)$ function of K
(warped disk model)	

pressure point, the outer edge and the geometrical maximum point have been also considered.[46–57]

3.3. *Tori geometrical characteristics*

Frequencies models of Table (2) have been evaluated on the outer r_{out} and the inner $r_\times$ tori edges, the tori geometrical maximum $r_{\rm max}$ and tori center r_{center}. The evaluation of the tori geometrical characteristics is relevant in the determination of inner ringed structure and tori collision. In this section we provide $(r_\times, r_{out}, r_{center}, r_{\rm max})$, the torus height h and the inner Roche lobe maximum high. These quantities are functions of tori parameters (ℓ, K) for quiescent (not cusped) tori, considered in Sec. (3.3.1) and ℓ *or* K (or alternately the critical pressure points $r_\times$ and r_{center}) for cusped tori analyzed in Sec. (3.3.2).

3.3.1. *Roche lobes in quiescent and cusped tori*

For quiescent and cusped tori, we provide below the outer and inner torus edge and the tori elongations λ on the tori symmetry plane–see[11]

$$\textbf{Torus outer edge:} \quad r_{out} \equiv \frac{2\left[1 + \mathbb{K}\tau\cos\left(\frac{1}{3}\cos^{-1}(\alpha)\right)\right]}{3\mathbb{K}}, \tag{10}$$

$$\textbf{Tori elongation:} \quad \lambda \equiv \frac{2\tau\cos\left(\frac{1}{6}\left[2\cos^{-1}(\alpha) + \pi\right]\right)}{\sqrt{3}},$$

$$\textbf{Torus inner edge:} \quad r_{inner} \equiv \frac{2\left[1 - \mathbb{K}\tau\sin\left(\frac{1}{3}\sin^{-1}(\alpha)\right)\right]}{3\mathbb{K}}.$$

where $\mathbb{K}:\ K\equiv\sqrt{1-\mathbb{K}}$, $\mathcal{Q}\equiv\ell^2$ and $(\alpha,\mathbb{K},\tau)$ are functions of (ℓ,K)–see.[11] (Note in the case of cusped tori $r_{inner}=r_\times$).

For the inner Roche lobe, the inner edge an the elongation of the lobe on the symmetry plane are

$$r_{inner}^{BH}\equiv\frac{2\left[\frac{1}{\mathbb{K}}-\tau\sin\left(\frac{1}{6}\left[2\cos^{-1}(\alpha)+\pi\right]\right)\right]}{3},$$
$$\lambda_{inner}^{BH}\equiv\frac{2}{3}\tau\left[\sin\left(\frac{1}{6}\left[2\cos^{-1}(\alpha)+\pi\right]\right)-\sin\left[\frac{1}{3}\sin^{-1}(\alpha)\right]\right]. \tag{11}$$

The geometrical maximum for the outer $r^o_{\max}$ and inner Roche lobes $r^i_{\max}$ are

$$\text{Outer lobe}:\quad r^o_{\max}(K,\ell)\equiv\sqrt{\frac{K^2\mathcal{Q}}{K^2-1}+4\sqrt{\frac{2}{3}}\psi\cos\left[\frac{1}{3}\cos^{-1}(\psi_\pi)\right]},$$
$$\text{Inner lobe}:\quad r^i_{\max}(K,\ell)\equiv\sqrt{\frac{K^2\mathcal{Q}}{K^2-1}-4\sqrt{\frac{2}{3}}\psi\sin\left[\frac{1}{3}\sin^{-1}(\psi_\pi)\right]},$$

and the torus height is

$$h^o_{\max}(K,\ell)\equiv\sqrt{\frac{K^2\mathcal{Q}}{1-K^2}+\mathbf{Z}-4\sqrt{\frac{2}{3}}\psi\cos\left[\frac{1}{3}\cos^{-1}(\psi_\pi)\right]},$$

where $(\psi,\psi_\pi,\mathbf{Z})$ are functions of (ℓ,K).[11]

3.3.2. *Cusped tori*

In this section we specialize the analysis of Sec. (3.3.1) for cusped misaligned tori, which are described by one only independent parameter K or ℓ (or equivalently $r_\times$ or r_{center}).

We can express the critical points of pressure in the tori in terms of the parameter ℓ. The torus center and the point of minimum density (and hydrostatic pressure) are

$$r_{center}(\ell)\equiv\frac{1}{3}\left[\mathcal{Q}+2L_\ell\cos\left(\frac{1}{3}\iota_a\right)\right],\quad r_\times(\ell)\equiv\frac{1}{3}\left[\mathcal{Q}-2L_\ell\cos\left(\frac{1}{3}\left[\iota_a+\pi\right]\right)\right],$$

where $L_\ell, L_{\updownarrow\updownarrow}$ are functions of ℓ and $\mathcal{Q}\equiv\ell^2$.[11] The cusped torus outer edge is located at

$$r^\times_{out}\equiv\frac{2\ell^2\hat{\psi}_2}{3\ell^2\hat{\psi}_2+\hat{\psi}_0^2(6-\hat{\psi}_0)}+2\hat{\psi}_4\sqrt{\frac{\ell^2\left[\hat{\psi}_0^2\left(3\ell^2\hat{\psi}_2(6-\hat{\psi}_0)+\hat{\psi}_0^2(\hat{\psi}_0^2-12\hat{\psi}_0+36)\right)+12\ell^2\hat{\psi}_2^2\right]}{3\left(3\ell^2\hat{\psi}_2+\hat{\psi}_0^2(6-\hat{\psi}_0)\right)^2}},$$

(where $(\hat{\psi}_0, \hat{\psi}_2)$ are functions of ℓ). Similarly to functions (ℓ^o, ℓ^i) of Eqs (6), the leading function can be expressed in terms of the energy function K as

$$K_{center}(\ell) \equiv \sqrt{\frac{\left[\mathcal{Q} + 2L_\ell \cos\left(\frac{\iota_a}{3}\right) - 6\right]\left[\mathcal{Q} + 2L_\ell \cos\left(\frac{\iota_a}{3}\right)\right]^2}{3\mathcal{Q}\left[3\ell^4 + 2\left(2\mathcal{Q} - 15\right)L_\ell \cos\left(\frac{\iota_a}{3}\right) - 39\mathcal{Q} + 2L_\ell^2 \cos\left(\frac{2\iota_a}{3}\right) + 54\right]}},$$

$$K_\times(\ell) \equiv \sqrt{\frac{\left[\mathcal{Q} - 2L_\ell \sin\left(\frac{\iota_b}{3}\right) - 6\right]\left(\mathcal{Q} - 2L_\ell \sin\left(\frac{\iota_b}{3}\right)\right)^2}{3\mathcal{Q}\left[3\ell^4 + 2\left(15 - 2\mathcal{Q}\right)L_\ell \sin\left[\frac{\iota_b}{3}\right] - 39\mathcal{Q} - 2L_\ell^2 \cos\left(\frac{2\iota_b}{3}\right) + 54\right]}},$$

$$\iota_a \equiv \cos^{-1}(L_{\updownarrow\updownarrow}), \quad \iota_b \equiv \sin^{-1}(L_{\updownarrow\updownarrow}) \tag{12}$$

(here $L_\updownarrow$ is a function of the momentum ℓ). Function $K_{center}(\ell)$ describes the rings seeds, while $K_\times(\ell)$ refers the tori cusps ($\mathcal{Q} \equiv \ell^2$).

The cusped tori outer edge can be expressed as function of the cusp $r_\times$ as follows:

$$r_{out}^\times(r_\times) = \frac{2}{3}\left[\sqrt{\frac{(r_\times - r_{mso})^2 r_\times^2}{(r_\times - r_{mbo})^2}}\ \cos\left[\frac{1}{3}\cos^{-1}\mathbf{X}\right] + \frac{r_\times}{r_\times - r_{mbo}} + r_\times\right]$$

where $\mathbf{X}$ is a function of $r_\times$, and the the geometrical maxima of cusped tori for the outer (o) and inner (i) Roche lobes are

$$r_{\max}^o(r) = \sqrt{4\sqrt{\frac{2}{3}}\psi_\lambda \cos\left[\frac{1}{3}\cos^{-1}\left(-\frac{3}{4}\sqrt{\frac{3}{2}}\psi_\lambda\psi_\sigma^2\right)\right] + \frac{r^2}{(r - r_\gamma)\psi_\sigma}}$$

$$r_{\max}^i(r) = \sqrt{\frac{r^2}{(r - r_\gamma)\psi_\sigma} - 4\sqrt{\frac{2}{3}}\psi_\lambda \cos\left[\frac{1}{3}\left(\cos^{-1}\left[-\frac{3}{4}\sqrt{\frac{3}{2}}\psi_\lambda\psi_\sigma^2\right] + \pi\right)\right]},$$

(here r is the fluid pressure critical point where $\psi_\lambda, \psi_\sigma$ are functions of r).

The cusped torus height is

$$h_{\max}^o(r_\times) = \left(-2\sqrt{6}\sqrt{\frac{(r_\times - r_\gamma)(r_\times - r_+)^2 r_\times^4}{(r_\times - r_{mbo})^3}}\sec\left[\frac{1}{3}\cos^{-1}(\psi_\rho)\right] + \right.$$

$$\left.\frac{9(r_\times - r_+)^2 r_\times^2 \sec^2\left[\frac{1}{3}\cos^{-1}(\psi_\rho)\right]}{8(r_\times - r_{mbo})(r_\times - r_\gamma)} + \frac{(r_\times - r_+)(5r_\times - 18)r_\times^2}{(r_\times - r_{mbo})^2}\right)^{1/2},$$

(ψ_σ is a function of $r_\times$.) Finally we can express the cusped tori geometrical thickness $\mathbf{S}_\times = 2h_\times/(\lambda_\times)$ in terms of the pressure critical points where $\lambda_\times$ is the cusped torus elongation on its symmetry plane and $h_\times$ the cusped torus height.

4. Conclusion

We explored models of tori clusters orbiting around a central SMBH, detailing the morphological characteristics of the toroidal components. Configurations considered here can be used as initial data for dynamical (time-dependent, evolutive) GRMHD analysis. A "leading function" as been used to constraint the tori distribution around the central attractor, together with the energy function $K(r)$ regulating the agglomerate stability (cusp emergence and tori collision), the flow thickness, mass accretion rate and cusp luminosity.

From the observational viewpoint the inner ringed structure offers several interesting scenarios arising from the unstable states associated to its inner activity, as the presence of multiple accretion points and inter disk shells of multiple jets. Eventually observational evidence of the RAD and the associated inter disk activity could be found in the obscuration of the X-ray emission spectrum, as a track of the agglomerate inner composition. An indication of the presence of multiple orbiting tori could be seen in an increasing BH accretion mass rate and the presence of interrupted phases of BH accretion, or in the emission associated to oscillation tori modes as in HF QPOs. The establishment of runaway instability and the tori self-gravity can be relevant further factors for eRAD tori agglomerate around SMBHs[37,38] and the Bardeen–Petterson effect is main relevant in the misaligned tori case.[39]

Hydrodynamical transport of angular momentum in accretion disks in the presence of nonlinear perturbations due to noise

Subham Ghosh* and Banibrata Mukhopadhyay†
Department of Physics, Indian Institute of Science, Bangalore, Karnataka, 560012, India
*subham@iisc.ac.in
†bm@iisc.ac.in

The origin of hydrodynamical instability and turbulence in the Keplerian accretion disk is a long-standing puzzle. The flow therein is linearly stable. Here we explore the evolution of perturbation in this flow in the presence of an additional force. Such a force, which is expected to be stochastic in nature hence behaving as noise, could result from thermal fluctuations (however small be), grain–fluid interactions, feedback from outflows in astrophysical disks, etc. We essentially establish the evolution of nonlinear perturbation in the presence of Coriolis and external forces, which is the modified Landau equation. We obtain that even in the linear regime, under suitable forcing and Reynolds number, the otherwise least stable perturbation evolves to a very large saturated amplitude, leading to nonlinearity and plausible turbulence. Hence, forcing essentially leads a linear stable mode to unstable. We further show that nonlinear perturbation diverges at a shorter time-scale in the presence of force, leading to a fast transition to turbulence. Interestingly, the emergence of nonlinearity depends only on the force but not on the initial amplitude of perturbation, unlike the original Landau equation-based solution.

Keywords: Accretion, accretion disks – hydrodynamics – instabilities – turbulence

1. Introduction

Origin of instability and plausible turbulence in Rayleigh stable flows, e.g., the Keplerian accretion flow, is a long-standing problem. While such flows are evident to be turbulent, they are linearly stable for any Reynolds number (Re). Although people[1,2] described the underlying flow in accretion disks to be turbulent with an effective turbulent viscosity, the origin of turbulence therein was not clear until Balbus and Hawley[3] proposed the idea of magnetorotational instability (MRI) following Velikhov[4] and Chandrasekhar.[5] MRI is a Magnetohydrodynamical (MHD) instability, and it operates due to the coupling between the weak magnetic field and the rotation of the fluid parcel. Although MRI is a popular instability mechanism, it poses several problems. There are astrophysical bodies where the ionization fraction is tiny as they are cold. In such systems, MRI gets suppressed.[6] Apart from that, beyond a certain value of the toroidal component of the magnetic field for compressible plasma, MRI gets suppressed.[7,8] There are several other cites too where MRI seizes to work or becomes suppressed.[9,10] We, therefore, venture for a hydrodynamical origin of nonlinearity and hence plausible turbulence in the accretion disk. Our emphasis is the conventional linear instability when perturbation grows

exponentially, unlike the case of transient growth. We particularly consider here an extra force,[11] to fulfill our purpose. The examples[12] of the origin of such force in astrophysical context, particularly in accretion disks, could be: the interaction between the dust grains and fluid parcel in protoplanetary disks, back reactions of outflow/jet to accretion disks.

2. Formalism of the problem

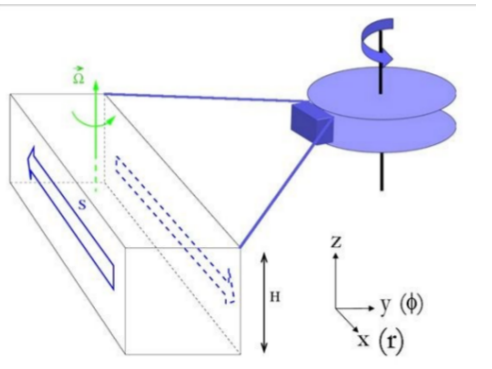

Fig. 1. Model picture of local cubical box in accretion disk where we perform the analysis (http://ipag.obs.ujf-grenoble.fr/ longarep/astrophysics.html). Within the box, the Cartesian coordinate x is along the radial cylindrical coordinate r (with respect to the center of the accretion disk), y is along ϕ, and z is same in both the systems.

To formulate the problem, we have considered a local box at a local patch in the accretion disk, as shown in the Fig. 1. Although the accretion disk possesses cylindrical geometry, In the local box, we study the motion of the local fluid element using the Cartesian coordinates. The one to one correspondence between the Cartesian (x, y, z) and cylindrical (r, ϕ, z) coordinates are shown in the Fig. 1. The Cartesian coordinates x, y, z are along the cylindrical coordinates r, ϕ, z. The details of the local formulation are in Mukhopadhyay et al.,[13,14] and Ghosh and Mukhopadhyay.[15] As we confine ourselves in the local region of the accretion disks, the corresponding flow has been considered incompressible.[9,13,16–18] The governing equations are the ensemble-averaged Orr-Sommerfeld and Squire equations in the presence of Coriolis force and an additional stochastic force,[12,19] which is delta correlated with nonzero mean. The Orr-Sommerfeld and Squire equations are obtained by eliminating the pressure term from the corresponding Navier-Stokes equations and utilizing the continuity equation for the incompressible flow. The governing equations are given by,

$$\left(\frac{\partial}{\partial t} + U\frac{\partial}{\partial y}\right)\nabla^2 u - U''\frac{\partial u}{\partial y} + \frac{2}{q}\frac{\partial \zeta}{\partial z} - \frac{1}{Re}\nabla^4 u + \Gamma_1 = NL^u, \tag{1}$$

$$\left(\frac{\partial}{\partial t}+U\frac{\partial}{\partial y}\right)\zeta - U'\frac{\partial u}{\partial z} - \frac{2}{q}\frac{\partial u}{\partial z} - \frac{1}{Re}\nabla^2\zeta + \Gamma_2 = NL^{\zeta}, \tag{2}$$

where u and ζ are respectively the x-component of the velocity and vorticity perturbations after ensemble averaging, U the y-component of background velocity which for the present purpose of plane shear in the dimensionless units is $-x$, q the rotation parameter with $\Omega(r) \propto 1/r^q$, $\Omega(r)$ being the angular frequency of the fluid parcel at radius r, Γ-s are the corresponding constant means of stochastic forces (white noise with nonzero mean due to gravity making the system biased[11]) in the system described below, and NL-s are the non-linear terms due to the perturbation. The x-component of vorticity and the non-linear terms are given by

$$\zeta = \frac{\partial w}{\partial y} - \frac{\partial v}{\partial z}, \tag{3}$$

$$NL^u = -\nabla^2\{(\mathbf{u}'\cdot\nabla)u\} + \frac{\partial}{\partial x}\nabla\cdot\{(\mathbf{u}'\cdot\nabla)\mathbf{u}'\}, \tag{4}$$

$$NL^{\zeta} = -\frac{\partial}{\partial y}\{(\mathbf{u}'\cdot\nabla)w\} + \frac{\partial}{\partial z}\{(\mathbf{u}'\cdot\nabla)v\}, \tag{5}$$

where $\mathbf{u}' = (u, v, w)$, which is the perturbed velocity vector. For the complete description of the flow, equations 1 and 2 are supplemented with the equation of continuity, which is given by

$$\nabla\cdot\mathbf{u}' = 0, \tag{6}$$

To solve the governing equations, we have no-slip boundary conditions along x-direction,[12,13,20] i.e. $u = v = w = 0$ at $x = \pm 1$ or equivalently

$$u = \frac{\partial u}{\partial x} = \zeta = 0, \text{ at } x = \pm 1. \tag{7}$$

2.1. *Linear theory*

In the evolution of linear perturbation, let the linear solutions be

$$u = \hat{u}(x,t)e^{i\mathbf{k}\cdot\mathbf{r}}, \tag{8}$$

$$\zeta = \hat{\zeta}(x,t)e^{i\mathbf{k}\cdot\mathbf{r}}, \tag{9}$$

with $\mathbf{k} = (0, k_y, k_z)$ and $\mathbf{r} = (0, y, z)$. Substitute these in equations (1) and (2), neglecting non-linear terms, we obtain

$$\frac{\partial}{\partial t}Q + i\mathcal{L}Q + \Gamma = 0, \tag{10}$$

where

$$Q = \begin{pmatrix}\hat{u}\\ \hat{\zeta}\end{pmatrix}, \ \mathcal{L} = \begin{pmatrix}\mathcal{L}_{11} & \mathcal{L}_{12}\\ \mathcal{L}_{21} & \mathcal{L}_{22}\end{pmatrix}, \ \mathcal{D} = \frac{\partial}{\partial x}, \tag{11}$$

$$\mathcal{L}_{11} = (\mathcal{D}^2 - k^2)^{-1}\Big[k_y U\left(\mathcal{D}^2 - k^2\right) - k_y U'' - \frac{1}{iRe}\left(\mathcal{D}^2 - k^2\right)^2\Big],$$
$$\mathcal{L}_{12} = \left(\mathcal{D}^2 - k^2\right)^{-1}\frac{2k_z}{q},$$
$$\mathcal{L}_{21} = -\left(U' + \frac{2}{q}\right)k_z,$$
$$\mathcal{L}_{22} = k_y U - \frac{1}{iRe}\left(\mathcal{D}^2 - k^2\right),$$

and

$$\Gamma = e^{-i\mathbf{k}\cdot\mathbf{r}}\begin{pmatrix}(\mathcal{D}^2 - k^2)^{-1}\Gamma_1\\ \Gamma_2\end{pmatrix}. \tag{12}$$

Let us subsequently assume the trial solution of the equation (10) be

$$Q = AQ_x e^{-i\sigma t} - \frac{1}{\mathcal{D}_t + i\mathcal{L}}\Gamma, \tag{13}$$

where σ is the eigenvalue corresponding to the particular mode and it is complex having real (σ_r) and imaginary (σ_i) parts,

$$Q_x = \begin{pmatrix}\phi^u(x)\\ \phi^\zeta(x)\end{pmatrix} \tag{14}$$

and $\mathcal{D}_t$ stands for $\partial/\partial t$. Q_x is the eigenfunction corresponding to the homogeneous part of the equation (10), i.e., Q_x satisfies $\mathcal{L}Q_x = \sigma Q_x$. The first term of the right-hand side of the equation (13) is due to the homogeneous part of the equation (10), and the second term is due to the inhomogeneous part, i.e., the presence of Γ, of the same equation. Hence, Q is influenced by the force Γ. However, the typical eigenspectra for the Keplerian flow ($q = 1.5$), constant angular momentum flow ($q = 2$) and plane Couette flow ($q \to \infty$) for $Re = 2000$ and $k_y = k_z = 1$ are shown in the Fig. 2. Since $\mathcal{L}_{12}$ and $\mathcal{L}_{21}$ in the equation (11) are zero for the plane Couette flow and constant angular momentum flow, respectively, we obtain the same eigenspectra for both plane Couette, and constant angular momentum flows. We perform the whole analysis for the least stable modes for the respective flows, and these least stable modes are shown in the dotted box in Fig. 2.

2.2. *Nonlinear theory*

For the non-linear solution, following similar work but in the absence of force,[20–22] we assume the series solution for velocity and vorticity, i.e.

$$\psi = \sum_{n\to-\infty}^{\infty}\psi_n = \sum_{n\to-\infty}^{\infty}\bar{\psi}_n(t,x)e^{in(\mathbf{k}\cdot\mathbf{r}-\sigma_r t)}, \tag{15}$$

when obviously $\bar{\psi}_{-n} = \bar{\psi}_n^*$ and ψ could be any one of u and ζ.

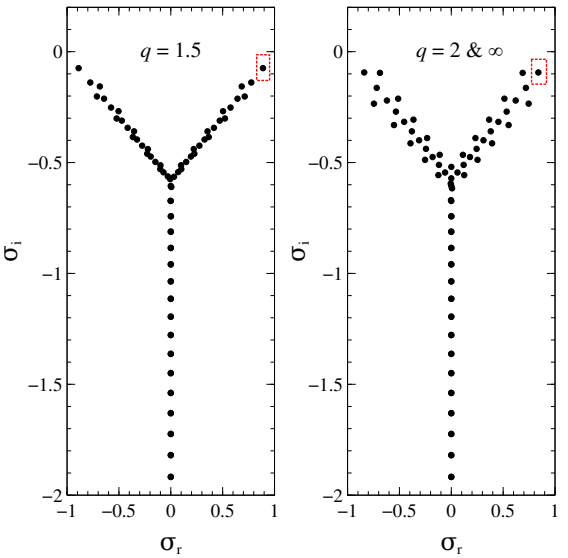

Fig. 2. Variation of σ_i with σ_r for $Re = 2000$ and $k_y = k_z = 1$ for the Keplerian flow ($q = 1.5$), constant angular momentum flow ($q = 2$) and plane Couette flow ($q \to \infty$). The latter two eigenspectra are identical. The dotted box represents the least stable mode for the respective cases.

We substitute these in equations (1) and (2) and collect the coefficients of the term $e^{i(\mathbf{k}\cdot\mathbf{r}-\sigma_r t)}$, to capture least nonlinear effect following, e.g.,,[12,20,22] from both sides and obtain

$$\frac{\partial Q_1}{\partial t} - i\sigma_r Q_1 + i\mathcal{L}Q_1 = NL_1, \tag{16}$$

where $NL_1 = \begin{pmatrix} \left(\mathcal{D}^2 - k^2\right)^{-1} NL_1^u \\ NL_1^\zeta \end{pmatrix}$ and $Q_1 = \begin{pmatrix} \bar{u}_1(x,t) \\ \bar{\zeta}_1(x,t) \end{pmatrix}$. We assume the solution for Q_1 to be

$$Q_1 = \sum_{m=1}^{\infty} A_{t,m} Q_{x,m} - \frac{1}{\mathcal{D}_t + i\mathcal{L}}\Gamma, \tag{17}$$

where m stands for various eigenmodes.

However, to the first approximation, our interest is in the least stable mode. Similar descriptions in two dimensions[20] without Γ and three-dimensional Keplerian disks[22] without Γ are already there in the in the literature and we mostly follow their formalism. We, therefore, omit the summation, and subscript m in the equation (17), and obtain

$$Q_1 = A_t Q_x - \frac{1}{\mathcal{D}_t + i\mathcal{L}}\Gamma. \tag{18}$$

We then substitute the equation (18) in the equation (16) and using bi-orthonormality between Q_x and its conjugate function $\tilde{Q}_x$, we obtain

$$\frac{dA_t}{dt} - \sigma_i A_t + \mathcal{N} = p|A_t|^2 A_t, \tag{19}$$

where

$$\mathcal{N} = \int_{-1}^{1} dx \tilde{Q}_x^{\dagger} \Gamma' \tag{20}$$

and

$$p = \int_{-1}^{1} dx \tilde{Q}_x^{\dagger} \mathcal{S}, \tag{21}$$

where

$$\begin{aligned} \Gamma' &= -\Gamma + i\sigma_r \Big(\frac{1}{\mathcal{D}_t + i\mathcal{L}} \Big) \Gamma \\ &= -\Gamma + i\sigma_r (t - i\mathcal{L}t^2)(1 + \mathcal{L}^2 t^2)^{-1} \Gamma, \end{aligned} \tag{22}$$

$\mathcal{S}$ is the spatial contribution from the nonlinear terms. For the greater details, see Ghosh and Mukhopadhyay.[12]

Throughout the paper, Γ from the equation (12) has been decomposed as $\Gamma \rightarrow \Gamma \begin{pmatrix} 1 \\ 1 \end{pmatrix}$ by adjusting Γ_1 and Γ_2, as they are only the free parameters.

The evolution of $\mathcal{N}$ has been shown in Fig. 3 for the parameters mentioned in the figure. It shows that $\mathcal{N}$ becomes saturated beyond a certain time, and the saturation depends on Re. As Re increases, the saturation increases. Fig. 4 shows the variation of the least stable (the one in the dotted box in Fig. 2) as a function of Re in the case of the Keplerian flow. It tells us that the least stable mode approaches zero as Re is increased.

3. Results

Equation (19), which is a nonlinear equation, tells us about the evolution of the amplitude of the perturbation. To explore the evolution of linear and nonlinear perturbations, we use the equation (19) accordingly. For the evolution of the linear perturbation, we get rid of the nonlinear term in equation (19).

3.1. *Evolution of $|A|_t$ in the linear regime*

In the linear regime, the equation (19) becomes

$$\frac{dA_t}{dt} = \sigma_i A_t - \mathcal{N}. \tag{23}$$

This equation tells that at large t, $|A_t|$ becomes $|\mathcal{N}|/|\sigma_i|$.[12]

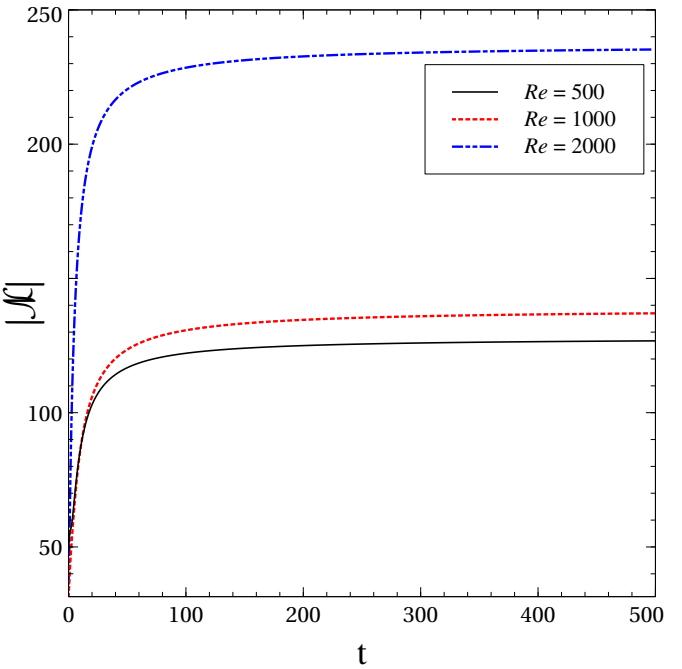

Fig. 3. Variation of $\mathcal{N}$ as a function of t for $Re = 500,\ 1000$ and 2000, for $\Gamma = 10^4$ and $k_y = k_z = 1$, corresponding to the respective least stable modes.

Fig. 5 shows the variation of $|A_t|$ as a function of t for various values of Re and Γ. Fig. 5 also suggests the scaling relation between saturated $|A_t|$ and Γ to be

$$|A_t| \propto \Gamma \tag{24}$$

for a fixed Re. Apart from that, we notice that for a fixed Γ, $|A|_t$ becomes saturated at $|\mathcal{N}|/|\sigma_i|$ beyond a certain time, and the saturation increases as Re increases. This saturation is independent of the initial condition.[12] This is because at a fixed Γ, $|\mathcal{N}|$ becomes saturated (see Fig. 3) at a fixed value, and the saturated value increases as Re increases, as well as $|\sigma_i|$ increases as Re increases (see Fig. 4). Now, in the accretion disk, Re is huge[19] ($\gtrsim 10^{14}$). The smaller Γ, therefore, can bring nonlinearity in the accretion disk, as for huge Re, $|\sigma_i|$ is infinitesimally small. Hence, $|\mathcal{N}|/|\sigma_i|$ becomes enormous. This huge saturation of $|A_t|$ could bring nonlinearity and hence plausibly turbulence in the underlying Keplerian flow.

3.2. *Evolution of $|A_t|$ in the nonlinear regime*

In the nonlinear regime, the evolution of $|A_t|$ is described by the equation (19). Fig. 6 describes the variation of $|A_t|$ as a function of t for nonlinear perturbation in the Keplerian flow. In the figure, $RE(A_t)$ and $IM(A_t)$ indicate the real and

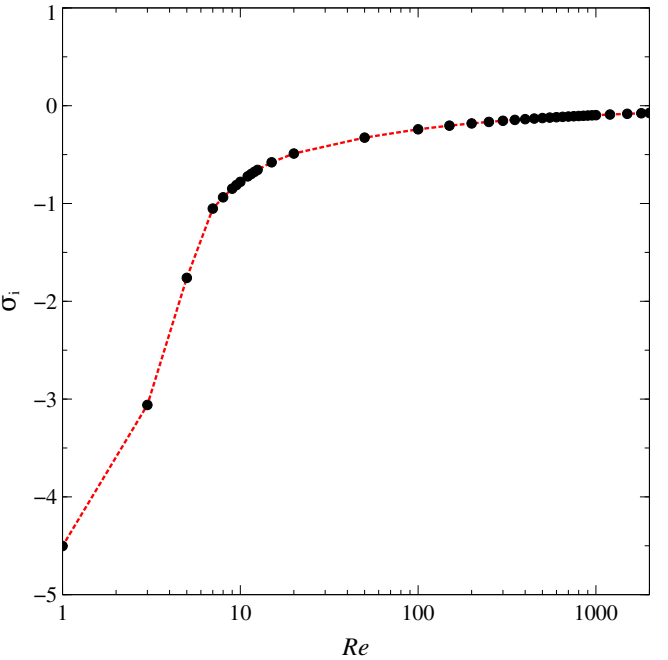

Fig. 4. Variation of the least stable σ_i as a function of Re for $k_y = k_z = 1$ in the Keplerian flow.

imaginary parts of initial A_t, respectively. It tells us that for $\Gamma = 0$, depending on the initial amplitude, $|A_t|$ may diverge (green line) or $|A_t|$ may decay (continuous black line) to zero from the initial amplitude. When there is no noise, i.e., $\Gamma = 0$, the diverging solution of $|A_t|$ occurs when the initial amplitude is beyond a critical amplitude.[12] It is apparent that the onset of the nonlinearity depends on the initial amplitude of perturbation in the absence of the force, but it does not depend on the same in the presence of force.[12] The divergence of $|A_t|$ and hence the onset of nonlinearity and plausible turbulence depends only on the strength of the force, as shown by dashed (magenta) line, compared to dot-dashed (blue) and dotted (red) lines, in Fig. 6.

4. Conclusion

If there is no extra force involved in the system, then the equation (19) becomes the usual Landau equation, which is

$$\frac{dA_t}{dt} = \sigma_i A_t + p|A_t|^2 A_t, \tag{25}$$

which can be further recast to

$$\frac{d|A|^2}{dt} = k_1|A|^2 + k_2|A|^4, \tag{26}$$

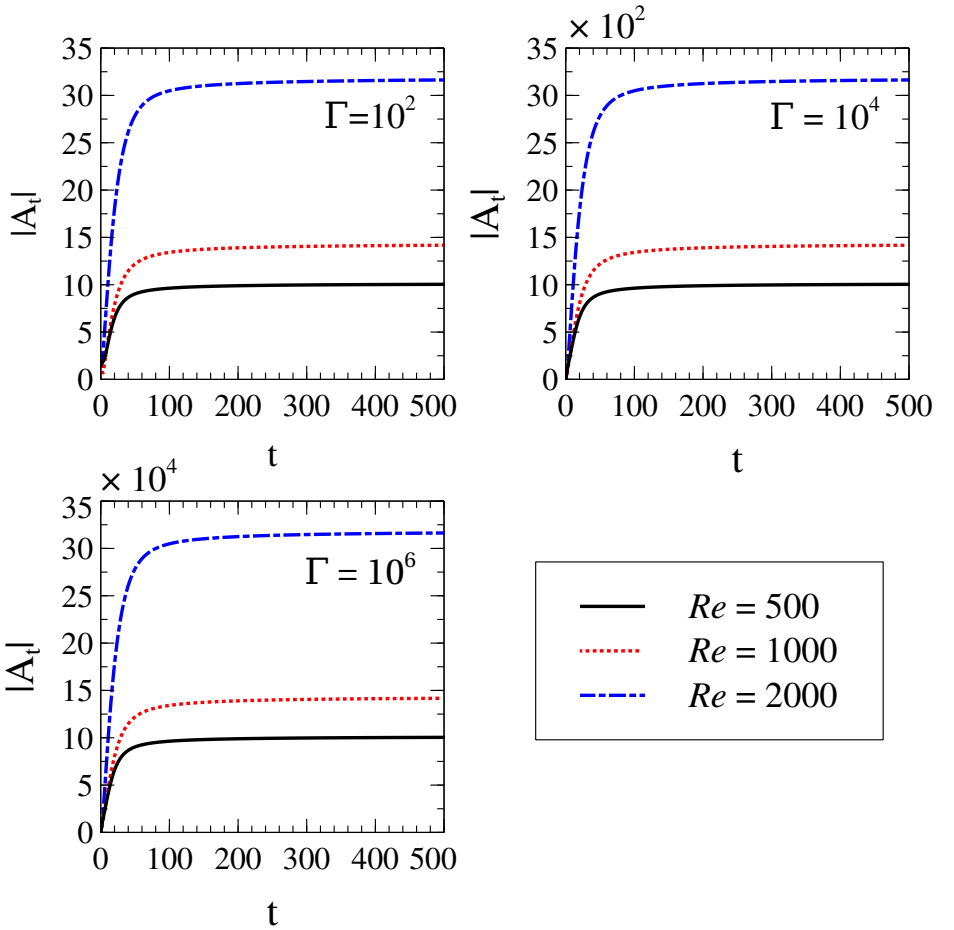

Fig. 5. Variation of $|A_t|$ as a function of t for three sets of Re and Γ with $k_y = k_z = 1$ for linear analysis in the Keplerian flow ($q = 1.5$).

where A is the amplitude of the nonlinear perturbations for the corresponding system, k_1 is $2\sigma_i$ and k_2 is the real part of $2p$, i.e., $2p_r$. Its solution is

$$|A|^2 = \frac{A_0^2}{-\frac{k_2}{k_1}A_0^2 + \left(1 + \frac{k_2}{k_1}A_0^2\right)e^{-k_1 t}}, \tag{27}$$

where A_0 is the initial amplitude. Depending on the sign (positive/negative) of k_1 and k_2, there are four[21,23] different possible evolutions of $|A|$. These given below.

- In the present context of shear flows, k_1 (i.e., σ_i) is negative, but k_2 is positive. Therefore, there will be a threshold for initial amplitude A_i, determining the growth of perturbation. If the initial amplitude $A_0 < A_i$,

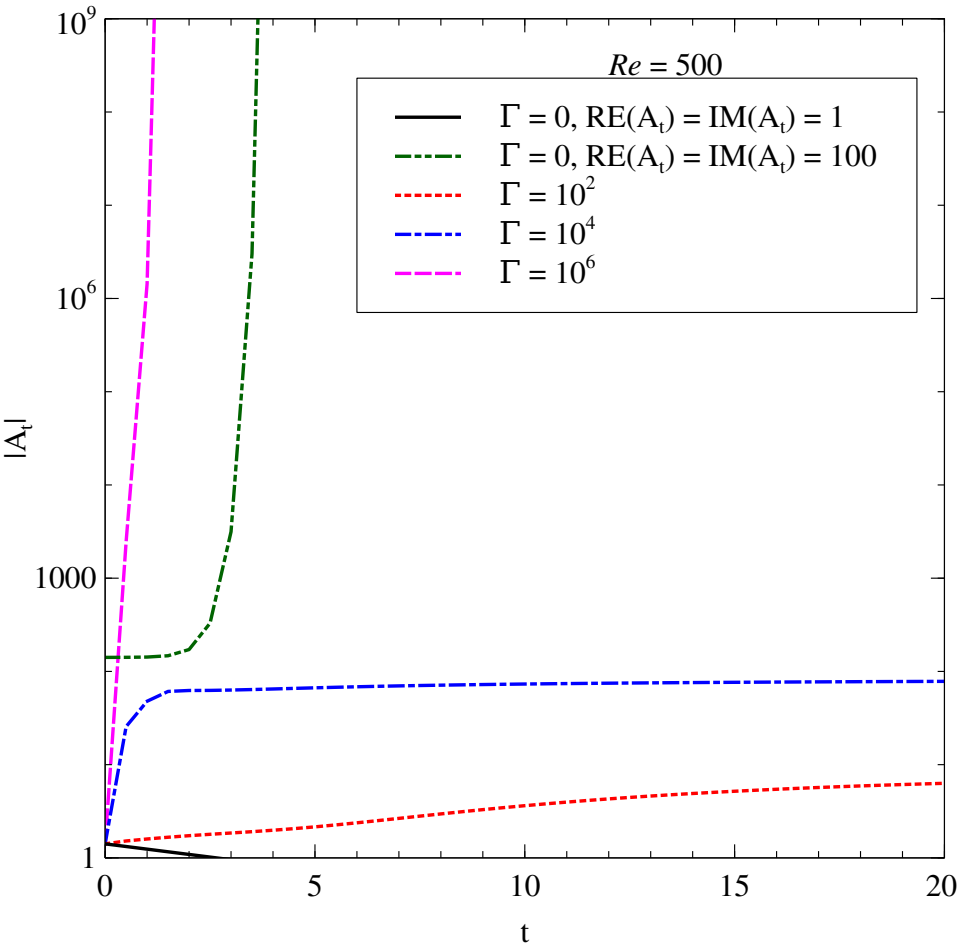

Fig. 6. Variation of $|A_t|$ as a function of t with $k_y = k_z = 1$ for nonlinear analysis in the Keplerian flow for $Re = 500$ and four different Γ. For $\Gamma \neq 0$, initial condition is $\mathrm{RE}(A_t) = \mathrm{IM}(A_t) = 1$.

then

$$|A|^2 \sim \frac{A_i^2 A_0^2 e^{k_1 t}}{A_i^2 - A_0^2} \tag{28}$$

at a large t. Therefore, $|A|^2 \to 0$ for $A_0 < A_i$ at $t \to \infty$. However, if $A_0 > A_i$, then $|A|^2 \to \infty$ at $t \to \ln(1 - A_i^2/A_0^2)/k_1$.

- If both k_1 and k_2 would be positive, $|A|^2$ blows up after a finite time. Hence, there will be a fast transition to turbulence.
- On the other hand, if $k_1 > 0$ but $k_2 < 0$, then $|A|^2 \to k_1/|k_2|$ at $t \to \infty$. In this case, $|A|^2$ at a large t does not depend on A_0.
- Obviously, for k_1 and k_2 both negative, $|A|^2$ decays fast.

However, we have shown that the saturation in $|A_t|$ is $|\mathcal{N}|/|\sigma_i|$ in the linear regime. We have also argued that depending on Re and Γ, the system may already be in the nonlinear regime. The evolution of $|A_t|$ at the linear regime in our case, i.e., with extra force, is similar to that of $|A|$ from the equation (26), i.e. without force, for $k_1 > 0$ and $k_2 < 0$. In the Keplerian flow, k_1, i.e. σ_i, is negative, but k_2, i.e. p_r, could be positive. In the presence of extra force, the Landau equation modifies in such a way that the solution in the linear regime itself mimics the Landau equation without force (i.e., equation 26), however, with $k_1 > 0$ and $k_2 < 0$. Further, in the nonlinear regime, the amplitude A_t (i.e., with extra force included) diverges beyond a certain time, depending on Re and Γ. In the nonlinear regime, the Landau equation in the presence of extra force but negative k_1 (σ_i) is, therefore, mimicking the Landau equation without force but with positive k_1 and k_2. Essentially, the extra force effectively changes the sign of k_1 (i.e., σ_i) for the Landau equation without force. Speaking in another way, the very presence of extra force destabilizes the otherwise stable system. Thus, the presence of force plays an important role in developing nonlinearity and turbulence in the case of Rayleigh stable flows.

Properties of accretion disc models in the background quadrupole

Shokoufe Faraji

University of Bremen, Center of Applied Space Technology and Microgravity (ZARM), 28359 Germany

We consider a static and axially symmetric metric containing two quadrupole parameters. In the present contribution, we study the quadrupole moments constraints on the properties of the relativistic accretion disc models, also explore the relation of oscillatory frequencies of charged particles to the frequencies of the twin high-frequency quasi-periodic oscillations observed in some microquasars. We also compare the results with Schwarzschild and Kerr metrics.

Keywords: Accretion discs; Quadrupole moment; Black hole physics; QPOs

1. Introduction

In this paper, we are interested in studying how the presence of quadrupole moments in the metric affects the nature of astrophysical properties. This metric may link the observable effects to the system due to taking these parameters as the new dynamical degrees of freedom.

The first static and axially symmetric solution of Einstein equation containing arbitrary quadrupole moment were described in.[1] Later, Zipoy and Voorhees[2,3] found an equivalent transformation which can be treated analytically. Later on, with introducing a new parameter is known as q-metric.[4] In this regard, quadrupoles can be seen as perturbation parameters of the Schwarzschild spacetime from a dynamical point of view. This metric represents the exterior gravitational field of an isolated static axisymmetric mass distribution. Of course, there are different ways of including quadrupole in the metric, but we consider ones that can be treated analytically. One simple and straightforward extension of q-metric involves introducing an external field in addition to the dynamical metric. This class of theories is referred to as generalized q-metric. The astrophysical motivation for choosing such fields is the possibility to constitute a reasonable model for a more realistic situation occurring in vicinity of compact objects.

This work studies thin and magnetized thick accretion disc models,[5] and quasi-periodic oscillations (QPOs)[6] in this static and axisymmetric background.

2. q-metric with an external source

Most of the astrophysical studies considered the Kerr black hole. However, here, we choose to work on the generalized q-metric that considers the existence of a static and axially symmetric external distribution of matter in its vicinity up to

quadrupole like adding a magnetic surrounding.[7] In fact, due to their strong gravitational field, compact objects are not necessarily isolated or spherically symmetric as a response to their environments. This metric describes the outer of a deformed compact object up to quadrupole and reads as[8]

$$\begin{aligned} \mathrm{d}s^2 = &-\left(\frac{x-1}{x+1}\right)^{(1+\alpha)} e^{2\hat{\psi}} dt^2 + M^2(x^2-1)e^{-2\hat{\psi}} \\ &\times \left(\frac{x+1}{x-1}\right)^{(1+\alpha)} \left[\left(\frac{x^2-1}{x^2-y^2}\right)^{\alpha(2+\alpha)} e^{2\hat{\gamma}} \right. \\ &\left. \times \left(\frac{dx^2}{x^2-1} + \frac{dy^2}{1-y^2}\right) + (1-y^2)d\phi^2\right], \end{aligned} \tag{1}$$

where $t \in (-\infty, +\infty)$, $x \in (1, +\infty)$, $y \in [-1, 1]$, $\phi \in [0, 2\pi)$, and in principle $\alpha \in (-1, \infty)$. Metric function $\hat{\psi}$ plays the role of gravitational potential, and once we have it by an integration of its explicit form, $\hat{\gamma}$ is obtained. These are given by

$$\hat{\psi} = -\frac{\beta}{2}\left[-3x^2y^2 + x^2 + y^2 - 1\right], \tag{2}$$

$$\begin{aligned} \hat{\gamma} = &-2x\beta(1-y^2) \\ &+ \frac{\beta^2}{4}(x^2-1)(1-y^2)(-9x^2y^2 + x^2 + y^2 - 1). \end{aligned} \tag{3}$$

By its construction, this metric is valid locally.[9] This metric has two parameters aside from the mass; deformation parameter α and distortion parameter β, which are not independent of each other. These are chosen to be relatively small and connected to the q-metric and the surrounding external mass distribution, respectively. It can easily be checked that for vanishing β we recover the q-metric, and in the limits $\alpha = 0$ and $\beta \neq 0$ distorted Schwarzschild written in the prolate spheroidal coordinates,[9] and for $\alpha = 0$ and $\beta = 0$ we recover the Schwarzschild solution. The relation between the prolate spheroidal coordinates (t, x, y, ϕ), and the Schwarzschild coordinates (t, r, θ, ϕ) is

$$x = \frac{r}{M} - 1\,, \quad y = \cos\theta. \tag{4}$$

To the end, we explore this background by analyzing the thick and thin accretion disc models, and Quasi-periodic oscillations.

3. Accretion discs

In this analysis, we consider two well known Thin and Thick analytical models of accretion onto a compact object.

3.1. *Thin model*

The standard thin disc model has been used to explain a variety of observations where gas is cold and neutral. Therefore, the coupling between the magnetic field and

gas is negligible. In general, observations provide the luminosity and the maximum temperature of the disc that fit the data model.

In this model, the steady axisymmetric fluid configuration is assumed. In addition, as a result of the geometrically thin assumption, effectively, all physical quantities only depend on the vertical distance from the equatorial plane and the radial distance to the central object so that we can consider vertically integrated quantities. Therefore, the two-dimensional disc structure can be decoupled to one-dimensional configurations. One is responsible for the radial quasi-Keplerian flow another for the vertical hydrostatic structure.[10,11]

Three fundamental equations govern the radial structure of the thin disc model

$$(\rho u^{\mu})_{;\mu} = 0, \tag{5}$$

$$u_{\mu} T^{\mu\nu}{}_{;\nu} = 0, \tag{6}$$

$$h_{\mu\sigma}(T^{\sigma\nu})_{;\nu} = 0. \tag{7}$$

where u^{μ} is the four-velocity of the fluid and ρ is the rest mass density, $T^{\sigma\nu}$ is the stress-energy tensor containing non-vanishing shear part, and $h^{\mu\nu}$ is the projection tensor. These equations, together with the radial velocity, which is stated in terms of surface density and mass accretion rate, alpha viscosity prescription and heat flow, govern the radial structure of the disc.[10,11]

For the vertical profile in the comoving fluid frame, the force due to vertical pressure gradient is balanced with gravity, the centrifugal force, and vertically Euler force. The pressure is the sum of gas pressure from nuclei and the radiation pressure, which in practical is derived from the relativistic Euler equation.[12]

Finally, by solving this system of linear equations, one obtains a unique solution for considering positive temperature and pressure. Besides quadrupoles, three parameters describe a thin disc solution in this background, namely M, mass accretion rate $\dot{M}$, and viscosity parameter α. Consequently, the geometric configuration of an accretion disc located around this space-time depends explicitly on the value of the quadrupole parameter. An analysis shows the astrophysical quantities possess almost the same pattern. Figure 1 shows the temperature and flux profiles for different values of quadrupole parameters. As it shows, the intensity of these quantities is much higher closer to the central object and for negative values than Schwarzschild and positive values. This links to the location of ISCO, which is considered the inner edge of the thin accretion disc. For negative quadrupoles, ISCO is closer to the central object, pushing away for positive ones. Therefore, for negative values, the inner part of the disc is located closer to the central object, which causes more intense characteristics in all quantities. It means the behaviour of positive quadrupole moments is smoother than negative ones in general. We may compare this result with the Kerr solution if we consider the rotation parameter a kind of quadrupole counterpart in this background. In the Kerr background, the intensity of these quantities for co-rotating is also smaller than the counter-rotating

case. However, the main difference in the Kerr background is this pattern is valid everywhere, not only closer to the inner part of the disc. Therefore, in general, there are distinguishable differences in both cases regarding observational data.[13]

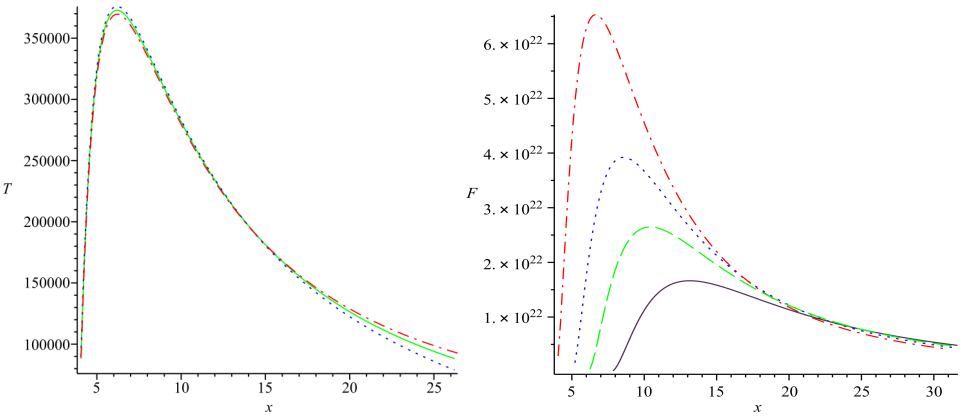

Fig. 1. The left plot is temperaturee T profile for $\alpha = -0.2$; blue line shows $\beta = -0.00001$, green one $\beta = 0$ (Schwarzschild), and red one $\beta = -0.00001$. The right plot is flux profile F for vanishing β (q-metric) and different values of α; from top $\alpha = -0.2$, $\alpha = 0$ (Schwarzschild), $\alpha = 0.2$, $\alpha = 0.5$.

3.2. *Thick model*

The thick disc model describes a general method of constructing perfect fluid equilibria in an axially symmetric and stationary background, which is the simplest analytical model of discs with no accretion flow and is radiatively inefficient. In this work, we considered its magnetic version. The evolution of an ideal magnetised fluid is described by the baryon conservation, energy-momentum conservation, and induction equation.[14,15] The final well known equation in this model reads as[16]

$$W - W_{\rm in} + \frac{\kappa}{\kappa - 1}\frac{p}{w} + \frac{\eta}{\eta - 1}\frac{p_m}{w} = \int_{\ell_{in}}^{\ell} \frac{\Omega \mathrm{d}\ell}{1 - \Omega\ell}, \tag{8}$$

where $W = \ln |u_t|$, magnetic pressure and gas pressure are p_m and p, η and κ are parameters, and w is enthalpy. Therefore, one can construct this model by specifying Ω or ℓ to fix the geometry of the equipotential surfaces. In the constant case, the disc surface is fully determined by the choice of the potential in the inner part of the disc, $W_{\rm in}$, independent of the magnetic field.[17] Thus, the value of angular momentum ,ℓ_0, determines the total potential.[16]

In this work we also considered two more angular momentum distributions; the power-law,[18] and the trigonometric function.[19] In the power-law distribution it is

assumed that

$$\Omega(\ell) = c\ell^n. \tag{9}$$

where by using this equation, the right hand side of the equation (8) can be calculated easily.[18] In the trigonometric function distribution, it is assumed that[19]

$$\ell(x,y) = \begin{cases} \ell_0 \left(\frac{\ell_K(x)}{\ell_0}\right)^{\sigma} (1-y^2)^{\delta}, & x \geq x_{\rm ms}, \\ \ell_0(\zeta)^{-\sigma}(1-y^2)^{\delta}, & x < x_{\rm ms}, \end{cases} \tag{10}$$

where $\ell_0 = \zeta \ell_K(x_{\rm ms})$, and ℓ_K is the Keplerian angular momentum in the equatorial plane, η, σ, and δ are parameters, and $x_{\rm ms}$ is the place of marginally stable orbit. In this model, one only needs to solve function F to obtain the solution[19]

$$\frac{\partial_x p}{\partial_y p} = \frac{\partial_x g^{tt} + \ell^2 \partial_x g^{\phi\phi}}{\partial_y g^{tt} + \ell^2 \partial_y g^{\phi\phi}} := -F(x,y). \tag{11}$$

Analysis of results shows that changing parameter β_c has a strong effect on the location and amplitude of the rest-mass density and spreading the matter through the disc for any chosen value of quadrupoles.

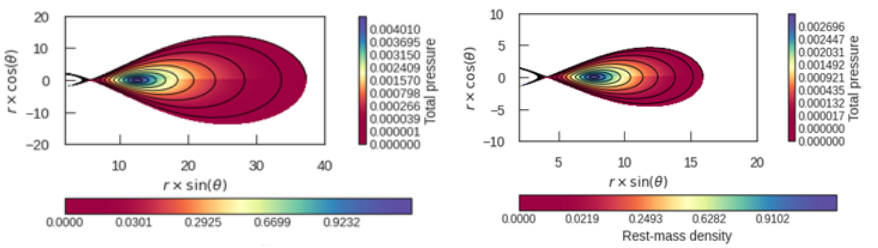

Fig. 2. The left plot is for $(\alpha, \beta) = (0.4, 0.000001)$, the right one is for $(\alpha, \beta) = (-0.1, 0.000001)$ with constant angular momentum.

In fact, a higher magnetic pressure causes the matter to concentrate more in the inner part of the disc. The rest-mass density maximum and its location also depend on the quadrupoles values. Although the effect of quadrupoles correlates with the other parameters, we can conclude that quadrupoles are more responsible for shifting the position of the disc and have a positive contribution to its radial extension. However, this effect for β is not easy to see, as the values of quadrupole parameters that we chose in our models are minimal.[20,21] Moreover, there is a possibility of having two tori in a row for any value of β but negative values for the parameter $\alpha \in (-0.5, -0.553]$. In Figure 3 this situation is plotted with constant angular momentum. However, with two other angular momentum distributions discussed in the paper it is also possible to have two tori.[20]

Furthermore, in the trigonometric distribution, the σ and δ parameters influence each other. However, one can say that σ is more responsible for the location and

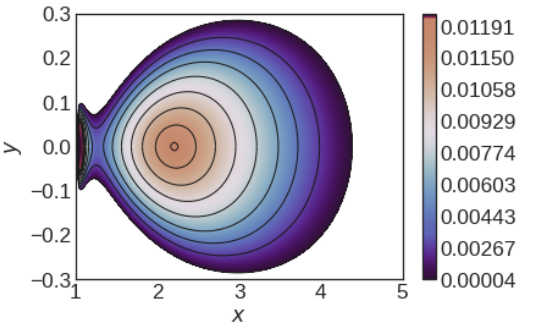

Fig. 3. Possibility to have two tori in a row for $\alpha \in (-0.5, -0.553]$ regardless of the β values.

amplitude of the rest-mass density, and δ affects the distribution of equidensity surfaces. In the case of the power-law distribution, steeper angular momentum tends to shrink the disc and decrease the amplitude of the rest-mass density and pushes away the location of its maximum simultaneously.

4. Quasi-periodic oscillations

Quasi-periodic oscillations (QPOs) of X-ray power spectral density have been observed at low (Hz) and high (kHz) frequencies.[22,23] There have been many models to explain QPOs in the past years. Among them is the Relativistic Precession Model (RPM), which relates the twin-peak QPOs to the Keplerian and periastron precession frequency on an orbit located in the inner part of the accretion disc.[24] Regarding, the high frequencies QPOs (the two-picks in Fourier power density spectra) are considered as the resonances between oscillation modes. Within the ratio 3 : 2 epicyclic resonance, the resonant frequencies are identified with frequencies of radial and vertical epicyclic axisymmetric modes.[25–27]

In this work, we are interested in the dynamics that occur when a static, axisymmetric central compact object is embedded in a weak uniform magnetic field of strength B aligned with the central body's symmetry axis and described by the ϕ-component of the vector potential[28]

$$A_\phi = \frac{1}{2} B(x^2-1)e^{-2\hat{\psi}} \left(\frac{x+1}{x-1}\right)^{(1+\alpha)}. \tag{12}$$

In addition, the specific energy and angular momentum of the particle read as[29]

$$E = \left(\frac{x-1}{x+1}\right)^{(1+\alpha)} e^{2\hat{\psi}} \frac{dt}{ds}, \tag{13}$$

$$L = (x^2-1)e^{-2\hat{\psi}} \left(\frac{x+1}{x-1}\right)^{(1+\alpha)} \left(\frac{d\phi}{ds} + Q\right), \tag{14}$$

where $Q := \frac{qB}{2m}$ is magnetic parameter. Further, the effective potential is

$$V_{\rm Eff} = \left(\frac{x-1}{x+1}\right)^{(\alpha+1)} e^{2\hat{\psi}}\Bigg[\epsilon + e^{-2\hat{\psi}}\left(\frac{x+1}{x-1}\right)^{\alpha}(1-y^2) \times \left(\frac{Le^{2\hat{\psi}}}{(x+1)(1-y^2)}\left(\frac{x-1}{x+1}\right)^{\alpha} - Q(x+1)\right)^2\Bigg], \tag{15}$$

The second term corresponds to the central force potential and electromagnetic potential energy. In what follows, we investigate the stability of circular motion in this background in the presence of a homogeneous magnetic field. We followed the method described in[30,31] and extend the result to this background. The results are in good agreement with these papers regarding vanishing quadrupoles, also rotation in their works.

We need to describe the more general class of orbits slightly deviated from the circular orbits in the equatorial plane x^μ using the perturbation expansion, $x'^\mu = x^\mu + \xi^\mu$. By considering this relation into the geodesic equation with non-vanishing external force and making the integration, for the t and ϕ components, up to linear order in ξ^μ, and we obtain[30,31]

$$\omega_x^2 = \partial_x U^x - \gamma^x{}_\eta \gamma^\eta{}_x, \tag{16}$$

$$\omega_y^2 = \partial_y U^y. \tag{17}$$

These equations describe radial and vertical oscillations of the charged particle about circular orbits. The sign of frequencies determines the dynamic ω_x^2 and ω_y^2 so that if they have a positive sign, we have a stable orbit; otherwise, even a minimal perturbation can cause a substantial deviation from the unperturbed orbit.

In Schwarzschild solution, the vertical epicyclic frequency is a monotonically decreasing function of x, and we have $\omega_x^2 < \omega_y^2 = \Omega^2$. On the contrary to the Schwarzschild case, the interesting situation in this background is to have various orderings among frequencies and thus different possibilities to reproduce the ratio of $3:2$, also other ratios via different combinations of parameters[29] which is not the case in either Schwarzschild or in q-metric.

Among the various models of the resonance of accretion disc oscillations, we consider the group of QPO models (WD, TD, RP, Ep, Kp, RP1, RP2) considered in[32] and examined them in this background and compared with observational data of three microquasars XTE 1550-564, GRS 1915+105, and GRO 1655-40.[29,33] However, the physical details of these models are different and depend explicitly on the time evolution of the desired system. Indeed, the case of relatively slowly rotating XTE 1550-564 source is more compatible with our static set-up. However, different sets of parameters can fit the data even for the two other fast-rotating sources. An analysis shows for chosen parameters Q, α, and β, the best fit almost corresponds to RP2, RP, and RP1 models in low spin cases. Besides, results reveal that even the regular orbits for some combinations of parameters of metric turn to behave chaotically with a higher magnetic field.

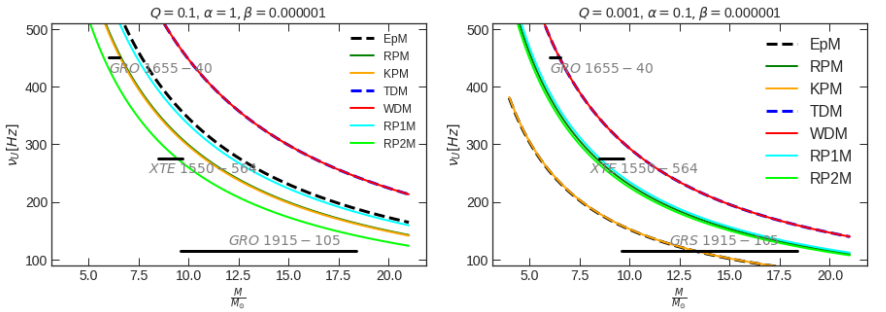

Fig. 4. The upper oscillation frequencies compared to the mass limits obtained from observations of three microquasars for some chosen parameters.

5. Conclusion

In this paper, we mentioned astrophysical features of two accretion disc models in the background of a compact object containing quadrupole moments. We have shown that the presence of quadrupoles changes the accretion disc's geometric properties in both models drastically. In particular, in the Thin accretion disc model, the spectral features would be significantly different and distinguishable in the observation from a black hole. The structure and the shape of the magnetized Thick accretion disc model are also influenced strongly by these parameters.

In addition, the dependency of these two parameters reflects into epicyclic frequencies of particles that cost substantial deviation from the correspondence quantities in the Schwarzschild case. In fact, the resonant phenomena of the radial and vertical oscillations at their frequency ratio 3 : 2 depending on chosen parameters, also in this background can be well related to the frequencies of the twin HF QPOs 3 : 2 observed in the microquasars. Although the fitting depends on the combination of parameters, we still can expect to have a better fitting for choosing a larger quadrupole moment in the combination.

Directions for the future could be adding the strong magnetic field which also influences the metric itself, considering rotation, studying the self-gravity of the Thin disc model, and studying the stability of this solution to extend this work. Further, this theoretical model can be served as the initial data for numerical simulations in the astrophysical setting.

Magnetized tori around a uniformly accelerating black hole

Shokoufe Faraji, Audrey Trova

University of Bremen, Center of Applied Space Technology and Microgravity (ZARM), 28359 Germany

We generalize the relativistic accretion thick disc model to the background of a spinning charged accelerating black hole described by the C-metric to study the effects of this background on the disc model. We show the properties of this accretion disc model and its dependence on the initial parameters. This background can be distinguishable from the Kerr space-time by analyzing the observing features of accretion discs.

Keywords: C-metric; Magnetic field; Accretion disc; Black hole physics

1. Introduction

In this paper we investigate the spinning charged C-metric, with the aim of studying the properties of the well known magnetised Thick accretion disc model and the morphology of the equipotential surfaces.

The family of C-metric has accelerating nature and is considered as describing an accelerating black hole.[1] The spinning charged C-metric in Boyer-Lindquist-type coordinates[2] reads as

$$ds^2 = \frac{1}{\Omega^2}\left(-\frac{f}{\Sigma}\left[dt - a\sin^2\theta\frac{d\varphi}{K}\right]^2 + \frac{\Sigma}{f}dr^2 + \Sigma r^2\frac{d\theta^2}{g} + \frac{g\sin^2\theta}{\Sigma r^2}\left[adt - (r^2+a^2)\frac{d\varphi}{K}\right]^2\right), \tag{1}$$

where

$$\Omega = 1 + \alpha r\cos\theta, \tag{2}$$

$$f(r) = \left(1-\alpha^2 r^2\right)\left(1 - \frac{2m}{r} + \frac{e^2+a^2}{r^2}\right), \tag{3}$$

$$g(\theta) = (e^2+a^2)\alpha^2\cos^2\theta + 2m\alpha\cos\theta + 1, \tag{4}$$

$$\Sigma(r,\theta) = \frac{a^2}{r^2}\cos^2\theta + 1, \tag{5}$$

$$\xi = \alpha^2(e^2+a^2) + 1, \tag{6}$$

$$K = \xi + 2m\alpha, \tag{7}$$

where $t \in (-\infty, +\infty)$, $\theta \in (0, \pi)$, $r \in (0, +\infty)$. The metric has four independent parameters: the mass m, the electric charge e, the rotation a, and the so-called acceleration parameter α. In this metric $r = 0$ is the curvature singularity, and there

is a conical singularity on the θ axis. The parameter K affects the distribution of conical defects in the space-time and allows φ to be 2π-periodic (see for example[3–5]).

Almost all studies with this metric are revolved around the coordinate ranges, which are dictated by the metric functions and their root configurations. The main constrains are

$$r_b = -\frac{1}{\alpha \cos\theta}, \tag{8}$$

$$e^2 + a^2 \leq m^2, \tag{9}$$

and

$$2m\alpha \leq \begin{cases} 2\sqrt{\xi - 1} & \xi > 2, \\ \xi & 0 < \xi \leq 2. \end{cases} \tag{10}$$

2. Properties of the disc model

The Thick accretion disc is an analytical model that provides a general method to build equilibrium configurations of the perfect fluid matter orbiting around a stationary and axially symmetric black hole.[6,7] In this procedure, we considered the approach of Komissarov[8] to attach a dynamically toroidal magnetic field to the model.

An analysis shows[9] that by increasing the acceleration parameter α, almost the possibility of having solutions decreases dramatically. On the contrary, the charge parameter e positively contributes to having solutions; mainly, its effect manifests more for a relatively large α. Furthermore, the possibility of having solutions for larger α depends on having large values for e, so the effect of higher α on the disc could be neutralized partially with the higher charge.

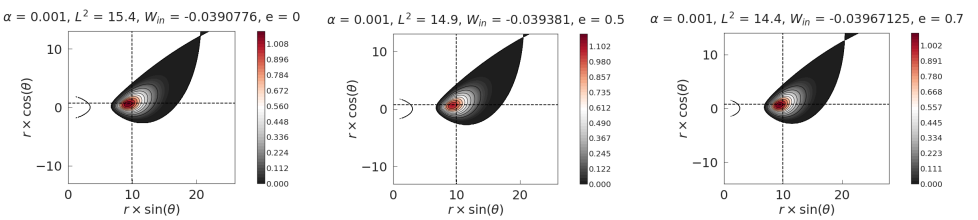

Fig. 1. Contour map of the rest-mass density of magnetised disc. The dashed lines point the center of the disc at $r_c = 10$. The discs are all highly magnetised disc.

The effect of rotation parameter a on having solutions is not strong compared to α but more substantial than the charge parameter e. In fact, parameter a, like α, has a negative effect on having solutions. In general, as e increases, we expect the matter is concentrated closer to the inner edge of the disc. On the contrary, the higher values of a spread the matter more through the disc. Moreover, Increasing a

decreases the size of the disc and change the distribution of matter. In addition, it shifts the disc farther from the compact object, contrary to an increase in e, which shift the disc closer to the central object.

For a fixed value of acceleration parameter α and vanishing rotation, the magnetization parameter does not influence the geometry of the disc; however, it changes the distribution of matter inside the disc and shifts the location of the rest-mass density maximum. In addition, we have a larger oriented disc for larger values of e.

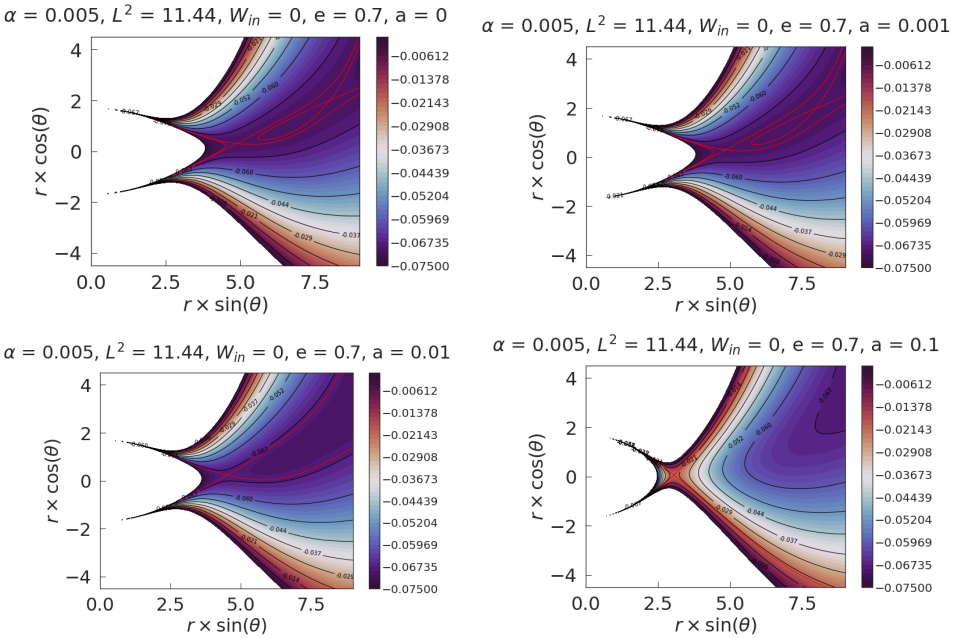

Fig. 2. Contour map of the equipotential surfaces. no solution for $\alpha = 0.005$ unless for high e and very low a. Show no solution for higher α and rotation.

3. Conclusion

In this work, we discussed the influence of the magnetisation parameter, charge e, rotation a, and accelerating parameter α in the spinning charged C-metric on the structure of the magnetised thick disc model.

In general, we can have the Thick disc model for relatively small values of α, while by increasing α, the disc structure becomes smaller and gradually vanishes. The same is true for a. On the contrary to these two parameters, an increase in e increases the disc size and possibility of having a solution. However, we should mention that the strength of the parameters are not the same, as α has the strongest and e has the weaker effect on the disc structure, in comparison.

A further step of this work can be a study on the oscillation of the disc in this setup which is in progress. In addition, this is interesting to examine the Thick disc model with different angular momentum profiles in this space-time.

Multifrequency behaviour of high mass X-ray binaries (Time lag between optical and X-ray outbursts)

Franco Giovannelli
INAF - Istituto di Astrofisica e Planetologia Spaziali, Roma, Italy
Email: franco.giovannelli@iaps.inaf.it

In this work, without any claim to completeness, I will review the zoo of binary systems emitting X radiation, the multi-frequency behaviors of high-mass X-ray systems (HMXBs), with particular emphasis on the X-ray/Be system A 0535 + 26/HDE 245770, which for a favorable series of concomitant causes it is the most studied system. I will also discuss the time lag between events occurring in the high-energy and low-energy bands in galactic accreting systems.

Keywords: X-ray binaries; High mass X-ray binaries; individual: A 0535+26/HDE 245770; accretion, accretion disks

1. Introduction

Among X-ray emitters, X-ray binaries are cauldrons of fundamental physical processes which appear along practically the whole electromagnetic spectrum. The sub-class of X-ray transient sources show multifrequency behaviour which deserve particular attention in order to understand the causing physics. These binary systems consist of a compact star and an optical star, therefore there is a mutual influence between these two stars that drive the low energy (LE) (i.e. radio, IR, optical) and high energy (HE) (i.e. UV, X-ray, γ-ray) processes. The LE processes are produced mostly on the optical star and the HE processes mostly on the compact star, typically a neutron star. Thus it appears evident that through the study of LE processes it is possible to understand also the HE processes and vice versa. In this paper we will discuss this problem starting from the experimental evidence of a delay between LE and HE processes detected for the first time in the X-ray/Be system A0535+26/HDE245770 (e.g. Giovannelli & Sabau-Graziati;[40] Giovannelli, Bisnovatyi-Kogan & Klepnev[41] (here after GBK13); Giovannelli et al.[43]). This delay is common in cataclysmic variables (CVs) and other binary systems with either a neutron star or a black hole.

Giovannelli[30] published an extensive review about X-ray binary systems. Briefly we can summarize the main characteristics of these systems.

2. The zoo of X-ray binary systems

The trivial definition of X-ray binaries (XRBs) is that they are binary systems emitting X-rays. However it has been largely demonstrated that X-ray binary systems

emit energy in IR, Optical, UV, X-ray, Gamma-ray and sometimes they show also valuable radio emission. They can be divided in sub-classes, namely:

1. High Mass X-ray Binaries (HMXB) in which the optical companion is an early type giant or supergiant star and the collapsed object is a neutron star or a black hole. They are concentrated around the galactic plane. The mass transfer is usually occurring via stellar wind; they show hard pulsed X-ray emission (from 0.069 to 1413 s) with KT $\geq$ 9 keV; typical X-ray luminosity is ranging from 10^{34} to 10^{39} erg s^{-1}, and the ratio of X-ray to optical luminosity is $\sim 10^{-3}$–10. The HMXBs can be divided in two sub-classes:

1.1. Hard Transient X-ray Sources (HXTS) in which the neutron star is eccentrically (e $\sim$ 0.2–0.5) orbiting around a V-III luminosity-class Be star ($P_{orb} >$ 10 days); they show strong variable pulsed hard X-ray emission ($L_{Xmax}/L_{Xmin} >$ 100) with KT $\geq$ 17 keV, and P_{spin} ranging from 0.069 to 1413 s; $L_X = 10^{34} - 10^{39}$ erg s^{-1}.

1.2. Permanent X-ray Sources in which the neutron star or black hole is circularly orbiting (e $\sim$ 0) around a giant or supergiant OB star ($P_{orb} <$ 10 days); they show an almost steady permanent pulsed hard X-ray emission ($L_{Xmax}/L_{Xmin} \ll$ 100), and P_{spin} ranging from 0.069 to 1413 s; $L_X \sim 10^{37}$ erg s^{-1}.

1.3. Supergiant X-ray Binaries (SGXBs): obscured sources, which display huge amount of low energy absorption produced by the dense wind of the supergiant companion, surrounded by a weakly magnetized neutron star.

1.4. Supergiant Fast X-ray transients (SFXT), a subclass of SGXBs and a new subclass of transients in which the formation of transient accretion discs could be partly responsible for the flaring activity in systems with narrow orbits. They show $L_{Xpeak} \approx 10^{36}$ erg s^{-1}, and $L_{Xquiecence} \approx 10^{32}$ erg s^{-1}.

2. Low Mass X-ray Binaries (LMXB) in which the optical companion is a low-mass-late-type star and the collapsed object is a neutron star or a black hole (P_{orb} from 41 min to 11.2 days). They are concentrated in the globular clusters, and in the halo around the galactic center. The mass transfer in these systems is usually occurring via Roche lobe overflow. Their emission in soft X-ray range is usually not pulsed with KT $\leq$ 9 keV. Their X-ray luminosity is ranging from 10^{36} to 10^{39} erg s^{-1} and $L_X/L_{opt} \sim 10^2$–10^4; many LMXBs show Quasi Periodic Oscillations (QPOs) between 0.02 and 1000 seconds and few of them also pulsed X-ray emission, such as Her X1, 4U 1626-27 and GX 1+4.

Many LMXB show transient behaviour in the form irregular X-ray bursts, when their luminosity increases several tens or hundreds times. During these luminous stages, steady periodical signals, with millisecond periods, have been observed in several of them. In few of them ms X-ray pulsars have been discovered in quiescent stages between bursts. The ms X-ray pulsars in LMXB form a link between binary X-ray sources and recycled binary radio pulsars, with ms periods and low

magnetic fields (Bisnovatyi-Kogan & Komberg[5]), which are formed on the place of these LMXB after ceasing of accretion, due to evolution of the companion star, transforming into low mass white dwarf, or a giant degenerate planet.

3. Cataclysmic Variables (CVs) in which the optical companion is a low-mass-late-type star and the compact object is a white dwarf. The detected CVs are spread roughly around the solar system at distance of 200-300 pc. Orbital periods are ranging from tens of minutes to about ten hours. The mass transfer is occurring either via Roche lobe overflow or via accretion columns or in an intermediate way depending on the value of the magnetic field. Typical X-ray luminosity is ranging from 10^{32} to 10^{34} erg s^{-1}. Updated reviews about CVs are those by Giovannelli[29]) and Giovannelli & Sabau-Graziati.[42]

4. RS Canum Venaticorum (RS CVn) type systems, in which no compact objects are present and the two components are a F or G hotter star and a K star. Typical X-ray luminosity is ranging from 10^{30} to 10^{31} erg s^{-1}. Usually in the current literature they are excluded from the class of X-ray binaries since historically they were discovered as X-ray emitters only with the second generation of X-ray experiments.

In binary systems there are essentially two ways for accreting matter from one star to the other: via accretion disk or via stellar wind (Giovannelli & Sabau-Graziati,[37] adapted from Blumenthal & Tucker[7]) (left panel of Fig 1). But in some cases there is a third way which is a mixture between the two, as for instance in eccentric binary systems close to the periastron passage where a temporary accretion disk can be formed around the neutron star (e.g. Giovannelli & Ziółkowski[35]), like shown in the right panel of Fig. 1 (Giovannelli & Sabau-Graziati,[37] after Nagase[64]).

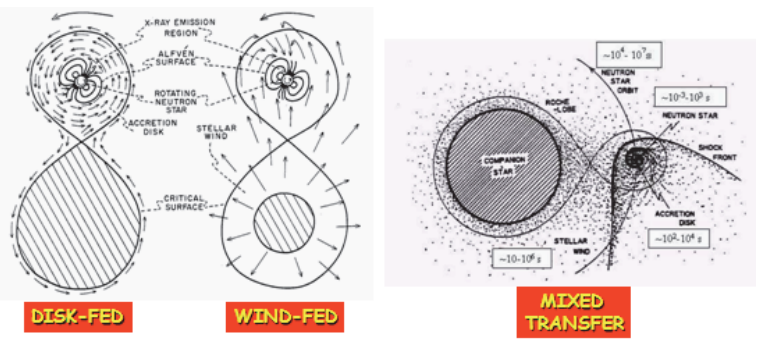

Fig. 1. Left panel: accretion in X-ray binary systems disk-fed and wind-fed (adopted from Giovannelli & Sabau-Graziati,[37] adapted from Blumenthal & Tucker[7]). Right panel: mixed transfer (adopted from Giovannelli & Sabau-Graziati,[37] after Nagase[64]).

XRBs are the best laboratory for the study of accreting processes thanks to their relative high luminosity in a large part of the electromagnetic spectrum. For

this reason, multifrequency observations are fundamental in understanding their morphology and the physics governing their behaviour.

Because of the strong interactions between the optical companion and collapsed object, low and high energy processes are strictly related.

Often, it is easier to perform observations of low energy processes (e.g. in radio, near-infrared (NIR) and optical bands) since the experiments are typically ground-based, on the contrary to observations of high energy processes, for which experiments are typically space-based.

2.1. *High mass X-ray binaries*

Among the X-ray binaries, the class of High Mass X-ray Binaries (HMXBs) constitutes an important group for studying the interactions either via stellar wind either via accretion disk between the optical and the compact companions.

2.2. *X-ray/Be systems*

The X-ray/Be binaries are the most abundant group of massive X-ray binaries in the galaxy, with a total inferred number of between 10^3 and 10^4. The ones which do occasionally flare-up as transient X-ray/Be systems are only the "tip" of this vast "iceberg" of systems (van den Heuvel & Rappaport[46]). The mass loss processes are due to the rapid rotation of the Be star, the stellar wind and, sporadically, to the expulsion of casual quantity of matter essentially triggered by gravitational effects close to the periastron passage of the neutron star. The long orbital period (> 10 days) and a large eccentricity of the orbit (> 0.2) together with transient hard X-ray behavior are the main characteristics of these systems. Among the whole sample of galactic systems containing 114 X-ray pulsars (Liu, van Paradijs & van den Heuvel[56]), only few of them have been extensively studied. Among these, the system A 0535+26/HDE 245770 – HDE 245770 was nicknamed Flavia star by Giovannelli & Sabau-Graziati[36]) – is the best known thanks to concomitant favorable causes, which rendered possible forty six years of coordinated multifrequency observations, most of them discussed in the past by e.g. Giovannelli & Sabau-Graziati,[36] Burger et al.[9]), Piccioni et al.,[68] and later by Giovannelli & Sabau-Graziati[40] and Giovannelli et al.[43, 44]). Accretion powered X-ray pulsars usually capture material from the optical companion via stellar wind, since this primary star generally does not fill its Roche lobe. However, in some specific conditions (e.g. the passage at the periastron of the neutron star) and in particular systems (e.g. A 0535+26/HDE 245770), it is possible the formation of a temporary accretion disk around the neutron star behind the shock front of the stellar wind. This enhances the efficiency of the process of mass transfer from the primary star onto the secondary collapsed star, as discussed by Giovannelli & Ziolkowski[35] and by Giovannelli et al.[38] in the case of A 0535+26.

Optical emission of HMXBs is dominated by that of the optical primary component, which is not, in general, strongly influenced by the presence of the X-ray

source. The behavior of the primary stars can be understood in the classical (or almost) frame-work of the astrophysics of these objects, i.e. by the study of their spectra which will provide indications on mass, radius, and luminosity. Both groups of HMXBs (transient and permanent) differ because of the different origin of the mass loss process: in the first, the mass loss process occurs via a strong stellar wind and/or because of an incipient Roche lobe over-flow; in the second group, the mass transfer is probably partially due to the rapid rotation of the primary star and partially to stellar wind and sporadically to expulsions of a casual quantity of matter, essentially triggered by gravitational effects because of periastron passage where the effect of the secondary collapsed star is more marked. A relationship between orbital period of HMXBs and the spin period of the X-ray pulsars is shown in Fig. 2 (updated from Giovannelli & Sabau-Graziati[37] and from Corbet[20,21]). It allows to recognize three kinds of systems, namely disk-fed, wind-fed [$P_{pulse} \propto (P_{orb})^{4/7}$], and X-ray/Be systems [$P_{pulse} \propto (P_{orb})^{2}$].

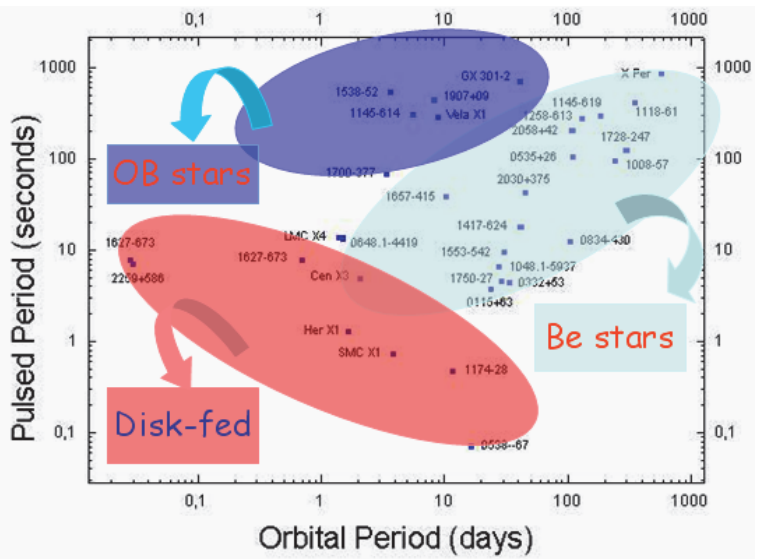

Fig. 2. Spin period vs orbital period for X-ray pulsars. Disk–fed systems are clearly separated by systems having as optical counterparts either OB stars or Be stars (adopted from Giovannelli & Sabau-Graziati,[37] after Corbet[20,21]).

Most of the systems having a Be primary star are hard X-ray (KT $>$ 10 KeV) transient sources (HXTS). They are concentrated on the galactic plane within a band of $\sim$ 3.9°. The orbits are quite elliptic and the orbital periods large (i.e. A 0538-66: e = 0.7, P_{orb} = 16.6 days (Skinner et al.[76]); A 0535+26: e = 0.47 (Finger, Wilson & Hagedon[23]), P_{orb} = 111.0 days (Priedhorsky & Terrell[69]). The X-ray flux during outburst phases is of order 10-1000 times greater than during

quiescent phases. For this reason, on the contrary, the stars belonging to the class of permanent X-ray sources, which do not present such strong variations in X-ray emission, can be also named "standard" high mass X-ray binaries. In X-ray/Be systems, the primary Be star is relatively not evolved and is contained within its Roche lobe. The strong outbursts occur almost periodically in time scales of the order of weeks-months. Their duration is shorter than the quiescent phases. During X-ray outbursts, spin-up phenomena in several systems have been observed (i.e. A 0535+26 and 4U 1118-61 (Rappaport & Joss[70]). The observed spin-up rates during the outbursts are consistent with torsional accretion due to an accretion disk (e.g. Ghosh[26]). So, the formation of a temporary accretion disk around the collapsed object should be possible during outburst phases (e.g. Giovannelli & Ziółkowski[35]).

3. Old & news from the transient X-ray/Be system A0535+26/HDE245770

The most studied HMXB system, for historical reasons and due to concomitant favourable causes, is the X-ray/Be system A 0535+26/HDE 245770. By means of long series of coordinated multifrequency measurements, very often simultaneously obtained, it was possible to:

- identify the optical counterpart HDE 245770 of the X-ray pulsar;
- identify various X-ray outbursts triggered by different states of the optical companion and influenced by the orbital parameters of the system;
- identify the presence of a temporary accretion disc around the neutron star at periastron.

Multifrequency observations of A 0535+26 started soon after its discovery as an X-ray pulsar by the Ariel-5 satellite on April 14, 1975 (Coe et al.[17]). The X-ray source was in outburst with intensity of ~ 2 Crab and showed a pulsation of ~ 104 s (Rosenberg et al.[73]). The hard X-ray spectrum during the decay from the April 1975 outburst became softer, so that the 19 May spectrum had $E^{-0.8}$ and the 1 June spectrum $E^{-1.1}$ (Ricketts et al.[71]). Between 13 and 19 April, 1975, as the nova brightened, the spectra showed some evidence of steepening. The best fit of the experimental data between roughly 27 and 28 April was compatible with an 8 keV black-body curve (Coe et al.[17]). The X-ray source decayed from the outburst with an *e*-folding time of 19 days in the energy range of 3-6 keV (Kaluzienski et al.[51]).

In the X-ray error box of the X-ray source A 0535+26, detected by Ariel V, were present 11 stars up to 23^{rd} magnitude and one of them (HDE 245770) of magnitude around 9 showed the H_α and H_β in emission, H_γ filled in with emission, and H_δ, H_ϵ,..., H_{10} in absorption (Margon et al.[59]). A priori probability of finding a 9 mag star in such a field is 0.004, thus HDE 245770 was considered as the probable optical counterpart of A0535+26.

But in order to really associate this star with the X-ray pulsar, it was necessary to find a clear signature proving that the two objects would belong to the same binary system. This happened thanks to a sudden insight of the author, Franco Giovannelli (FG), who predicted the fourth X-ray outburst of A 0535+26 around mid December 1977. For this reason, Giovannelli's group was observing in optical HDE 245770 around the predicted period for the X-ray outburst of A 0535+26. Figure 3 shows the X-ray flux intensity of A 0535+26 as deduced by various measurements available at that time, with obvious meaning of the symbols used (Giovannelli[28]). FG's intuition was sparked by looking at the rise of the X-ray flux (red line) and at the 24th May 1977 measurement (red asterisk): he assumed that the evident rise of the X-ray flux would have produced an outburst similar to the first one, which occurred in 1975. Then with a simple extrapolation he predicted the fourth outburst, similar to the second: and this happened!

Optical photoelectric photometry of HDE 245770 showed significant light enhancement of the star relative to the comparison star BD +26 876 between Dec. 17 and Dec 21 (here after 771220-E) and successive fading up to Jan. 6 (Bartolini et al.[1]), whilst satellite SAS-3 was detecting an X-ray flare (Chartres & Li[16]). The observed enhancement of optical emission followed by the flare-up of the X-ray source gave a direct argument strongly supporting the identification of HDE 245770 – later nicknamed Flavia' star by Giovannelli & Sabau-Graziati[36] – with A 0535+26.

Soon after, with spectra taken at the Loiano 152 cm telescope with a Boller & Chivens 26767 grating spectrograph (831 grooves/mm II-order grating: 39 Å mm^{-1}) onto Kodak 103 aO plates, it was possible to classify HDE 245770 as O9.7IIIe star. This classification was so good that it survives even to the recent dispute attempts made with modern technology. The mass and radius of the star are 15 $M_\odot$ and 14 $R_\odot$, respectively; the distance to the system is 1.8 ± 0.6 kpc (Giangrande et al.[27]).

UV spectra taken with the IUE enabled the reddening of the system to be determined as E(B-V) = 0.75 ± 0.05 mag, the rotational velocity of the O9.7IIIe star ($v_{rot} \sin i = 230 \pm 45$ km s^{-1}), the terminal velocity of the stellar wind ($v_\infty \simeq 630$ km s^{-1}), the mass loss rate ($\dot{M} \sim 10^{-8}$ $M_\odot$ yr^{-1} in quiescence (Giovannelli et al.[33]). During the October 1980 strong outburst, the mass loss rate was $\dot{M} \sim 7.7 \times 10^{-7}$ $M_\odot$ yr^{-1} (de Martino et al.[61]).

Complete reviews of this system can be found in Giovannelli et al.,[34] Giovannelli & Sabau-Graziati,[36] and Burger et al.[9]

Briefly, the properties of this system, placed at a distance of 1.8 ± 0.6 kpc (Giangrande et al.[27]), can be summarized as follows: a hard X-ray transient, long-period X-ray pulsar – the secondary star – is orbiting around the primary O9.7IIIe star. The masses are of $\sim 1.5 \pm 0.3$ $M_\odot$ (Joss & Rappaport;[50] Thorsett et al.;[79] van Kerkwijk, van Paradijs, J. & Zuiderwijk[52]), and 15 $M_\odot$ (Giangrande et al.[27]) for the secondary and primary star, respectively. The eccentricity is e = 0.47 (Finger, Wilson & Hagedon[23]). Usually the primary star does not fill its Roche lobe (de Loore et al.[58]). However, the suggestion that there might be a temporary accretion disk

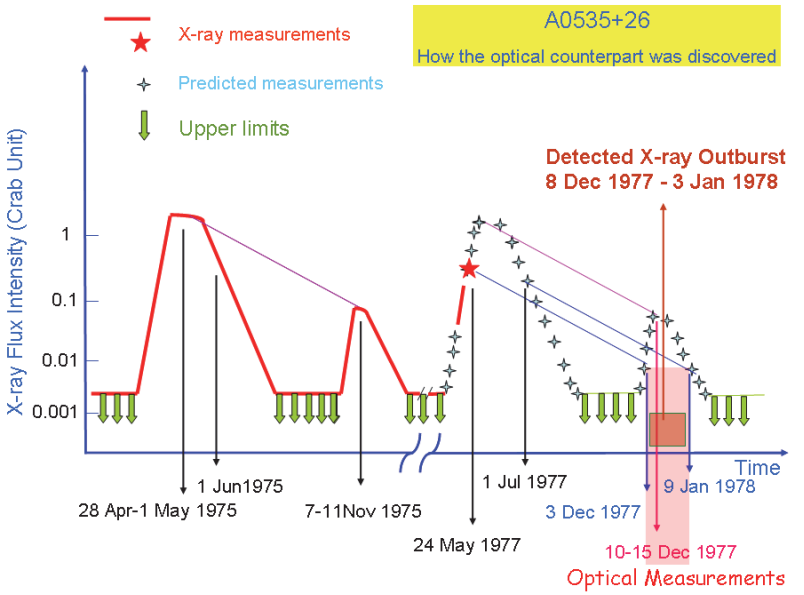

Fig. 3. X-ray flux versus time of A 0535+26. X-ray measurements are reported with red lines and asterisk, upper limits with green arrows, and predicted fluxes with light blue stars. Periods of real detected X-ray outburst and optical measurements are also marked (adopted from Giovannelli[28]).

around the X-ray pulsar when it approaches periastron (Giovannelli & Ziółkowski[35]) was confirmed by the X-ray measurements of Finger, Wilson & Harmon[24] and was discussed by Giovannelli et al.[38]

The first suggestion of Bartolini et al.[2] about the value of the orbital period ($P_{orb} = 110.856 \pm 0.002$ days), allowed Giovannelli & Sabau-Graziati[40] to discover a systematic delay (~ 8 days) of the X-ray outbursts with respect to the periastrons passages of the neutron star. Just a little before or simultaneously to the periastron, the system experiences an optical brightening ranging from ≈ 0.02 to ≈ 0.2 magnitudes.

The trigger of this discovery was the optical flare occurred at JD 2,444,944 (5th December 1981) (hereafter 811205-E; E stands for event) (Giovannelli et al.[34]) and followed by a short X-ray outburst (811213-E) (Nagase et al.[65]) – predicted by a private communication of Adriano Guarnieri (member of Giovannelli's group) to the team of Hakucho Japanise X-ray satellite. Unfortunately in the following years simultaneous optical and X-ray measurements were not always obtained around periastron passage. However, the available data were sufficient for showing the aforementioned systematic delay.

In order to explain and describe the 8-day delay between periastron passage and X-ray outbursts, GBK13 constructed a model adopting the orbital period determined by Priedhorsky & Terrell[69] from X-ray data ($P_{orb} = 111.0 \pm 0.4$ days), and

the ephemeris $JD_{opt-outb} = JD_0(2{,}444{,}944) \pm n(111.0 \pm 0.4)$ days; the 111-day orbital period agrees within the error bars with many other determinations reported in the literature: from optical data (e.g. Guarnieri et al.;[45] de Martino et al.;[60] Hutchings;[47] Janot-Pacheco, Motch & Mouchet[48]), and from X-ray data (e.g. Nagase et al.;[65] Priedhorsky & Terrell;[69] Motch et al.;[63] Finger, Wilson & Harmon;[24] Coe et al.;[18] Finger et al.[25]).

4. Time delay between optical and X-ray outbursts in A 0535+26/HDE 245770

A description of the time–delay among many optical and X-ray events occurring around the periastron passages in the system A 0535+26/HDE 245770 have been presented in the papers by GBK13 and Giovannelli et al.[43,44] However, just to remark the importance of the experimental evidence of such a time–delay I will present a few more examples that in my opinion definitively support the validity of the model developed in GBK13. Briefly, the model is the following: in the vicinity of periastron the mass flux $\dot{M}$ increases (depending on the activity of the Be star) between $\approx 10^{-8}$ and $\approx 10^{-7}$ $M_\odot$ yr^{-1}. The outer part of the accretion disk – geometrically thin and optically thick without advection (Shakura & Sunyaev;[75] Bisnovatyi-Kogan[4]) – becomes hotter, therefore the optical luminosity (L_{opt}) increases. Due to large turbulent viscosity, the wave of the large mass flux is propagating toward the neutron star, thus the X-ray luminosity (L_x) increases due to the appearance of a hot accretion disk region and due the accretion flow channeled by the magnetic field lines onto magnetic poles of the neutron star. The time–delay τ is the time between the optical and X-ray flashes appearance. Figure 4 shows a sketch of this model.

By using the ephemerides given by GBK13, namely:

$$JD_{opt-outb} = JD_0(2{,}444{,}944) \pm n(111.0 \pm 0.4) \text{ days}$$

that fixed the reference point at the date 5th December 1981 (811205-E), it was possible to explain the behaviour of the system during the year 2014 (Giovannelli et al.[43]). It was possible not only to predict the arrival time of the X-ray outbursts following the optical flashes, but also the intensity I_x of the X-ray flares, thanks to the relationship I_x versus ΔV_{mag}, where ΔV_{mag} is the relative variations of the V magnitude of the Be star around the periastron passage with respect to the level before and after such a passage. This relationship is shown in Fig. 5 (adapted from Giovannelli et al.[44]).

An impressive strong optical event have been detected on March 19, 2010 (JD 2,455,275). On the basis of such a strong optical activity – especially H_γ in emission – Giovannelli, Gualandi & Sabau-Graziati[39] predicted the incoming X-ray outburst of A 0535+26, which actually occurred (Caballero et al.[11]). The X-ray intensity reached was 1.18 Crab on April 3, 2010 in the range 15–50 keV of BAT/SWIFT

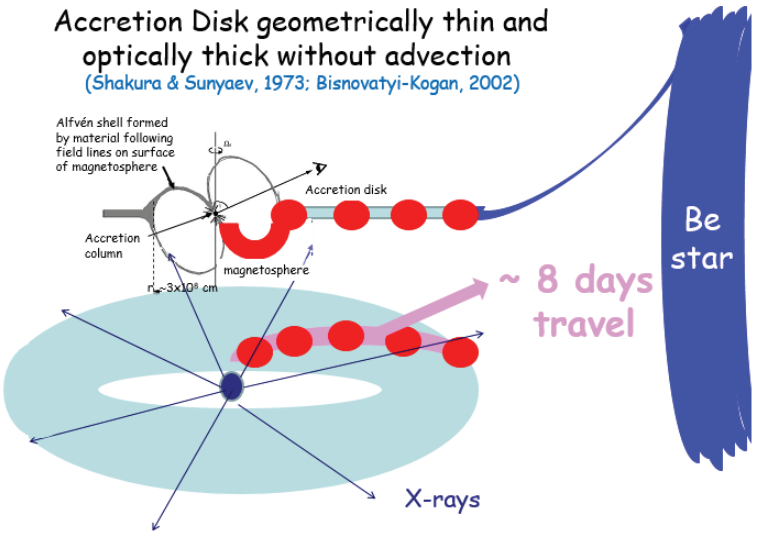

Fig. 4. Sketch of the viscous accretion disk model for explaining the time-delay between X-ray and optical flashes (adopted from:[41] GBK13).

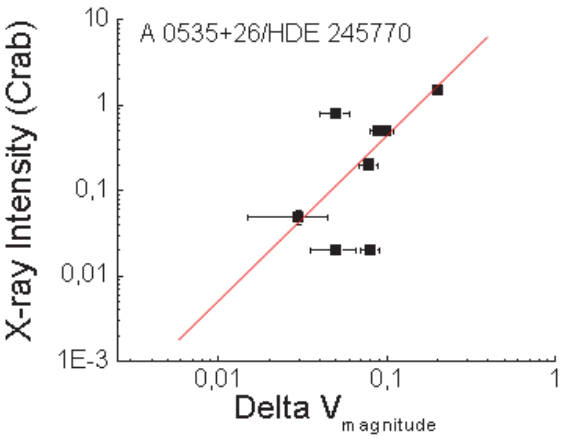

Fig. 5. Intensity of the X-ray flare of A 0535+26 versus the variation of V magnitude of HDE 245770 around the periastron passage (adapted from Giovannelli et al.[44]).

(Caballero et al.;[10–13] Caballero et al.[14]). Figure 6 shows the March–April 2010 event. The X-ray flare started about 8 days after the 93th periastron passage after the 811205-E, just when optical spectroscopy was performed by Giovannelli, Gualandi & Sabau-Graziati,[39] and reached the maximum about 12 days later and decayed in about 20 days roughly as occurred in 1975 when A0535+26 was discovered by the Ariel V satellite.

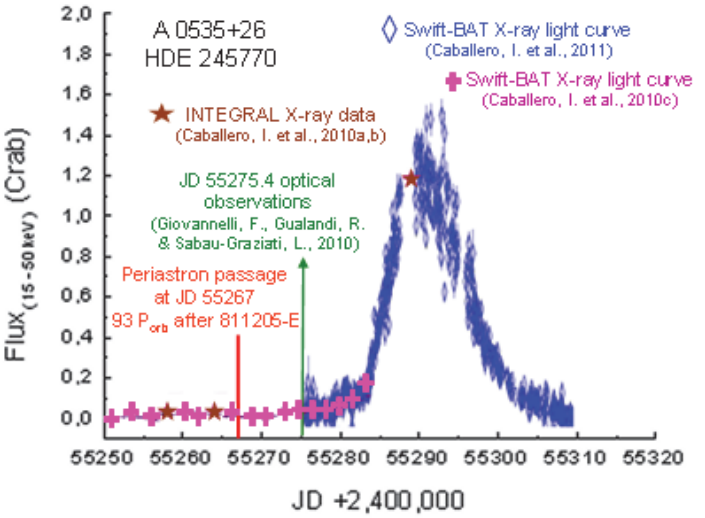

Fig. 6. The predicted March–April 2010 X-ray outburst of A 0535+26 (Giovannelli, Gualandi & Sabau-Graziati[39]) after the 93th passage at the periastron after 811205-E (Caballero et al.;[10–13] Caballero et al.[14]

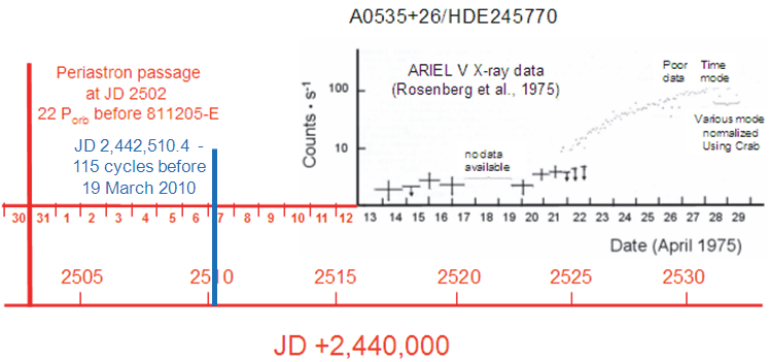

Fig. 7. The Periastron passage at the 22nd cycle before 811205-E (JD 2502) (red line) precedes of $\sim$ 14 days the X-ray outburst of A 0535+26 which starts approximatively on JD 2516 (after Rosenberg et al.[73]). The vertical blue line indicates the day April 7, 1975 (JD 2,442,510.4) just 115 cycles before the strong optical spectroscopic activity detected on March 19, 2010 (JD 2,455,275.4) (after:[41] GBK13).

The astonishing fact that definitively demonstrate the goodness of GBK13's ephemerides and the mechanism triggering the X-ray outburst with a time–delay with respect to the optical flare around the periastron passage is reported in Fig. 7. Indeed, in this figure, the measurements of the first detection of A 0535+26 by Ariel V satellite are reported. Unfortunately in 1975, around the time of the discovery of A 0535+26 no optical measurements are available for obvious reasons. The vertical red line indicates the time of the periastron passage following GBK13's ephemeris.

This passage occurred at the 22nd cycle before the 811205-E. The vertical blue line indicates the day April 7, 1975 (JD 2,442,510.4) just 115 cycles before the strong optical spectroscopic activity detected on March 19, 2010 (JD 2,455,275.4), that preceded the strong X-ray outburst reported in Fig. 6.

The similarity between the first X-ray outburst and that of March–April 2010 is evident, and the separation of the two events is exactly 115 cycles.

5. General model of time lag between optical and X-ray outbursts in binary accreting sources

In LMXBs (Low-Mass X-ray Binaries) the compact object can be either a neutron star or a black hole and the optical companion is a low mass star. The exchange of matter occurs via Roche lobe overflow, like shown in the left panel of Fig. 1. In HMXBs (High-Mass X-ray Binaries) the compact object can be either a neutron star or a black hole and the optical companion is a high mass star: giant or supergiant. The exchange of matter occurs mainly via stellar wind since usually the optical star does not fill its Roche lobe (Fig. 1, left panel). However, sometimes, the exchange of matter can occur in a mixed way because of the formation of an accretion disk around the compact object around the periatron passage (e.g. Giovannelli & Ziółkowski[35]) (Fig. 1, right panel).

As well known, X-ray/Be systems are formed by a compact star and an optical star. Obviously there is a mutual influence between the two stars. Low-energy (LE) processes influence high-energy (HE) processes and vice versa. Never confuse the effect with the cause. There is a general law in the Universe: **Cause and Effect**. The *Cause* generates an *Effect* and NOT vice versa!

It is right to remind that the mechanism proposed by GBK13 for explaining the X-ray-optical delay in A 0535+26/HDE 245770 is based on an enhanced mass flux propagation through the viscous accretion disk. This mechanism, known as UV-optical delay (the delay of the EUV flash with respect to the optical flash) was observed and modeled for cataclysmic variables (e.g. Smak;[77] Lasota[55]). Time delays have been detected also in several other X-ray transient binaries. This is the reason that urged Bisnovatyi-Kogan & Giovannelli[6] (BKG17) to generalize the aforementioned model, developed for the particular case of A 0535+26/HDE 245770 (Flavia' star). This general model provides the formula (1) of the time delay between the optical and X-ray flashes appearance in transient cosmic accreting sources:

$$\tau = 6.9 \frac{\mathrm{m}^{2/3} \dot{\mathrm{m}}^{1/15}}{\alpha^{4/5} \left(\mathrm{T}_4\right)^{28/15}} \tag{1}$$

where:

$\mathrm{m} = \mathrm{M}/\mathrm{M}_\odot$; $\dot{\mathrm{m}} = \dot{\mathrm{M}}/(10^{-8}\ \mathrm{M}_\odot/\mathrm{yr})$; $\mathrm{T}_4 = \mathrm{T}_0/10^4$ K; α = viscosity, and T_0 = maximum temperature in optics.

By using this formula it is possible to obtain an excellent agreement between the experimental and theoretical delays found in:

- X-ray/Be system A0535+26/HDE245770: $\tau_{\rm exp} \simeq 8$ days (GBK13); $\tau_{\rm th} \simeq 8$ days;
- Cataclysmic variable SS Cygni; $\tau_{\rm exp} = 0.9$–1.4 days (Wheatley, Mauche & Mattei[81]); $\tau_{\rm th} \simeq 1.35$ days;
- Low-mass X-ray binary Aql X-1/V1333 Aql: $\tau_{\rm exp} \sim 3$ days (Shahbaz et al.[74]); $\tau_{\rm th} \simeq 3.2$days
- Black hole X-ray transient GRO J1655-40: $\tau_{\rm exp} \sim 6$ days (Orosz et al.[67]); $\tau_{\rm th} \simeq 6.5$ days.

In this general formula the α-viscosity parameter plays an important role, and usually it is hard to be determined. However, if the other parameters are known, because experimentally determined, the formula (1) can be used for determining α, taking into account the experimental delay measured in a certain source.

Over the last couple of decades we have witnessed the discovery of a multitude of highly ionized absorbers in high-resolution X-ray spectra from both BH and NS XRBs. The first detections were obtained thanks to ASCA on the BH binaries GROJ1655-40 and GRS 1915+105. Narrow absorption lines in the spectra of these systems identified as Fe XXV and Fe XXVI indicated the first of many discoveries of photo-ionized plasmas in LMXBs (Chandra, XMM-Newton and Suzaku). Black hole hot accretion flows occur in the regime of relatively low accretion rates and are operating in the nuclei of most of the galaxies in the universe. One of the most important progress in recent years in this field is about the wind or outflow. This progress is mainly attributed to the rapid development of numerical simulations of accretion flows, combined with observations on, e.g., Sgr A*, the SMBH in the Galactic center. The mass loss from a BH via wind is related to the mass accretion rate onto the BH as (Yuan[82]):

$$\dot{\rm M}_{\rm wind}({\rm r}) = \dot{\rm M}_{\rm BH} \times ({\rm r}/20{\rm r_g})^{\rm s} \quad \text{with} \quad {\rm s} \approx 1 \quad \text{and} \quad {\rm r_g} = \frac{2{\rm GM_{BH}}}{{\rm c}^2} \tag{2}$$

At this point it is useful to make a sort of summary about the number of XRBSs, including CVs. Liu, van Paradijs & van den Heuvel[56,57] and Ziółkowski[84] report 315 galactic XRBs: 197 LMXBs (63%) and 118 HMXBs (37%), 72 of which are Be/X-ray systems; moreover there are 62 BH candidates. Coleiro & Chaty[19] report that in the Milky way there are $\geq$ 200 HMXBs. Ritter & Kolb[72] catalogue, in the 7.20 (Dec. 2013) version, reports 1166 CVs. Buckley[8] reports about the discoveries of 530 new CVs from MASTER-Network and 855 CVs from Catalina Real Time Survey (CRTS) (http://nesssi.cacr.caltech.edu/DataRelease/). Ferrario, de Martino & Gänsicke[22] report the number of MCVs as $\approx$ 250, and $\sim$ 60 of which IPs, and considering those systems for which the magnetic field intensity has not yet been determined, their number is of $\approx$ 600. Table 1 shows the content of XRBSs, including CVs,

Table 1. Comparison of numbers of different classes of X-ray Binary Systems in the Milky Way and in the Magellanic Clouds (Ziółkowski;[84] Ferrario, de Martino & Gänsicke;[22] Buckley[8]).

Name of the Class	Milky Way	LMC	SMC
Total mass of the galaxy (in M_{SMC} units)	100	10	1
High Mass X-ray Binaries	118	26	83
in this Be/X-ray	72	19	79
Low Mass X-ray Binaries	197	2	-
Black Hole Candidates	62	2	-
Cataclysmic Variables	≈ 2000	-	-
in this MCVs	≈ 250	-	-
IPs	~ 60	-	-
B not yet determined	≈ 600	-	-

in the Galaxy, and in the LMC and SMC (Ziółkowski;[84] Ferrario, de Martino & Gänsicke;[22] Buckley[8]). The mass are expressed in unit of SMC.

Some attempts of evaluation of the number of SBHs in the Galaxy have been done. For instance, taking into account the γ-ray emissivity of the Galaxy (1.3×10^{43} s^{-1} for E > 100 MeV) measured by the SAS II satellite (Strong, Wolfendale & Worral[78]) and the processes of disk-fed accretion onto black holes, Giovannelli, Karakuła & Tkaczyk[31,32] – considering a spherical accretion flow with a constant Mach number, corresponding to the adiabatic power $\gamma = 5/3$ – found a possible upper limits to the number of black holes ($M \sim 10\ M_\odot$ and $\dot{M} \approx 10^{-8}\ M_\odot\ yr^{-1}$) of 10^{-5} - 10^{-4} of the total star population of the Galaxy for Mach's number 1 and 2, respectively.(*)

There is a class of intermediate-mass black holes (IMBHs), with masses > 100 $M_\odot$ up to $\approx 10^5\ M_\odot$. It contains a dozen systems, as listed in Johnstone.[49] However, black holes with masses of several hundred to a few thousand solar masses remain elusive, as reported in a review by Casares & Jonker[15] where a deeply discussion about the mass measurements of SBHs and IMBHs is contained.

Supermassive black holes (SMBHs) are 10^6–10^{10} times more massive than our Sun and are found in the centers of galaxies (see the exhaustive review by Kormendy & Ho[54]). Most galaxies, and maybe all of them, harbor such a black hole. So in our region of the Universe, there are some 10^{11} SMBHs. The nearest one resides in the center of our Milky Way galaxy. The most distant one we know of resides in a quasar

(*)The Mach number is given by the ratio of the velocity of the gas to the local sound speed. In order to evaluate the temperature, concentration and velocity of the plasma near the black hole it is necessary to solve the system of equations describing the plasma motion (Michel[62]) taking into account the distance from the black hole in units of gravitational radius and the u = R-component of four velocity. Mach's number 1 and 2 correspond to different values of u_0^2 (1.0266 and 2.1213, respectively) at a distance r_0 from the black hole (Giovannelli, Karakuła & Tkaczyk[31,32]).

galaxy billions of lightyears away. SMBHs grow in size as they gorge on surrounding matter.

A list of BH candidates has been reported by Johnston[49] and provides the input for constructing the map of sky locations of BH candidates. Source list includes results reported in Kormendy & Gebhardt,[53] Orosz,[66] Tremaine et al.,[80] and Ziółkowski.[83]

6. Conclusions

The zoo of X-ray binary systems has been presented together with the main characteristics of the single constituent element. A particular emphasis has been devoted to the individual X-ray/Be system A 0535+26/HDE 245770 for which I discussed its history since its discovery by the Ariel-V satellite. Thanks to the long term survey of this system a delay between X-ray and optical flares has been recognized. This fact triggered the work for understanding the physical reasons of this phenomenon that allowed Bisnovatyi-Kogan & Giovannelli[6] to develop a model of time lag between optical and X-ray flashes for close-binary galactic sources with accretion disks.

The time lag in disk-accreting galactic close-binary sources is based on a sudden increase in the accretion flow that starts at the disk periphery and is related to the optical maximum. The massive accretion layer propagates to the central compact source as a result of the turbulent viscosity. The X-ray flash occurs when this massive layer reaches the inner hot regions of the accretion disk and falls into the central compact object. The matter in the accretion disk moves inside with a speed that is determined by the turbulent viscosity. They described this model quantitatively and derived an analytic formula that determines the value of the time lag. This formula gives results that agree well with observational values.

Rotation of the crescent image of M87* and polarization of its ESE hotspot

Krzysztof Nalewajko
Nicolaus Copernicus Astronomical Center, Polish Academy of Sciences
Bartycka 18, 00-716 Warsaw, Poland
E-mail: knalew@camk.edu.pl

The first image of the black hole (BH) M87* obtained by the Event Horizon Telescope (EHT) has the shape of a crescent extending from the E to WSW position angles, with a tentative 'ESE hotspot'. Assuming that the BH spin vector is aligned with both the inner accretion axis and the projected direction of the kpc-scale relativistic jet, the position of the ESE hotspot is inconsistent with the axisymmetric accretion flow. Recent polarimetric EHT images of M87* show that the ESE hotspot is essentially unpolarized, which strongly supports its distinct origin. If the hotspot emission is due to the synchrotron radiation, its depolarization requires either isotropically tangled magnetic fields or an additional Faraday dispersion measure. The 6-day EHT observing campaign in April 2017 allowed in principle to detect orbital motions advancing by up to $\sim 60°$. The apparent rotation rate of the major axis of the EHT crescent image is consistent with the rotation rate of the Faraday-corrected polarization angle measured by the ALMA. However, the counterclockwise (CCW) sense of these rotations is opposite to the clockwise (CW) rotation of the plasma flows implied by the N-S brightness asymmetry, which might indicate that accretion in M87 is retrograde.

Keywords: Black hole physics; Galaxies:active; Galaxies:individual:M87; Relativistic processes.

1. Introduction

The Event Horizon Telescope (EHT) resolved at 1.3 mm the core M87* of the nearby (distance of $D \simeq 16.8$ Mpc) radio galaxy Virgo A (M87) into a crescent image of angular diameter of $\simeq 42$ μas, which corresponds to $\simeq 11$ gravitational radii $R_{\rm g} = GM_{\rm BH}/c^2$ for the black hole (BH) mass of $M_{\rm BH} \simeq 6.5 \times 10^9 M_\odot$ (G is the gravitational constant, c is the speed of light, $M_\odot$ is the mass of the Sun; $R_{\rm g}/c \simeq 8.9$ h).[1–6] M87* is thought to be the base of a relativistic jet observed in radio,[7–9] optical[10] and X-ray[11] bands, propagating in the WNW direction (position angle $\simeq 288°$) beyond the kpc scales. The inclination angle of the jet axis is estimated at $\simeq 17°$.[9] If the jet is powered by the Blandford-Znajek mechanism,[12] its direction of propagation should be aligned with the BH spin. Accreting plasma in the vicinity of spinning black hole would be forced to swirl with trans-relativistic velocities preferentially along the BH equatorial plane. The resulting difference in the Doppler beaming of emission should result in a roughly N-S brightness asymmetry of the crescent image. It is in fact observed by the EHT that the S side of the M87* crescent image is significantly brighter than the N side.

The angular extent of the M87* crescent is roughly from the E to WSW position angles. There is a hint of substructures in the angular brightness profiles that depends significantly on the image reconstruction method. The observed crescent may consist of the *proper crescent* extending from the SSE to WSW position angles and the *ESE hotspot*. Using simple axisymmetric models for the geometry of emitting regions, we have previously suggested that the proper crescent can be explained by emitting regions symmetric with respect to the BH spin/jet WNW axis, and that the ESE hotspot (opposite to the WNW jet) would be rather a localized perturbation of the accretion flow.[13] Such azimuthal perturbations are commonly observed in the results of GRMHD numerical simulations of magnetized BH accretion flows.[5,14,15]

2. Polarization of the ESE hotspot

More recently, the EHT Collaboration presented the first resolved polarimetric images of M87*.[16,17] These images show linear polarization at the level of $\sim 15\%$. In our interpretation, this polarization is largely limited the proper crescent, while the ESE hotspot is essentially unpolarized. Such a striking difference between the polarization properties of these two regions strongly supports their distinct origin.

The very low polarization degree of the ESE hotspot calls into question whether it is produced by the same emission mechanism (presumably synchrotron), whether it is optically thin (or a localized millimeter photosphere), or whether it involves ordered or tangled magnetic fields. It could also result from depolarization by an additional localized Faraday screen. Unresolved ALMA polarimetry simultaneous to the EHT campaign was performed in two bands — 1.3 mm and 3 mm — which allowed to estimate the simultaneous rotation measures as $\sim \pm 10^5$ rad/m^2.[18] Since depolarizing a 1.3 mm signal by factor e requires a dispersion measure of $\simeq 4 \times 10^5$ rad/m^2, depolarization of the ESE hotspot may require an additional dispersion measure of order $\sim 10^6$ rad/m^2. Such dispersion measures are plausible in the advection dominated accretion flow (ADAF) models[19] for the mass accretion rate of $\dot{M} \gtrsim 2 \times 10^{-3} M_\odot$/yr.[20]

3. Rotation of the crescent image and net polarization vector

The 2017 EHT observing campaign spanned 6 days, resolved images were obtained from data recorded on April 5th, 6th, 10th and 11th. This time scale can be compared with the orbital period of a source propagating along the innermost stable circular orbit (ISCO) in Schwarzschild[a] metric: $P_{\rm ISCO} \simeq 92 R_{\rm g}/c \simeq 34$ days. Hence, during the 6-day campaign one could expect to observe an orbital advance by $\sim 60^\circ$. Note that the estimated viewing angle of the M87 jet is sufficiently small that equatorial accretion flows would be well aligned with the plane of the sky.

[a]The effect of BH spin is not included in this basic analysis, but it would be an obvious next level of sophistication.

For comparison, in the case of Sgr A* ($R_{\rm g}/c \simeq 20$ s; $P_{\rm ISCO} \simeq 31$ min) the VLTI/GRAVITY Collaboration detected orbital motion at the period of $P_{\rm GRAVITY} \simeq 40$ min $\simeq 1.3 P_{\rm ISCO}$,[21] which corresponds to a circular Schwarzschild geodesic of radius $R_{\rm circ} \simeq 7.1 R_{\rm g}$.

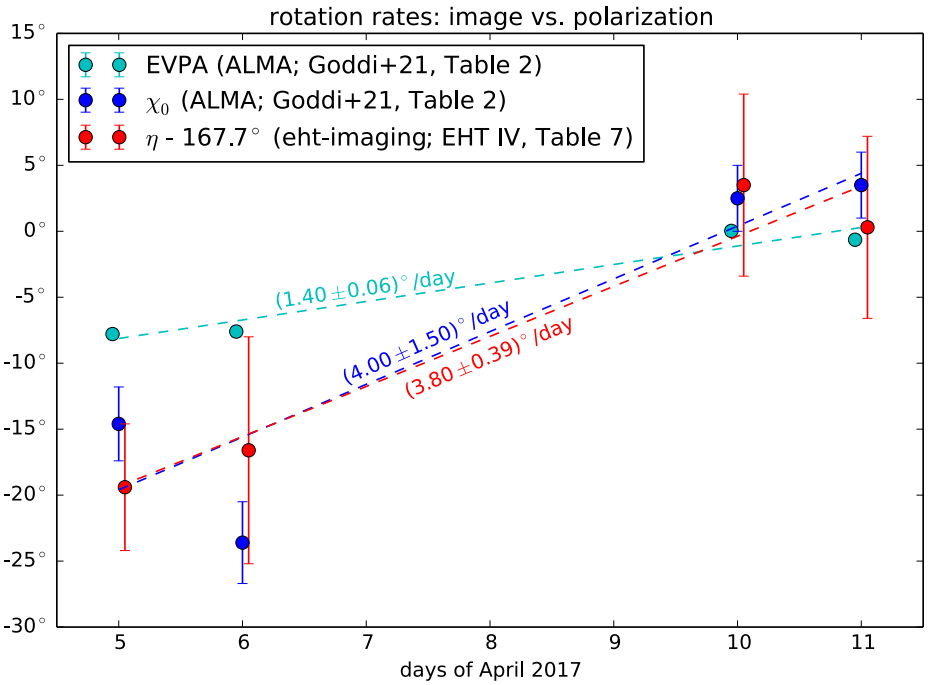

Fig. 1. Time evolution of the orientation angles of the total-intensity crescent image and net polarization. See the main text for details.

In Figure 1, we compare two kinds of orientation angles measured independently for each day of the M87 campaign. First, we consider the mean orientation angles η of the crescent image according to the `eht-imaging` algorithm from the Table 7 of EHT Paper IV.[4] This angle increases by $\simeq +23°$ between April 5th and April 10th, and the mean rotation rate is $(3.8 \pm 0.6)°$/day. Second, we consider the net polarization angles from the Table 2 of the ALMA Paper:[18] the observed angles EVPA, and the angles χ_0 corrected for Faraday rotation using the simultaneous rotation measure values. The EVPA increases by $\simeq +7.8°$ between April 5th and April 10th, while χ_0 increases by $\simeq +27°$ between April 6th and April 11th. The mean rotation rate is $(1.4 \pm 0.3)°$/day for the EVPA and $(4.0 \pm 1.2)°$/day for the χ_0. The rotation rate of the Faraday-corrected polarization angle is thus consistent with the rotation rate of the crescent. The rate of 3.9°/day corresponds to the orbital

period of $P \simeq 92$ days $\simeq 2.7 P_{\rm ISCO}$. The apparent rotation rate of the crescent image and net polarization would correspond to $R_{\rm circ} \simeq 11.6\, R_{\rm g}$.

The trend of increasing position angle measured from N to E corresponds to the counterclockwise (CCW) rotation on the sky for the relatively outer accretion flow. On the other hand, since the S side of the M87* image is clearly brighter than the N side, should this be attributed to the trans-relativistic Doppler beaming of the inner accretion flow (funnel wall), in light of the roughly W direction of the projected jet, the inner accretion flow (and the BH itself) should rotate in the clockwise (CW) direction on the sky. This situation of opposite outer and inner accretion flows corresponds to the bottom left panel of Figure 5 in EHT Paper V.[5] This would suggest that accretion in M87 is retrograde. And this in turn would constrain the range of GRMHD models listed in Table 2 of EHT Paper V[5] to two categories: the high-spin ($a_* = -0.94$) SANE models, and the medium-spin ($a_* = -0.5$) MAD models.

Black hole surroundings and relativistic jets host magnetically dominated regions and fast magnetic reconnection are likely to play an important role concerning astrophysical phenomena associated with such regions. In this contribution, we highlight the works related to turbulence-driven reconnection processes. These processes have been studied by us using analytical as well as numerical methods which showed that fast reconnection processes are powerful ways to giving rise to relativistic particles and associated non-thermal emissions around stellar-mass and supermassive black holes. The power released from the reconnection can even compete with those of extraction from black hole spin.

Keywords: Instabilities; Jets; Acceleration of Particles; Magnetic Reconnection; Magnetohydrodynamics; Numerical Methods

1. Introduction

Black holes are in a range of masses like 5-10 solar masses for stellar-mass to $10^6 - 10^{10}$ for supermassive black holes. Accretion disks, as well as relativistic jets, are quite common features for those black holes. Usually, relativistic jets can achieve high Lorentz factors and propagate several orders of magnitude in distances. Those are likely to be powered by the energy available from accretion disk or black hole spin. The base of the jets is supposed to be magnetically dominated which later becomes kinetically dominated so an efficient conversion is needed to explain

this picture. So magnetic reconnection can be a viable mechanism to make it happen. Another issue that requires explanation is regarding very high emissions (up to TeV) from highly under luminous radio galaxies which might occur close to the base of the jet and from a very compact region in magnetized surroundings around black holes. As standard processes in sites like shocks are likely to be weak, so promising candidate is magnetic reconnection processes and requires due attention.

In the presence of turbulence, the first-order Fermi process in the fast reconnection sites or current sheets is likely to accelerate particles to high energies as shown in analytical[1] and numerical works.[2,3] It was shown that the particles trapped within current sheets were found to undergo exponential growth in energy with time and the corresponding energy spectrum was power-law with spectral indices $\sim$ 1-2. Such a mechanism is well-suited for addressing very high energy phenomena seen in a range of systems containing black holes like galactic black holes or microquasars(GBHs), active galactic nuclei (AGNs), and gamma-ray bursts(GRBs). In this contribution, we discuss further works showing the role of fast magnetic reconnection in accretion disks and jets in such systems containing black holes.

2. Magnetic reconnection around black holes

de Gouveia Dal Pino and Lazarian[1] proposed a model showing that the first-order Fermi process in the coronal region around a black hole can accelerate particles due to the power extraction from fast magnetic reconnection between lines anchored in the accretion disk and black hole horizon. That model could address the origin of radio flares in GBHs and AGNs and later extended to gamma emissions and larger samples as well.[4] Further, the fundamental plane black hole activity which correlates the radio and X-ray emissions could be easily explained in the framework of fast magnetic reconnection model. In those models, a standard disk with corona as a central source around the black hole was used which is suitable for close to Eddington sources. Later the scenario was revisited for taking care of sub-Eddington sources as well by considering thick magnetically dominated accretion flow (MDAF).[5]

Figure 1 shows the calculated turbulence-driven fast magnetic reconnection power and the observed radio and gamma-ray luminosities for more than 270 sources including XRBs, low luminous AGNs (LLAGNs), and GRBs.[5] The diamonds in red and green colours represent the radio emissions in the case of LLAGNs and XRBs respectively. Some XRBs (Cyg X-1 and Cyg X-3) and LLAGNs (Cen A, IC 310, Per A, and M87) are highlighted which have been studied extensively in multi-wavelength studies. The reconnection power is much greater than the observed radio luminosities which means only a small fraction of this power is enough to explain the radio emission for most of the sources. Observed gamma-ray luminosities for 23 sources are included, represented by red and green circles for LLAGNs and XRBs respectively. The circles represent the emissions of 4 radio galaxies, 2 XRBs, and several Seyfert galaxies (most with upper limits in GeV). It is seen that the released

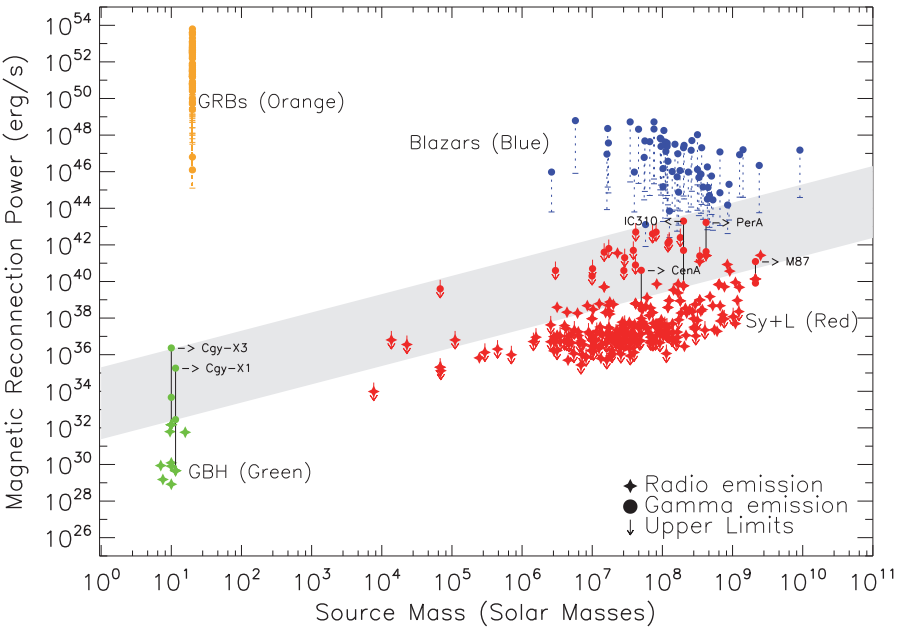

Fig. 1. Tubulent-driven magnetic power against black hole source mass compared to observed emissions of LLAGNs, GBHs, GRBs and blazars. In few cases, maximum and minimum values of gamma-ray luminosity are connected with a vertical black line that extends down to the radio emission. The inverted arrows for some sources indicate that the gamma-ray emission is an upper limit only. The gamma-ray emissions for blazars and GRBs are represented by blue and orange circles respectively. The vertical dashed lines correct the observed emissions by Doppler boosting effects (adopted from ref.[5]).

magnetic energy power is sufficient enough to produce gamma-ray emissions. The gamma-ray and radio emissions seem to be correlated and originating from the same core region around black holes and produced by the same acceleration mechanisms. However, the emissions of blazars and GRBs seem to originate along the jet rather than from the base of the jets. This is likely because the emissions from the core region of these sources are usually screened as the jets point towards our line of sight.

In another work,[6] we performed a semi-analytical comparison between black hole spin and fast magnetic reconnection power for accreting black holes based on fiducial astrophysical parameter space. Besides the rotational energy of the black hole, the fast reconnection power may play a similar role to power relativistic jets. Frame dragging effects of rotating black holes can lead to complicated magnetic structures and enhances the possibility of polarity inversion of the field lines leading to reconnection events and high energy emissions. The reconnection power is

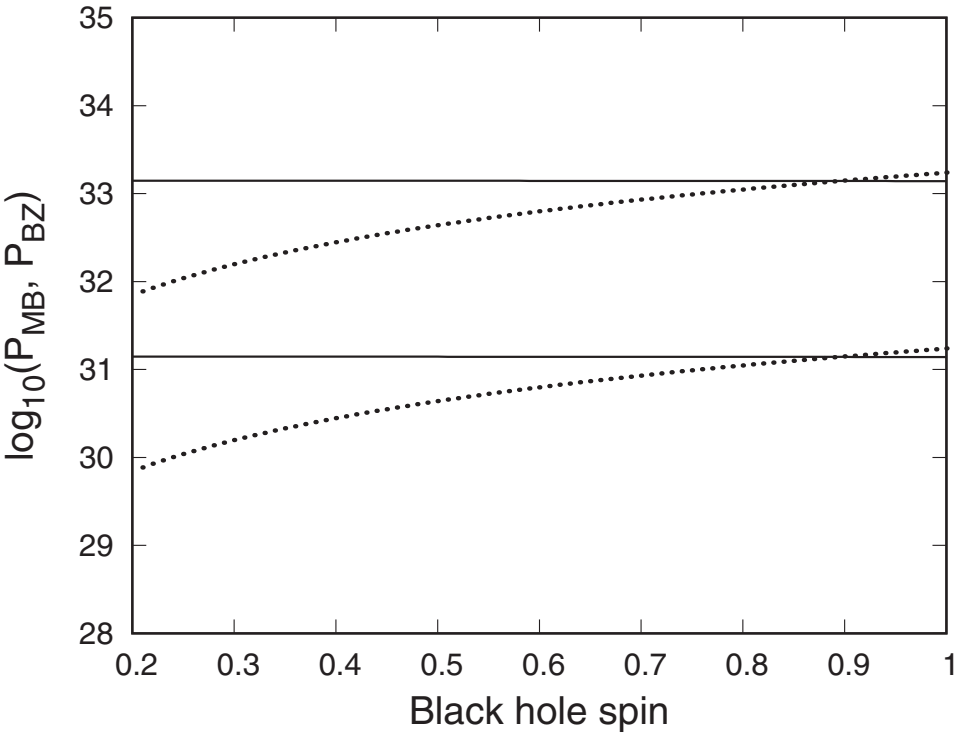

Fig. 2. Magnetic reconnection power P_{MB} and black hole spin power P_{BZ} ploted against black hole spin (adopted from ref.[6]).

a minimum close to the black hole and near the spin axis. It is likely to increase in magnitude with increase in the mass accretion rate. It may compete or even dominate the black hole spin power as shown in Fig. 2. It shows the maximum and minimum values for black hole spin and reconnection power as a function of black hole spin. The power available from the black hole spin and reconnection is comparable for rapidly rotating black holes and the same range of mass accretion rates. The black hole spin power obviously depends on the black hole rotation magnitude while the reconnection process seems to be independent of the black hole spin. The black hole spin-driven process gets suppressed in presence of reconnection. This may occur due to the destruction of large-scale magnetic fields following reconnection events. So state transitions from hard state to soft state can be triggered by this process.

3. Magnetic reconnection in relativistic jets

Using the three-dimensional relativistic magnetohydrodynamic code RAISHIN, we investigated the influence of radial density profile on the spatial development of the current-driven kink instability (CDKI) along magnetized rotating, relativistic jets.[7]

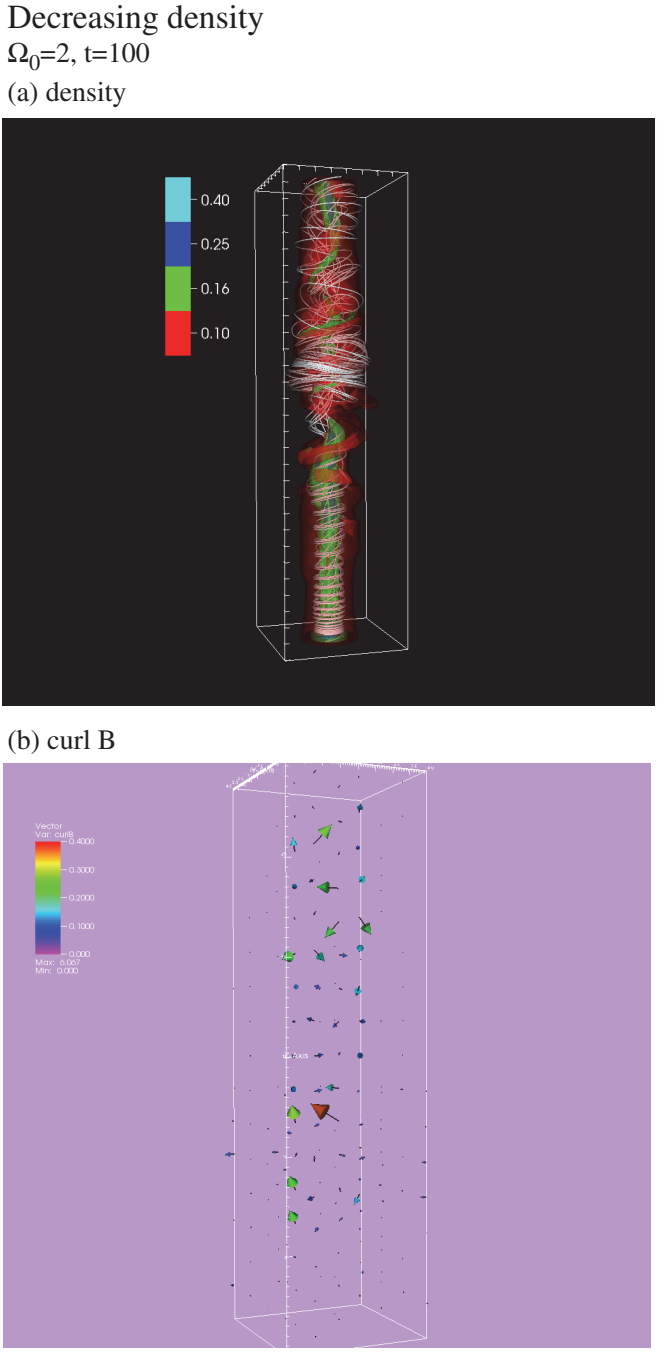

Fig. 3. Current driven kink instability and fast magnetic reconnection in a relativistic magnetized jet for decreasing density profile (heavier jet) with angular velocity amplitude of $\Omega_o = 2$. The upper panel shows 3D density isosurfaces, and bottom panel the locations of maximum current density as tracer of reconnection sites at t = 100 (adopted from ref.[7]).

We studied light as well as heavy jets with respect to the environment depending on the density profile. Different angular velocity amplitudes have been also tested. The results show the propagation of a helically kinked structure along the jet and a relatively stable configuration for the lighter jets. The jets appear to be collimated by the magnetic field and the flow is accelerated due to the conversion of electromagnetic into kinetic energy. We also identified the regions of high current density in filamentary current sheets, indicative of magnetic reconnection, which are associated with the kink unstable regions (Fig. 3) and correlated to the decrease of the sigma parameter of the flow. We discuss the implications of our findings for Poynting-flux dominated jets in connection with the magnetic reconnection process. We find that fast magnetic reconnection may be driven by the kink-instability turbulence and govern the transformation of magnetic into kinetic energy thus providing an efficient way to power and accelerate particles in AGN and gamma-ray-burst relativistic jets.

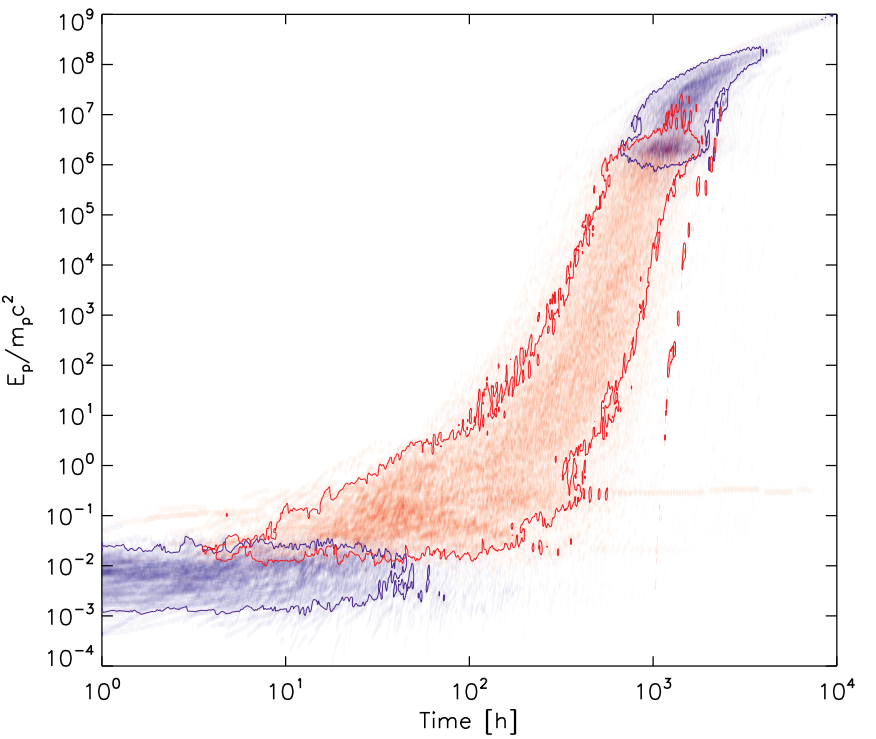

Fig. 4. Kinetic energy evolution, normalized by the proton rest mass energy, for the particles injected. Colours indicate which velocity component is being accelerated (red or blue for parallel or perpendicular component to the local magnetic field, respectively (adopted from ref.[8]).

Further, we also investigated the acceleration of particles injected in the jet subject to CDKI, which drives turbulence and fast magnetic reconnection.[8] Test protons injected in the nearly stationary snapshots of the jet, experience an exponential acceleration up to maximum energy. For a background magnetic field of B $\sim$ 0.1 G, this saturation energy is $\sim 10^{16}$ eV, while for B $\sim$ 10 G it is $\sim 10^{18}$ eV. The simulations also reveal a clear association of the accelerated particles with the regions of fast reconnection. In the early stages of the development of the nonlinear growth of CDKI in the jet, when there are still no sites of fast reconnection, injected particles are also efficiently accelerated, but by magnetic curvature drift in the wiggling jet spine. However, they have to be injected with initial energy much larger than that required for particles to accelerate in reconnection sites. Fig. 4 shows which component of the velocity of the particles is being predominantly accelerated (red for the parallel and blue for the perpendicular component to the direction of the local magnetic field). We note that in the exponential regime, there is a clear dominance of the parallel component, characterizing an effective electric field mostly parallel to the reconnection layers, as expected, though the stochastic nature of the whole process also allows for the acceleration of the perpendicular component. The slower drift acceleration regimes, both in the beginning and after the exponential growth regime, are dominated by the acceleration in the vertical direction. We also obtained from the simulations an acceleration time due to reconnection with a weak dependence on the particles energy E, $t_A \propto E^{0.1}$. The energy spectrum of the accelerated particles develops a high energy tail with a power-law index p $\sim$ -1.2 at the beginning of the acceleration, in agreement with earlier works. Our results provide an appropriate multi-dimensional framework for exploring this process in real systems and explain their complex emission patterns, especially in the very high energy bands and the associated neutrino emission recently detected in some blazars.

4. Summary and Conclusions

In this presentation, we discussed the role of magnetic reconnection in accretion-ejection phenomena around black holes based on results obtained in our theoretical and numerical studies. Our main conclusions can be summarized as follows:

1. Fast magnetic reconnection can play an important role in accretion/jet systems for particle acceleration, dissipation of magnetic energy, and conversion from magnetically dominated region to kinetically dominated region.
2. Power released by the fast magnetic reconnection can explain radio as well as gamma-ray emissions of XRBs and non-blazar AGNs as coming from the core around black holes with masses that span 10 orders of magnitude.
3. Black hole rotation and magnetic reconnection processes can drive jets of comparable power and even compete with each other.

4. The fast turbulent reconnection in magnetically dominated relativistic jets can be triggered by CDKI, possibly drive Fermi acceleration and lead to gamma-ray emissions as required by GRB and AGN blazar jets.

Exact fractal model of the universe and possible machine learning methods for the verification of the fractality

A. A. Kirillov, E. P. Savelova, P. O. Vladykina*

Department of Mathematical Modeling, Bauman Moscow State Technical University, Moscow, 105005, Russian Federation

**E-mail: vladykinapo@yandex.ru*

We discuss the possibility that the topological structure of the Universe may possess fractal properties. Relic wormholes and their fractal distribution are predicted in a natural way by lattice quantum gravity models. This gives a new approach to some long-standing problems. Those are the nature of dark matter phenomena, the origin of Faber-Jackson and Tully-Fisher relations, and the observed deficit of baryons. We consider open Friedman model and construct an exact fractal model by means of a factorization of the space over a discrete subgroup of the group of motion. We derive some basic features of the resulting fractal space and discuss applications of machine learning methods for the verification of the fractal properties.

Keywords: Dark matter; wormholes; fractal distribution; baryon deficit.

1. Introduction

The nature of dark matter represents one of the most challenging problems of modern astrophysics. Particle physics suggests many possible candidates. The most promising are WIMPs (weakly interacting massive particles) which can be both new particles beyond the standard model, or particles composed from already known. However, such particles can hardly solve the problem. Indeed, experiments at LHC do not show the presence of particles beyond the standard model. Moreover, such particles should possess very exotic properties. Firstly, in the early Universe at the moment of recombination such particles have a rather high density but do not interact with baryons or radiation, otherwise they essentially change the observed CMB power spectrum of $\Delta T/T$. Secondly, in the modern Universe in centers of galaxies dark matter particles have much more modest densities but they should possess a sufficiently strong interaction with baryons to form the observed cored distribution of dark matter $\rho_{DM}(r) \sim const$ as $r \to 0$, where r is the distance to the center of a galaxy.[1–3] We recall that numerical investigations based on DM particles predict the presence of a cusp $\rho_{DM}(r) \sim 1/r$ [4,5] in centers of galaxies which is the unavoidable consequence of the potential nature of initial velocities and the fact that DM particles interact via gravity only.

In principle, such a difficulty of DM models based on particles may be overcome in some of modified theories of gravity[6] which gain the popularity during the last decade.[7,8] However, any modification should be approved first from particle physics standpoint and most of such modifications can be rejected already at laboratory

scales. In other words, most of such theories have pure academic interest and have no astrophysical applications.

One of the possible solutions of the problem is based on the fact that local topology of space may possess a rather complex or fractal structure.[9,10] It has two basic advantages. First, it does not require any modification of general relativity or the presence of additional dark matter component. And second, it gives the natural explanation to the empirical Tully-Fisher and Faber-Jackson relations[11,12] for rotation curves in galaxies. We point out that except the exotic scheme suggested by Milgrom,[13] where such relations were incorporated from the very beginning, the fractal topology gives the only natural explanation to such relations.[14]

The origin of fractal topological structure comes out directly from predictions of lattice quantum gravity models.[15–17] Indeed lattice models predict that at Planckian scales space-time has a foamy structure which possesses fractal properties. In particular, numerical investigations[17] show that spectral dimension of space-time runs from the value $D = 3/2$ at sub-Planckian scales to the value $D = 4$ on macroscopic scales. At very small scales the space-time foam can be described by a distribution of virtual wormholes.[18] At laboratory scales vacuum is stable which means that all virtual wormholes appear and disappear permanently. However if we believe that the early Universe underwent through an inflationary phase, we should expect that the exponential expansion very rapidly stretches all scales and some virtual wormholes do not decay. They temper and form initial conditions for the topological structure of space. The subsequent evolution of wormholes is the pure classical process. Spherically symmetric wormholes rapidly collapse, while toroidal and more complex wormholes may survive till the present days.[19,20] In other words, the present topological structure of space is an instant print of the space-time foam picture existing on Planck scales. Since the vacuum state possesses homogeneity and isotropy properties, the topology of our Universe inherits the same properties upon the freezing out on the inflationary stage.

The fractal structure of space can be described as follows. Consider an arbitrary point x in space and fix the geodesic distance R. Then the volume $V_x(R)$ of space which gets inside the geodesic ball, i.e., all points y which obey the inequality $\ell(y, x) < R$ (where $\ell(y, x)$ is the geodesic distance between x and y), scales with R as $V_x \sim R^d$, where $d = D - 1$. The homogeneity and isotropy of space requires that the function $V_x(R)$ and the dimension D do not depend on the initial point x.

The initial point x and omnidirectional geodesic lines, issued from the point x, define the extrapolated reference system which is used in astrophysics. The coordinate volume of such a system has always the dimension $D = 4$ which reflects the fact that locally space is Euclidean with the dimension $d = 3$ (i.e., R^3). We point out that the dependence on the redshift (cosmological evolution) and the choice of the background metric (open, flat, or closed model) somewhat changes the behavior of $V(R)$ and the definition of the dimension d, but rough features and the value $d = 3$ remains valid.

The situation changes when the space is filled with a distribution of wormholes. A part of geodesics go through wormhole throats and return to the same physical region of space or get into a remote region. Therefore, the behavior of $V(R)$ and the dimension d may change essentially. From the pure mathematical standpoint this signals to the fact that the extrapolated coordinate system stops to work (the same point may have multiple images), which requires to introduce additional atlases. In general the dimension evaluated in such a manner may either exceed or be less than the coordinate dimension $d = 3$. What kind of the dimension is realized for physical space depends on properties and the distribution of wormholes.

It is curious that the distribution of galaxies gives roughly the analogous picture. In a homogeneous space the number of galaxies reflects sufficiently well the behavior of the physical volume of space. The galaxy counts show the fractal behavior $N(R) \sim R^d$ with the dimension $d \approx 2$ up to the distances $R \sim 200Mpc$[21, 22] where $N(R)$ is the number of galaxies within the distance R. The maximal scale changes with the increase of precision. First estimates[23] for the scale upon which the distribution of galaxies switches to the homogeneity have the order $\sim 200Mpc$. However more recent observations of SDSS[24] have found the existence of wall-type structures (Sloan Great Wall, etc.) on scales up to $0.1R_H$, where R_H is the Hubble radius, see also.[25] Such super-large structures have posed a serious problem for the standard scenario of the structure formation. Recall that according to latter the largest scale on which inhomogeneities may develop is $300Mpc$. Moreover, such structures seem to be inconsistent with the cosmological principle. We consider such data as an indirect evidence for the fractal (or at least complex) topological structure of space and the existence of relic wormholes. The development of perturbations and the formation of structures in the presence of relic wormholes is a rather complex problem which requires the further investigation.

We point out that in the flat space the light when passing through a wormhole throat is too scattered and may contribute only to the diffuse background radiation.[26] Most likely the scattered signal is too dim to observe a separate galaxy through wormhole throats. The exception may be only gigantic throats compared to the void and larger size. This means that the observed dimension counted by galaxies is always less than three $d < 3$. In particular, this may also explain the observed deficit of baryons.[27]

The fractal topological structure can be easily obtained in open Friedman models by means of a specific factorization of the negative curvature (Lobachevsky) space over a discrete subgroup of the group of motion of space.[19, 20] We point out that the fractal distribution of baryonic matter does not necessarily indicate the existence of a fractal topological structure. However such a distribution requires specific initial conditions and, to be consistent with the observed homogeneity of the background, it requires the presence of dark matter which is dually distributed in space. The fractal topological structure, in turn, is the direct prediction of lattice quantum gravity models and, therefore, it has the most rigorous theoretical ground.

At first glance the basic disadvantage of the factorization is the presence of multiple images. Why do we not see images of the same galaxy? To find the answer is not difficult. First, our Universe has flat space. For small throats of wormholes (of the galaxy size or less) the additional images are very small and cannot be directly observed. Indeed, as it was demonstrated[30] in the flat model the intensity of an image I have the order $I \sim \frac{R^2}{L^2} I_0$, where R is the characteristic radius of the throat and L is the distance between the throat center and the original source and the ratio $\frac{R^2}{L^2} \leq 1$. It reaches the order of $\frac{R^2}{L^2} \sim 1$ only for very large throats. Moreover, the position of the image will be seen only in the second entrance into the wormhole and, therefore the image may have an arbitrary distance from the original. We point out that for fractal distribution over distances between entrances into the same wormhole the mean distance between entrances diverges.

Therefore, different images contribute only to the scattered background radiation. For gigantic wormholes all such images are too far from each other and we may see the same galaxy at different stages of its evolution. Therefore, it is impossible to recognize that we indeed see the same galaxy.

Thus the basic disadvantage is that the factorization requires the negative curvature space only, while the position of Doppler picks in the CMB spectrum favor for the flat space. In flat space such a factorization is impossible, while a fractal structure can be obtained by inserting fractal distribution of wormholes by onset or by means of deforming the metric of the factorized Lobachevsky space. We point out that such a deformation is not an unusual phenomenon. For example, if the inflation starts in an open model, then the factorization takes actually place at sub-Planck scales, while the subsequent particle production may change the value of the mean spatial curvature and produce flat or even closed space which depends on the rate of particle production.

In the flat space the presence of wormholes was shown to produce a specific modification of the standard Newton's law.[28,29] If we interpret this as dark matter phenomenon, then we find the rigid relation between distribution of visible and dark components in a galaxy in the form $\rho_{DM}(k) = b(k)\rho_{vis}(k)$, where $\rho(k)$ is the Fourier components for dark and visible matter densities and $b(k)$ corresponds to the correction which depends on the distribution of wormholes around the galaxy. This gives the direct method for the determining of the correction $b(k)$ from observations and the subsequent modeling of the distribution of relic wormholes.

If our Universe is filled with relic wormholes, then how can we recognize this? To give an answer on such a question is not so easy. The investigation of possible independent effects related to the scattering of radiation on wormholes has revealed that almost all effects are well hidden under analogous effects related to the ordinary matter.[30] Here we see the three most promising possibilities. The first possibility relates to recently observed unexpected circular radio objects[31] and the possible role of torus-shaped wormholes in their origin.[32] The second relates to the gravitational wave Astronomy. In particular, several groups have claimed evidence for repeating echoes in the LIGO/Virgo observations of binary black hole mergers.[33–36] And such

echoes can be generated by the near-horizon or other strong field effects related to black holes or wormholes.[37–39] We stress that the scattering of GWs by wormholes produces much stronger effects as compared to the scattering by ordinary matter objects, e.g., see discussions in,[40] which allows to disentangle such effects and detect wormholes.

The third and the most promising possibility lies in the application of machine leaning methods for detecting unusual structures produced by wormholes on the sky maps. The structures we should look for are the ring-type structures, which in general case have elliptical or even rectangular form. The latter may appear in regions where the mean curvature is negative, see Fig. 2. Besides, one should also look for multiple images of galaxies, etc..

2. Stable wormholes and factorization of the open model

As it was discussed above, relic wormholes are remnants of the inflationary stage. A-priori such wormholes may have an arbitrary form and geometric structure. Stable spherically symmetric wormholes cannot exist without an essential modification of general relativity. In general relativity static spherical wormholes require the presence of exotic matter which does not show up in physical systems and laboratory experiments. The exotic matter can be replaced by a proper modification of theory, e.g., see also a recent paper[41] and references therein, but any modification requires first a verification from particle physics point of view. Any deviation from general relativity is not detected yet, while quantum corrections may stabilize only wormholes of a Planck size.[42] Therefore, spherical wormholes collapse very soon upon the inflationary stage and form couples of primordial black holes.

Situation changes when we consider less symmetric configurations. It was demonstrated[19,20] that in open Friedman models a collection of stable wormholes can be constructed simply by means of a factorization of space over a discrete subgroup of the group of motions for the Lobachevsky space. The simplest wormhole here has the throat in the form of a torus and in such a scheme spherical wormholes do not appear at all. Such wormholes expand in the agreement with the expansion of space and, in other words, in the expanding co-moving reference frame they are static. This does not mean that they cannot collapse as the spherical configurations do. In particular, the development of density perturbations may enforce to collapse a whole region of space which contains such a wormhole throat. In what follows we briefly describe the factorization scheme.

2.1. *Factorization of the open Friedman model*

Consider the open Friedman model with the metric

$$ds^2 = dt^2 - a^2(t)dl^2, \tag{1}$$

where the space-like metic corresponds to the Lobachevsky space

$$dl^2 = d\chi^2 + \sinh^2\chi\left(\sin^2\theta d\varphi^2 + d\theta^2\right). \tag{2}$$

For the sake of illustration and simplicity we demonstrate the factorization for 2D sections of the space which correspond to a plane $d\varphi = 0$. Such a plane corresponds to two values of the polar angle $\varphi = \varphi_0$ and $\varphi = \varphi_0 + \pi$ which formally can be covered by the angles $\theta \in [0, 2\pi]$ where the range $\theta \in [\pi, 2\pi]$ corresponds to the half-plane $\varphi = \varphi_0 + \pi$. Using the coordinate transformation as

$$z = x + iy = i\frac{1-w}{1+w} \tag{3}$$

where $w = \tanh\frac{\chi}{2}e^{i\theta}$, we get the realization of the section in the form of the upper complex half-plane $Im\, z > 0$ which is the Klein model of the Lobachevsky plane $dl^2 = \frac{dx^2+dy^2}{y^2}$. Consider two particular geodesic lines on the plane which correspond to semicircles $|z| = 1/R$ and $|z| = R$ with $R > 1$. Then the factorization can be determined by the map $z' = R^2 z$ which represents one of possible motions of the plane. The factorization means that any two points of the plane represent the same point, if they are connected by the relation

$$z_n = R^{2n} z,\ n = 0, \pm 1, \pm 2, ... \tag{4}$$

The above factorization corresponds to the cut along those two geodesic lines and subsequent gluing along them. The resulting space is a wormhole which connects two independent Lobachevsky planes (regions E_+ and E_-, see Fig. 1).

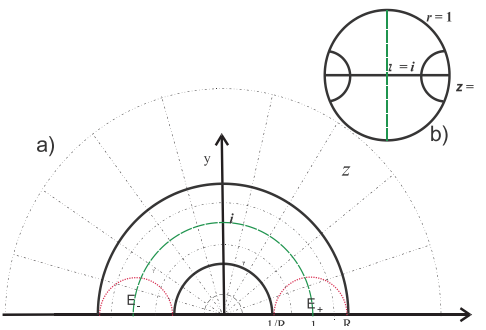

Fig. 1. a) The Lobachevsky plane. Dashed lines give the polar frame. The stripe between the two geodesic lines $r = 1/R$ and $r = R$ corresponds to the wormhole region. Regions below red dashed geodesics (semi-circles) correspond to two unrestricted Lobschevsky spaces $E_\pm$. The point $y = i$ corresponds to the center point of the wormhole throat ($\chi = 0$). The line $y = 0$ corresponds to infinity $\chi \to \infty$ for the plane. b) The same plane in coordinates $w = re^{i\theta}$, where $r = \tanh\frac{\chi}{2}$.

To understand how such a factorization looks in three dimensions let us return to the initial coordinates χ, θ, and φ. The geodesic lines $|z| = R$ and $|z| = 1/R$ are determined by

$$\tan^2\theta = \frac{\cosh^2\chi - \cosh^2\chi_0}{\cosh^2\chi \sinh^2\chi_0}, \tag{5}$$

where $R = e^{\chi_0}$ and χ_0 gives the shortest distance to the geodesic lines from the center point $\chi = 0$. The above equation corresponds to an arbitrary section $d\varphi = 0$ and describes two lines which can be seen in opposite directions $\theta = 0$ and $\theta = \pi$. Here the point $\chi = 0$ corresponds to the center of the throat (the point $z = i$ on Fig. 1). Using the symmetry with respect to the change of φ we find that in 3D space the above equation determines two semi-spheres (rigorously speaking they become semi-spheres in terms of the radial variable $r = \tanh\frac{\chi}{2}$ in which the infinity $\chi \to \infty$ becomes the sphere $r = 1$), while the factorization has the same form determined by (3) and (4). In this case the throat is not restricted. It is important that from the central point $\chi = 0$ such semi-spheres occupy the solid angles $\Delta\Omega = 2\pi\Delta\theta$ where $\Delta\theta$ can be found from (5) in the limit $\chi \to \infty$ which gives the asymptotic angles $\Delta\theta = 2\arctan(1/\sinh\chi_0)$. To get a restricted throat we have to place two more analogous semi-spheres e.g., in the orthogonal to $\theta = 0, \pi$ directions at a distance χ_1, see fig. 2. Moreover, the distances $\chi_{0,1}$ should be chosen in such a way that all

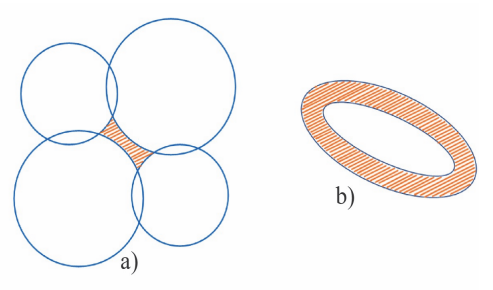

Fig. 2. a) The form of a throat as it is seen on sky in the open model. It represents the colored curved rectangle. Regions behind the circles are copies of the physical region. All additional images lay within the circles. b) The form of the throat as it is seen in flat models upon the deformation of the metric from the negative curvature space. The throat has the torus-like form and only part of the throat surface is seen. Additional images lay inside the surface of the torus.

four semi-spheres restrict a finite minimal section. It is also important that every semi-sphere envelopes a non-physical space, since every point within it represents an image of a point from the corresponding physical space.

Now let us consider how such a wormhole looks for a remote from the center of the throat observer. To this end we should simply shift the central point $\chi = 0$ from the middle of the throat. From qualitative standpoint the picture remains the same, every semi-sphere is determined by the same equation (5) but the distance to it χ_0 changes. Four such semi-spheres group and if they restrict a finite solid angle they form a remote wormhole. The angle they occupy on sky is $\Delta\theta \sim 2\exp(-\chi_0)$ and the throats (minimal sections) are seen as curved rectangles. We point out that from the topological standpoint throats are tori but in open model they will be seen on sky as rectangles. Such wormholes restore the torus-like form of throats only in

the case when the space is additionally deformed or curved in such a way that the mean curvature becomes zero or positive one.

Above we have described the factorization which forms a wormhole that connects two independent (connected only through the throat) Lobachevsky spaces. To get a wormhole whose both entrances lay in the same region requires one more analogous map as described in.[19] In this case we get couples of such throats (groups of semi-spheres) on sky. Now to get a pure fractal picture we may construct a Cantor set on sky by placing such groups of semi-spheres of smaller and smaller solid angles.

2.2. *Stability of wormholes*

The factorization described previously requires the negative curvature space which corresponds to an open Friedman model, while the position of Doppler picks in the power CMB spectrum favor for the flat space. In flat space such a factorization is impossible. However a fractal structure can be obtained by inserting fractal distribution of wormholes or by deforming the metric of a factorized Lobachevsky space. The deformation of the Lobachevsky space can be obtained rather naturally during the inflationary stage. Indeed, if the space had initially a negative curvature, then during the inflation stage production of wormholes and particles took place. Therefore, particle production process could essentially change the value of spatial curvature and essentially deform the picture described above. In this sense we may expect to see a distribution of analogous wormholes even in flat space. We point out that contrary to the open model in flat space upon the deformation throat sections will look as torus- like shapes. This poses the problem how such wormholes may evolve in flat space. Spherical wormholes are unstable and collapse very quickly. The stability of torus-like wormholes is not investigated yet. There are only some encouraging results. For example, the existence and stability of static cylindrical wormholes without exotic matter was demonstrated recently in Refs.[43, 44] We point out that the toroidal wormhole reduces to the cylindrical one in the limit when on of radii tends to infinity. Though the rigorous investigation of the behavior of toroidal wormholes during the cosmological evolution still is not completed, we may expect that such wormholes collapse much slower, than spherical wormholes do and may survive till the present days. As a result we get open or flat Friedman model filled with toroidal wormholes.

When we consider wormhole throats as objects of a finite size (e.g., they occupy a finite solid angle on sky) we may average out over possible random orientations of the throats in space. We point out that there are no strong physical arguments in favor for some particular characteristic size of wormholes, moreover, fractal structure of space-time at Planck scales predicts analogous fractal distribution over the throat sizes. In the case of the statistical averaging over possible orientations the spherical symmetry of the wormhole configuration restores and, therefore, estimates based on spherical wormholes should give correct predictions, at least to the leading order. In what follows we discuss the open Friedman model with almost zero value of the

space curvature where wormholes can be considered simply as quasi-static objects expanding only due to the scale factor $a(t)$. The cosmological evolution of $a(t)$ follows the standard Friedman equations

$$H^2 + \frac{k}{a^2} = \frac{8\pi G}{3}\rho,$$

where $H = \dot{a}/a$ is the Hubble constant, $k = -1$, and ρ is the matter density (baryons plus radiation). The metric has the standard form $ds^2 = dt^2 - a^2(t)dl^2$, where the space-like part dl^2 corresponds to the Lobachevsky space.

The behavior of small perturbations in such a model is determined by the standard Lifshitz theory[45] with one exception. The basic equations for perturbations have local character and, therefore, do not depend on the topological structure of space. However possible solutions do. In particular, in comparison to the ordinary Lobachevsky space the space with wormholes represents a space with a specific factorization. For example in flat space the factorization over translations in one of directions gives the space which is simply the cylinder and one of coordinates becomes a periodic one. This means that corresponding modes are classified by a discrete wave numbers instead of continues ones and, therefore, some modes are absent. Analogously, the factorization of the open model selects only particular solutions among all possible solutions for the unrestricted space. Therefore, from qualitative and quantitative standpoint the evolution of perturbations will show essential deviations from the behavior in standard Friedman models. Analogous deviations are indeed observed and are interpreted as the presence of dark matter, or a modification of general relativity. According to Ref.[17] the Hausdorff dimension of space should be $1 < d \leq 3$. At laboratory scales we see that $d = 3$ and no deviations from the standard Newton's law are observed. The number of galaxies counts show that starting from galactic scales ($R \sim 5Kpc$) at least up to $200Mpc$ the Hausdorff dimension is $d \approx 2$ and at those scales we observe the phenomenon of dark matter.

Indeed, the simplest estimate for the Newton's law gives $F \propto \frac{GM}{S(R)}$, where M is the mass within the volume $V(R)$ (ball of the radius R) and $S(R) = \frac{dV(R)}{dR}$ is the square of the sphere surrounding the volume $V(R)$. In the case of a fractal law $V \sim R^d$ and $S \sim R^{d-1}$. The value $d \approx 2$ is in the very good agreement with observations of dark matter in the range of scales $5Kpc < R < 200Mpc$. The value $d \approx 1$ gives too strong the gravitational bind and such structures should decouple the cosmological expansion very early, or it even should be suppressed during the inflationary stage.

From one standpoint, stable toroidal wormholes do surely exist in negative curvature spaces (in the open model), while in the flat model their stability requires additional study. From other point, the position of the Doppler picks in the CMB ($\Delta T/T$) spectrum points out to the fact that our Universe is very close to the flat space, which means that the matter density is close to the critical value. Here, however, one should be especially careful in making estimates. First, the positions of picks are evaluated on the basis of the standard Friedman models when the possible

factorization of the space is not taken into account (i.e., the possible presence of wormholes). Secondly, the presence of fluctuations $\Delta T/T \sim 10^{-5}$ means that at the moment of recombination analogous fluctuations are present in the metric and matter density $\Delta\Omega = \Omega - 1 \sim 10^{-5}$, where $\Omega = \rho/\rho_{cr}$ and $\rho_{cr} = 3H^2/(8\pi G)$ is the critical density. In other words, the space is split in regions of a positive ($\Omega > 1$, $k/a^2 \approx 10^{-5}H^2$) and negative ($\Omega < 1$, $k/a^2 \approx -10^{-5}H^2$) curvature. If in regions where $\Omega > 1$ the presence of stable wormholes requires the additional study, in the regions where $\Omega < 1$ stable wormholes do exist. Moreover, in the fractal Universe the observed mean value of the spatial curvature is somewhat different from the actual locall value. It contains the additional factor $V_{ph}(R)/V_{coor}(R)$, where $V_{ph}(R) \sim R^{D-1}$ is the actual physical volume of space, while $V_{coor}(R) \sim R^3$ is the coordinate, or extrapolated volume. In this estimate one should take the Hubble radius $R = R_H$, or the radius of the sphere of last scattering. In accordance to Ref.[6] the estimate $V_{ph}(R)/V_{coor}(R) \approx 10^{-5}$ is in the agreement with observations which means that at the moment of recombination the local value of the spatial curvature and the Hubble constant may have the same order ($k/a_{rec}^2 \approx H_{rec}^2$). We point out that the same value 10^{-5} characterizes the portion of actually observed baryons with respect to the value predicted by nucleosynthesis. Here we assume estimates of the number of baryons based only on counts of galaxies and discrete sources, while the diffuse background (e.g., the X-ray background) gives much higher estimate for such a ratio ~ 0.4.[46–48] In fractal picture the diffuse background does not rigorously reflects the actual number of baryons. It reflects merely the mean homogeneity and isotropy of space and the local density of baryons, while the actual number of baryons is proportional to the physical volume of space $N(R) \sim V_{ph}(R) \ll V_{coor}(R)$. In other words, rigorous estimates require further investigation.

3. Fractal distribution of wormholes and modification of Newton's law

The fractality of the topological structure of space requires the analogous fractal distribution of wormholes. At first glance the fractality is not consistent with the observed homogeneity and isotropy of the Universe. This however is not so, e.g., the diffuse background which appears due to the scattering on wormholes remains homogeneous and isotropic.[30] The basic feature of the fractal distribution is a scale - dependence of different mean values, such as mean density of wormhole throats n, the mean distance between entrances $\langle X \rangle$, the mean radius of the throat $\langle R \rangle$, etc.

Consider the simplest model suggested by us in Ref.,[28] which explicitly demonstrates that non-trivial topology can model effects of dark matter. The model is based on spherical wormholes, while actual stable wormholes should have torus like throats. We assume that throats are averaged over orientations then the spherical symmetry restores and such wormholes can be considered in the leading order as spherical ones.

In the case of weak gravitational fields and potential perturbations the Einstein's equations reduce to the Laplace equation for Newton's potential ($R_0^0 - \frac{1}{2}R = 8\pi T_0^0$)

$$\frac{1}{a^2}\Delta\phi = 4\pi G\left(\delta\rho + \frac{3}{c^2}\delta P\right),$$

where a is the scale factor, $\delta\rho$ and δP are perturbations in density and pressure respectively. The behavior of perturbations are determined by the Green function (Newton's law)

$$\Delta G\left(x, x'\right) = 4\pi\delta\left(x - x'\right).$$

In the Euclidean space the Newton's law gives $G_0 = -1/r$ (in the Fourier representation it gives $G_0 = -4\pi/k^2$). In the presence of wormholes the Green function changes.[28] It is convenient to describe corrections which appear due to wormholes by the presence of additional sources (fictitious sources). Then formally we may think that the space remains Euclidean, while proper periodic conditions on throats are accounted by the bias of sources

$$\Delta G\left(x, x'\right) = 4\pi\left[\delta\left(x - x'\right) + b\left(x - x'\right)\right].$$

Here the bias function $b\left(x\right)$ describes corrections to the Newton's law which appear due to non-trivial topology of space. Indeed the presence of the bias $b(x - x')$ gives rise to the transformation

$$\frac{1}{r^2} \to \frac{2}{\pi}\int_0^\infty [1 + b(k)]\frac{\sin(kr) - kr\cos(kr)}{kr^2}dk.$$

The asymptotically flat rotation curves in galaxies require that the correction to the Newton's potential should have the logarithmic behavior, i.e. the gravitational acceleration should switch from $1/r^2$ to $1/r$. The above expression implies that at galaxy scales the bias behaves as $b(k) \sim 1/k^\alpha$ with $\alpha \sim 1$ and $b(x-x') \sim 1/(x-x')^2$. When considering a galaxy with surface mass density distribution $\rho_L(x)$ the bias $b(x - x')$ forms an effective dark matter halo in the form

$$\rho_{DM}(x) = \int b(x - x')\rho_L(x')d^3x'.$$

In particular, for $b(k) \sim 1/k^\alpha$ and an infinitely thin disc $\rho_L(x) = \sigma e^{-r/R_D}\delta(z)$ this expression gives the pseudo-isothermal halo $\rho_{DM} = \rho_0 R_C^2/(R_C^2 + r^2)$, where R_C is the radius of the core, e.g., see.[6,14]

For a homogeneous distribution of wormholes the bias function $b\left(x\right)$ was first considered in[28] and more general case was constructed in.[18] The bias is expressed via the distribution of wormholes which in the homogeneous and isotropic case is a function $F = nf\left(X, R\right)$, where n is the density of wormhole throats in space, X is the distance between entrances into a wormhole, and R is the throat radius. In the Fourier representation ($b(k) = \int b\left(r\right)e^{-i\mathbf{kr}}d^3r$) it has the form[29]

$$b\left(k\right) = n\overline{R}\left(k\right)\frac{4\pi}{k^2}\left(\nu\left(k\right) - 1\right),$$

where we define

$$\overline{R}\,(k) = \frac{1}{k}\int \widetilde{f}(0,R)\sin(kR)\,dR = -\frac{1}{k}Im\int e^{-ikR}w(R)dR, \tag{6}$$

$$\nu\,(k) = \frac{1}{k\overline{R}\,(k)}\int \widetilde{f}(k,R)\sin(kR)\,dR, \tag{7}$$

and $\widetilde{f}(k,R) = \int f\,(X,R)\,e^{-i\mathbf{kX}}d^3X$ is the Fourier transform for the distribution function over distances. Here $k = |\mathbf{k}|$ and the dependence of the above functions only on k reflects the isotropy of the distribution f. The physical meaning of these two functions $\overline{R}\,(k)$ and $\nu\,(k)$ become quite clear in the limit $kR \ll 1$, when throat radii assumed to be small as compared to the characteristic scales. Then we may set $\sin(kR) \approx kR$ and we find $\overline{R} \approx \int Rw(R)dR = \int Rf\,(X,R)\,d^3X dR$ which is simply the mean value of the throat radius. We point out that $\overline{R}\,(k)$ is proportional to the imaginary part of the characteristic function for the distribution over radii $w(R) = \widetilde{f}(0,R)$ (6) (which is $w(k) = \int e^{-ikR}w(R)dR$). Analogously the function $\nu(k) \approx (1/\overline{R})\int R\widetilde{f}(k,R)dR$ is the characteristic function for the distribution over the distances between throat entrances. In the most general case the effective radius $\overline{R}\,(k)$ has the dependence on scales and it admits both signs. Thus, the presence of a distribution of wormholes gives rise to the specific modification of the Newton's law and the true Green function becomes

$$G(k) = -\frac{4\pi}{k^2}\,(1 + b(k))\,.$$

Consider the simplest particular situation when all distances between throats have the same value X_0 and all throat radii be R_0, then we find the homogeneous and isotropic distribution in the form

$$f(X,R) = \frac{1}{4\pi X_0^2}\delta(|X| - X_0)\delta(R - R_0),$$

and the Fourier transform is

$$\widetilde{f}(k,R) = \delta(R - R_0)\frac{\sin kX_0}{kX_0}.$$

The effective radius and the characteristic function which correspond to such a distribution are

$$\overline{R}\,(k) = R_0\frac{\sin(kR_0)}{kR_0}, \quad \nu\,(k) = \frac{\sin kX_0}{kX_0},$$

and the bias is

$$b\,(k) = -\frac{4\pi}{k^2}nR_0\frac{\sin(kR_0)}{kR_0}\left(1 - \frac{\sin kX_0}{kX_0}\right).$$

We see that the bias $b(k)$ (and, therefore, corrections to the Newton's potential) alternates the sign with the change of scales. It is completely determined by three typical scales related to wormhole distribution, which are the density $n \sim 1/L_w^3$, the typical throat radius R_0, and the typical distance between entrances into throats X_0.

In the general case (of the isotropic and homogeneous distributions) the above expressions can be rewritten as follows

$$\overline{R}\left(k\right)=\frac{\left\langle \sin\left(kR\right)\right\rangle }{k},\quad \nu\left(k\right)=\frac{1}{\overline{R}\left(k\right)}\left\langle \frac{\sin\left(kR\right)}{k}\frac{\sin kX}{kX}\right\rangle ,$$

where the mean value is determined as $\langle g(X,R)\rangle=\int g(X,R)f(X,R)d^{3}XdR$. For normal distributions, when all momenta are finite, we may expand the above expressions in series and find

$$b\left(k\right)=\lambda\sum_{N=1}^{\infty}\left(-1\right)^{N}\left(kL_{N}\right)^{2(N-1)}\approx-\lambda\left(1-\left(L_{2}k\right)^{2}+\left(L_{3}k\right)^{4}+...\right), \qquad (8)$$

where $\lambda=\frac{4\pi n}{6}\left\langle RX^{2}\right\rangle$ and the characteristic scales L_N are determined via mean values as follows

$$\left(L_{N}\right)^{2(N-1)}=\frac{6}{\left\langle RX^{2}\right\rangle }\sum_{l=0}^{N-1}\frac{\left\langle R^{2l+1}X^{2(N-l)}\right\rangle }{\left(2l+1\right)!\left(2\left(N-l\right)+1\right)!}.$$

The first term here determines the re-normalization of the gravitational constant, while next terms determine higher order corrections. The above analysis shows that using only normal distributions it is hardly possible to get the desirable form of corrections (observed in galaxies). This is confirmed by estimates presented in Introduction. Indeed, Gaussian distribution of wormholes is described by three typical scales those are $L_w\sim n^{-1/3}$ which characterizes the absolute value of corrections, R_0, and X_0. Starting from a typical scale $R>X_0$ $V_{phys}(R)\simeq V_{Coor}(R)$ and all corrections reduce to a some renormalization of gravitational constant, while at smaller intermediate scales ($R_0<R<X_0$) corrections have more complex behavior (partial screening, e.g., see[28]). This indicates that we should consider more general fractal distributions.

In the case of fractal distributions such an expansion does not work, since all momenta may diverge, while the density of wormholes n is badly determined (its value also depends on scales). In this case we should directly work with characteristic functions $w(k)$ ($\overline{R}\left(k\right)=-Im\, w(k)/k$) and $\nu(k)$. Indeed, consider the simplest example when $w(k)$ and $\nu(k)$ are independent. Then every function can be expressed as

$$\nu(k)=\exp\left\{-\left(kL_{1}\right)^{\alpha_{1}}\left(1-i\beta_{1}\tan\left(\frac{\alpha_{1}\pi}{2}\right)\right)\right\}, \qquad (9)$$

where $\beta_1\in[-1,1]$ determines an asymmetry of the distribution e.g., see Ref.[49] And analogously

$$w(k)=\exp\left\{-\left(kL_{2}\right)^{\alpha_{2}}\left(1-i\beta_{2}\tan\left(\frac{\alpha_{2}\pi}{2}\right)\right)\right\}, \qquad (10)$$

with its own parameters L, β, and α. The last equation defines the effective radius as

$$\overline{R}\,(k) = -Im\,\frac{w(k)}{k} = -L_2\frac{\exp\left(-\left(kL_2\right)^{\alpha_2}\right)}{kL_2}\sin\left[\left(kL_2\right)^{\alpha_2}\beta_2\tan\left(\frac{\alpha_2\pi}{2}\right)\right]. \qquad (11)$$

In the case $\alpha = 2$ the above characteristic functions corresponds to the standard Gaussian distribution, while for $\alpha < 2$ the dispersion which corresponds to such a distribution diverges as

$$\sigma = \frac{d^2}{dk^2}\ln\nu\,(k)\Big|_{k=0} \propto k^{\alpha-2} \to \infty$$

as well as all higher momenta. The parameters α_i relates to the Hausdorff dimension of space D and it characterizes the fractal structure of $f(X,R)$. To avoid misunderstanding we also point out that the scales L_i do not characterize the mean value between entrances into throats, or the mean radius, since for fractal distributions such moments diverge. In such a case the decomposition in series presented above (8) does not work. In this case we should expand directly the characteristic functions (9), (11) themselves. In the region of sufficiently small scales $kL_i \gg 1$ (i.e., at very small distances) the function $b(k)$ quickly oscillates and vanishes $b(k) \to 0$. In this region of scales the standard Newton's law does work. At sufficiently big scales, i.e., in the limit $kL_i \ll 1$, we find the first leading term as

$$b\,(k) \approx 4\pi\chi\frac{\left(kL_2\right)^{\alpha_2-1}\left(kL_1\right)^{\alpha_1}}{\left(kL_3\right)^2} + ... = 4\pi\chi\left(k\widetilde{L}\right)^{\alpha_1+\alpha_2-3} + ...\,, \qquad (12)$$

where $L_3 = 1/\sqrt{nL_2}$ and

$$\chi = \beta_2\tan\left(\frac{\alpha_2\pi}{2}\right)\left(1 - i\beta_1\tan\left(\frac{\alpha_1\pi}{2}\right)\right).$$

Corrections to the empirical Green function $b(k)$ can be restored directly from observations and by relations (6), (7) they determine the distribution of wormholes. In the present paper we do not analyze any actual data, since it requires an independent study. However some rough estimates can be obtained. Indeed, the first correction for the empirical Green function which follows from rotation curves[14] behaves roughly as $G_{emp} = -\frac{4\pi}{k^2}(1 + (k\widetilde{L})^{-\alpha})$ with $\alpha \simeq 1$ which determines parameters in (12) as $\chi \simeq 1$ ($\beta_1 = 0$), $\alpha_1 + \alpha_2 \simeq 2$, and $\widetilde{L} \sim 5Kpc$. As it was discussed in Ref.[14] the value of the parameter $\widetilde{L}$ may somewhat change from a galaxy to a galaxy which reflects the presence of initial inhomogeneities of the metric at the moment of recombination.

As it was demonstrated in[14] the bias in the form (12) and the homogeneity of total matter (baryon plus dark matter components)[6] straightforwardly lead to the origin of Tully-Fisher and Faber-Jackson relations. Therefore, this can be also considered as indirect indication of the fractal topological structure of space. Moreover, the recent SDSS data[24,25] show the traces of the fractal distribution of baryons up to scales $\sim 0.1R_H$.

4. Concluding remarks

As concluding remarks we point out to basic results of this paper. First, we have demonstrated that the most natural origin of dark matter phenomena relates to the existence of locally complex or fractal topological structure of our Universe. At extremely small (sub-Planckian) distances such a fractal structure is predicted by lattice quantum gravity models. During the inflationary period the topological fractal structure tempers and forms the initial conditions for the actual structure of space in Friedman models. One may imagine such a process as an instant enormous increase of a small (of the Planckian order) portion of space filled with virtual wormholes up to macroscopic scales. The stretched wormholes become real and form the initial topological structure, while their subsequent evolution is already governed by classical gravity. Spherical wormholes collapse and form primordial black holes, while torus-like wormholes may survive till the present days.

Secondly, the fractal structure is consistent with the apparent homogeneity and isotropy of space. The simplest rigorous model is the Lobachevsky space factorized over a discrete subgroup of the group of motion. The resulting space has a constant spatial curvature and it locally cannot be distinguished from Friedman model. However it is not a homogeneous space any more and in general it possesses a complex topological structure. The flat model can be obtained by a deformation (due to particle production) of the factorized Lobachevsky space. In this case the fractal topological structure will correspond to a specific distribution of relic wormholes which possesses fractal properties.

And finally, we have demonstrated that when the distribution of wormholes possesses fractal properties, corrections to the standard Newton's law have the necessary form to imitate carefully the presence of dark matter in galaxies. The empirical Green function restored from the analysis of rotation curves in galaxies allows directly restrict some of parameters of the fractal distribution of wormholes.

The rigorous verification of the fractal topological structure requires the use of machine leaning methods. Such methods allow for detecting unusual structures produced by wormholes on the sky maps. Those are the ring-type structures with a specific temperature profile, e.g., if a wormhole throat rotates, then due to the kinematic Sunaev-Zeldovich effect this produces a specific profile of T in CMB. In general case rings may have elliptical or rectangular form. Besides, the fractal structure predicts that galaxies may have multiple images given at different moments of their evolution. Such features cannot be detected without the use of machine leaning methods.

Estimating the photometric redshifts of galaxies and QSOs using regression techniques in machine learning

A. Momtaz, M. H. Salimi and S. Shakeri*
Department of Physics, Isfahan University of Technology, Isfahan, 84156-8311, Iran
** E-mail: s.shakeri@iut.ac.ir*

Measuring distances of cosmological sources such as galaxies, stars and quasars plays an increasingly critical role in modern cosmology. Obtaining the optical spectrum and consequently calculating the redshift as a distance indicator could instantly classify these objects. As long as spectroscopic observations are not available for many galaxies and the process of measuring the redshift is time-consuming and infeasible for large samples, machine learning (ML) approaches could be applied to determine the redshifts of galaxies from different features including their photometric colors. In this paper, by using the flux magnitudes from the Sloan Digital Sky Survey (SDSS) catalog, we develop two ML regression algorithms (decision tree and random forest) for estimating the redshifts taking color indices as input features. We find that the random forest algorithm produces the optimum result for the redshift prediction, and it will be further improved when the dataset is limited to a subset with $z \leq 2$ giving the normalised standard deviation $\overline{\Delta Z}_{\rm norm} = 0.005$ and the standard deviation $\sigma_{\Delta z} = 0.12$. This work shows great potential of using the ML approach to determine the photometric redshifts of distant sources.

Keywords: Spectroscopy; Photometry; Machine Learning; Random Forest; Decision Tree

1. Introduction

Spectroscopy is usually applied as a valuable technique to determine the redshift of extragalactic sources. However, its high wavelength resolution limits its accuracy, a problem that can only partially be solved with more observation time.[1]

In recent years, a growing number of studies have relied on less precise statistical but more efficient estimates of redshifts based on broadband photometry.[2–4] A lot of key projects for the upcoming survey telescopes will involve these photometric redshifts. The photometric redshift is a tool used by multiple fields of astronomy to estimate the distances between objects in the sky. Since the process of redshift estimation is of great importance in various endeavors such as astronomical transient events, galaxy clustering, the mass function of the galaxy and the weak-lensing approach through constraining the presence of Dark Energy, several methods have been developed to choose an optimum technique.[5] These methods include leveraging training sets,[6] utilizing template spectra for comparisons[7] and mostly template fitting methods.[8]

Additionally, for over a decade, cosmologists have used ML techniques based on neural networks and regression algorithms to determine photometric redshifts.[9] In an attempt to establish a quantitative approach towards the performance of Random

Forests, Carliles et al. 2010 concludes that in contrast to other regression techniques, Random Forest regression overcomes several vital weaknesses.[10] Random Forests algorithm as a non-parametric procedure does not use a statistical model to describe the underlying data. The performance of parametric methods depends on how well the model fits the underlying distribution of data.[11] However, with highly skewed noise distributions, the Random Forest still provides reliable estimate of the error distribution, and this behavior is backed up by strong theoretical support.[12]

In Hoyle et al. (2015), an analysis of feature importance selection applied to the photometric redshift estimation using the ML architecture decision trees was presented. Such an investigation in this regard remarked in five optical frequency bands known as u-g-r-i-z, the flux magnitudes available from the SDSS, as a determinative input feature that encodes the most information about the redshifts of galaxies or quasars.[13]

Over the last 20 years, the SDSS has made a map of the universe. SDSS measurements of the galaxies, quasars and intergalactic gas structure have contributed significantly to tests of the standard cosmological model that describes our understanding of the history and future of the universe. Data Release 16 of SDSS[14] includes infrared, extragalactic and integral field spectra for nearby galaxies. The survey has mapped 4846156 useful spectra, 2863635 of which are galaxies and 960678 are quasi-stellar objects or the so-called quasars.

In this paper, we focus on Data Release 16 of SDSS and design a decision tree and a random forest algorithm to obtain an accurate estimation of the redshifts and then investigated their evaluation procedures to obtain optimum algorithms. We create a dataset of color indices acting as an approximation for the spectrum and as our input features. A noteworthy aspect of this work is the effort put into incorporating more information than a simple point estimate of the redshift. We determine the uncertainty associated with redshift estimates and calculate a posterior distribution.[15]

The rest of the paper is organized as follows. In Sec. 2 we explain ML algorithms including decision trees and random forests. In Sec. 3 the last data release of SDSS, DR16, and our input features will be presented besides our ML methodology for training and learning. The analysis and results are presented in Sec. 4 where we apply optimizing process for Decision Tree and Random Forest algorithms and compare the results of these algorithms. Finally, we discuss our results and conclude in Sec. 5.

2. Machine Learning Algorithms

2.1. *Decision Trees*

A decision trees is a ML algorithm which is used for both classification and regression learning tasks.[16] Based on a set of input features, decision trees generates its corresponding output targets. This is accomplished by a series of single decisions, each representing a node or branching of the tree. Following the training data, the

decision tree learning algorithm determines which decision should be made at each branch. Various metrics are employed by each algorithm in order to determine what is the best way to split the data (e.g. Gini impurity or information gain).

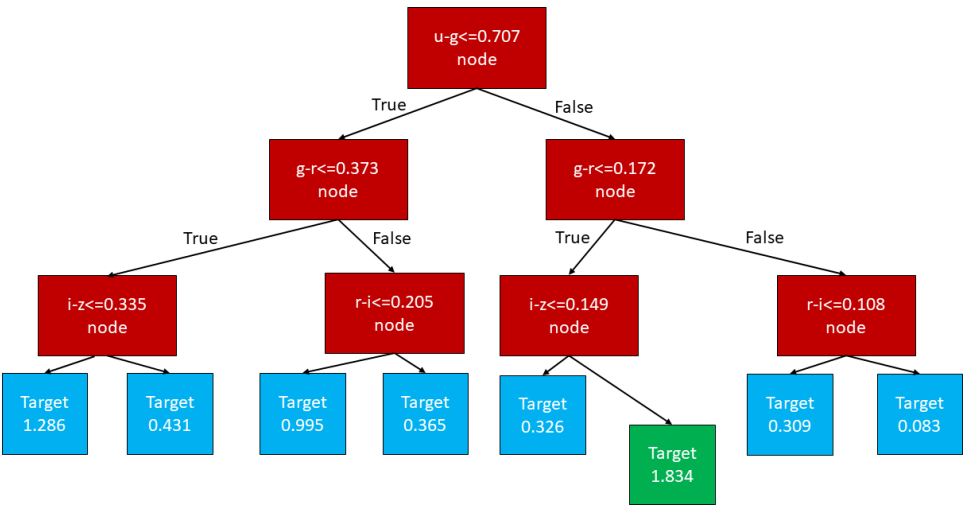

Fig. 1. Schematic of the decision tree algorithm.

The input of the calculated color indices into a series of decision nodes is shown above (Fig. 1), and the target redshift is calculated as output through the series of decision nodes. To implement ML, we will use Python's scikit-learn library. Using scikit-learn decision tree regression, a set of input features and target values are taken into account and then the model is constructed to adapt to new data.

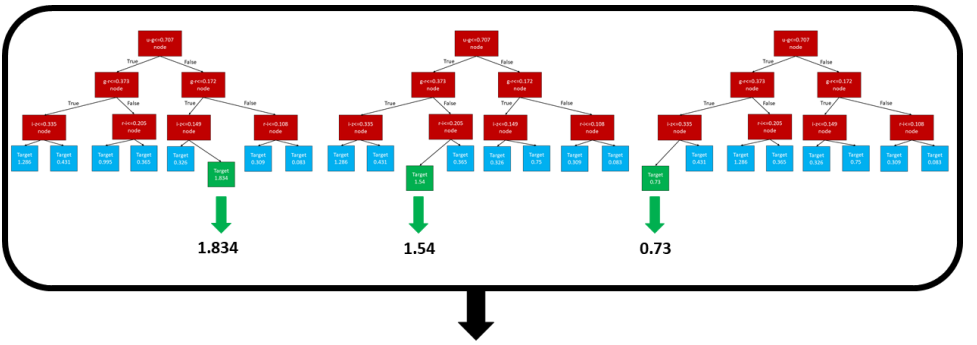
2.1.1. *Important Hyperparameters of Decision Tree*

The most significant hyperparameter of Decision Trees is the max-depth. In all other cases, the nodes are expanded until all leaves contain less than min-samples-split samples, or until all leaves are pure. In the case of a continuous value, as it is in this study, the most commonly used criteria to determine split locations are Mean Square Error (MSE), Poisson deviance as well as Mean Absolute Error (MAE).

2.2. *Random Forests*

Random forests can be viewed as an ensemble of decision trees in which random subsamples of the input attributes are used to create each tree (Fig. 2).[17] In this case, the trees will only learn a portion of the input attribute pattern and it will be poor classifiers.

Additionally, the trees learn only a part of the data, so they cannot learn artificial structures or be influenced by correlated attributes the same way as a neural network can. As final output, they give an average result based on the trained trees, which indicates the probability of each object belonging to one of the specified categories. This method gathers an attractive package of advantages. For instance, the model resists overfitting and is robust against correlated input attributes. In most cases, Random Forest produces excellent results. Moreover, it is one of the most common algorithms, owing to its simplicity and versatility.



$$\hat{Y}(x) = \frac{1}{B}\sum_{b=1}^{B} \hat{y}_b\,(x) = \frac{1.834 + 1.54 + 0.73}{3} = 1.36$$

Fig. 2. Schematic of the random forest algorithm.

2.2.1. *Important Hyperparameters of Random Forest*

First and foremost, there is the n-estimators hyperparameter, which is essentially the number of trees the algorithms build before taking the maximum voting or calculating the average prediction. It is generally true that a higher number of trees leads to better estimation and helps to predict more accurately, but it can also slow down the calculation speed.

3. Data

In this study, SDSS Data Release 16[14] is used as the data source. Observations for the SDSS have been carried out from Apache Point Observatory (APO) since 1998 (using the 2.5m Sloan Foundation Telescope[18] and from Las Campanas Observatory (LCO) since 2017 (using the du Pont 2.5m Telescope).

The newest DR16 contains the final sets of spectra collected as part of the main eBOSS observing program. SDSS's DR16 survey, then, ends a twenty-year stretch of performing a large-scale survey of the universe's structure at redshifts. SDSS has produced the largest catalog of spectroscopic redshifts of galaxies compare to any

other program over this time period. It is worth mentioning that DR16 provides spectra with usable redshifts for around 2.6 million unique galaxies. The photometric properties of around 100 million galaxies were also measured in this data set.

DR16 includes SDSS data products that are freely available through several channels. A large number of galaxy photometrically selected galaxies with spectroscopic redshifts are present in the SDSS that lend themselves well to the analysis presented in this paper to use as training, cross-validation and test samples.

3.1. *Input Features*

Using the color indices as our input features and the photometric redshift as the output, we have constructed a decision tree and a random forest. The data that we use for training are collected through accurate spectroscopic measurements of SDSS. These color indices have been created from flux magnitudes which are the total flux received in five frequency bands known as u-g-r-i-z (Fig. 3). Also, an astronomical color is derived from the difference in magnitudes of two filters, i.e. u - g. An object's color index provides an approximation to its spectrum, allowing it to be classified into various types.

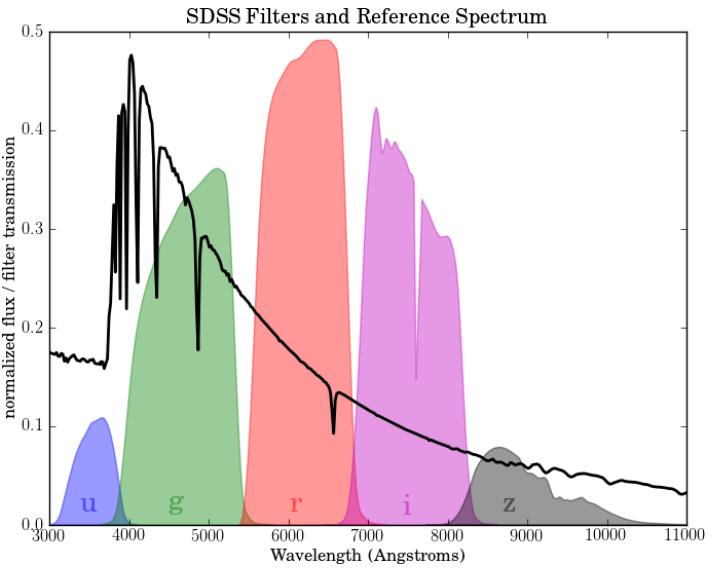


Fig. 3. SDSS filters and reference spectrum.[19]

We can get information about the physical processes taking place in distant astronomical sources by precise analysis of high-resolution spectra. Since the process of obtaining these spectra is very time-consuming and costly, astrophysicists usually observe objects through broadband filters and record them using the magnitude

system. As an example, we can define the magnitude in the u-band filter above as follows:

$$u = m_{\text{ref}} - 2.5 \log 10 \left[\int_0^\infty F(\lambda) S(\lambda) d\lambda \right] \tag{1}$$

where $F(\lambda)$ is the star's flux at wavelength λ, $S(\lambda)$ is a sensitivity function describes the fraction of the star's flux that is detected at a specific wavelength and m_{ref} is apparent bolometric magnitude.

3.2. *Training and Learning*

Following conventional ML methodology, the galaxy catalog is then subdivided into training and testing samples, with portions of 80 and 20, respectively. For each architecture and hyperparameter set, the ML system is trained using a training sample. Testing the learned machine's generalization ability based on a test sample is necessary to determine whether it truly generalizes to new data sets. Furthermore, k-fold cross-validation allows us to test the accuracy of our model. Our model is trained k times, with each training test recording the accuracy. We train the model every time using a different combination of k-1 subsets, and we test it with the final kth subset. Then, the overall accuracy of the model is calculated by taking the average of the k accuracy measurements.

4. Analysis and Results

In the current section, we start to analyze the final results of our structured algorithms. First we make a contour map of the redshifts based on a combination of color indices (Fig. 4), the results indicate that relatively well-defined regions of

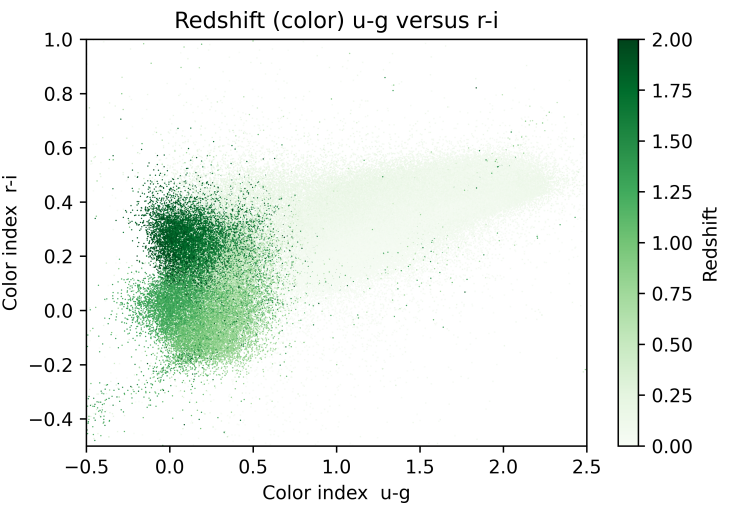

Fig. 4. Contour map of the redshifts based on a combination of color indices.

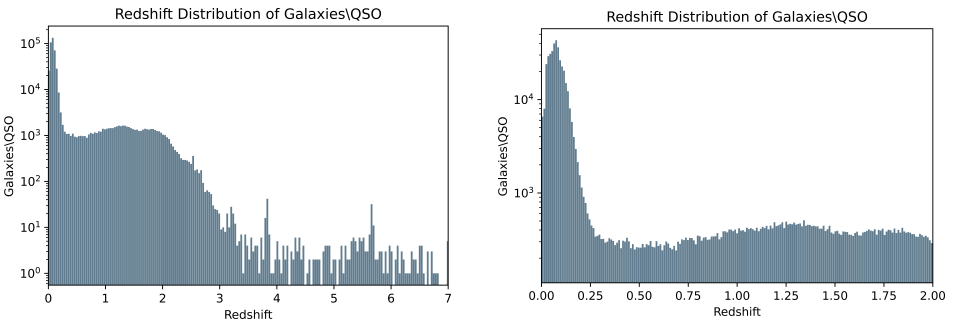
similar redshifts can be extracted and therefore the redshift of a new data point can be inferred from the color indices. So, this gesture underlines the fact that color indices are, indeed, appropriate input features for our ML algorithms.

In Fig. 5, the redshift distribution of galaxies and quasars are presented. In our dataset there are more galaxies in the dataset than quasars, and galaxies usually have lower redshifts.



(a) (b)

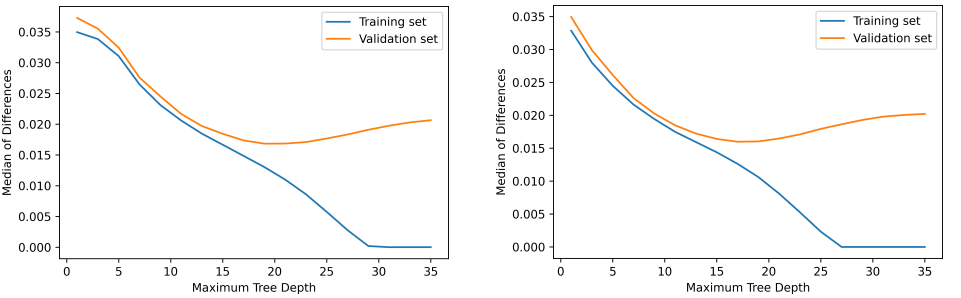
Fig. 5. Redshift distribution of Galaxies/QSOs. (a) Total range of the dataset. (b) limited range ($z \leq 2$) of the SDSS dataset.

We divide Our dataset into two ranges, i) contains all the measured redshifts ii) includes those below value 2. The reason behind this procedure is to achieve better performance of the algorithms, which will be discussed in detail in the following sections.

4.1. *Optimizing Process for Decision Tree*

There are some limitations for decision trees algorithm, including an over-fitting tendency. This means that it would potentially create a tree that is too complicated and does not address the statistical outliers in the data. In the process, general trends may not be accurately characterized.

Among the reasons for the over-fitting is the algorithm works by trying to optimize each node's decision locally. During our analysis, we will examine the impact of constraining the number of decision node rows (tree depth) on predictions. Various tree depths can be used to investigate whether the tree is over-fitting or not. We are particularly interested in comparing the algorithm performance on test data with its performance on training data (Fig. 6).



(a) (b)

Fig. 6. Analysis of the maximum tree depth (a) Total range of the dataset. (b) limited range (z≤2) of the SDSS dataset.

4.2. *Optimizing Process for Random Forest*

Creating a parameter grid prior to fitting is the first step in optimizing the Random Forest algorithm. A new combination of features is selected on each iteration, especially the n-estimators parameter, which represents the number of trees. In our Random Forest algorithm, we see that 600 trees will give the best result, as measured by the median value of the residual of measured and predicted redshifts. By setting the number of trees parameter to 600, we investigate the optimum amount of each tree's depth as in our prior grid search in the algorithm.

4.3. *Illustrations of the Models Performance*

Once the maximum tree depths have been determined, the algorithms are ready to take on the two different sets of data extracted from DR 16. We have used 450000 of the catalog's data based on our system's performance. There were 400000 data under value 2 in the parts of the paper where calculations had been executed on the filtered dataset. Fig. 7 and Fig. 8 present the measured redshifts from the survey versus the algorithms predicted redshifts. The color bars indicate the density of the galaxies or quasars in the datasets. A straight line with an angle of 45 degrees illustrates the success of the algorithms where measured redshifts is equal to the predicted ones. The overall performance of each algorithm was evaluated using three metrics:[20] model accuracy, the Root Mean Square Error (RMSE), and the normalized standard deviation. The normalized standard deviation is defined by:

$$\Delta z(\text{norm}) \equiv \frac{z_{\text{spec}} - z_{\text{phot}}}{z_{\text{spec}} + 1} \tag{2}$$

And, we calculate the standard deviation of the photometric redshifts from the spectroscopic redshift or namely the RMSE:

$$\sigma_{\Delta z} = \sqrt{\frac{1}{N}\sum_{i=1}^{N} \Delta z^2} \tag{3}$$

Fig. 7 illustrates how the Decision Tree algorithm has performed on both subsets of the dataset. Each datum's predicted redshift is plotted as a function of its spectroscopically measured value. The left panels show the the results for the whole range of the redshift data, while the right panels limited to the results with redshifts below value 2. Moreover, the error distributions of the predicted redshifts appear under each graph. The mathematical criteria for each model's performance are provided in the corresponding tables, however, it can obviously be inferred from both of the diagrams that filtering the redshift to below 2 values has indeed enhanced the accuracy of results.

As the Table 1 shows, filtering data into lower redshifts leads to a significant improvement in the model's performance. The accuracy of the algorithm has increased by 15%, the median difference, the normalized error as well as the standard deviation were all decreased by corresponding amounts. The explanation which underlies this improvement could be the fact that by splitting the dataset, there are no more considerable biases in the values of target redshifts and the algorithm would not experience a scattered distribution of values in the training procedure. Thereby, there should be no excessive miscalculation or poor estimation in the testing mode.

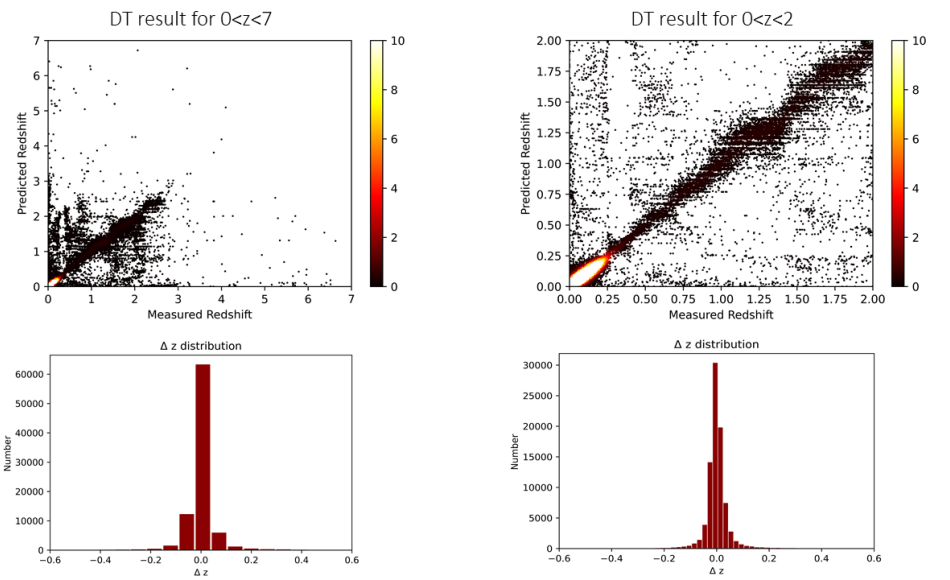


Fig. 7. The predictions of the Decision Tree algorithm for two ranges of redshifts in SDSS dataset.

Table 1. Analytical overview of statistical parameters for the Decision Tree algorithm for two ranges of redshifts z≤7 and z≤2.

Parameters	Decision Tree (z≤7)	Decision Tree (z≤2)
Accuracy	70.17%	85.26%
Max Depth	19	17
Median Difference	0.017	0.0156
$\overline{\Delta Z}_{\mathrm{norm}}$	0.0135	0.005
$\sigma_{\Delta z}$	0.28	0.16

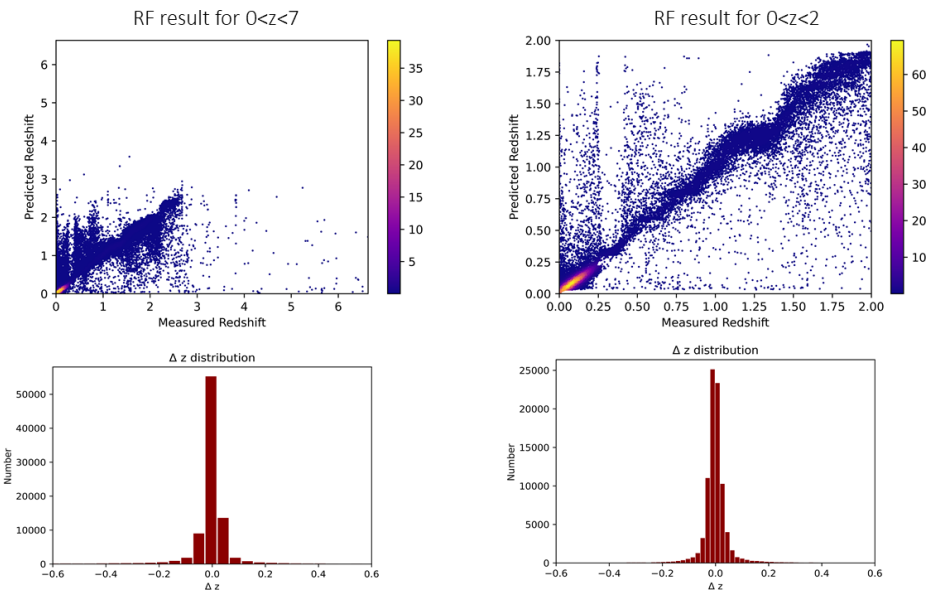

Fig. 8. The predictions of the Random Forest algorithm for two ranges in SDSS dataset.

Contemplating what was discussed in section 2.2, as the number of trees grow, the accuracy of the predicted value increase. Thus, it is expected that the Random Forests would have a better overall performance in terms of making more accurate predictions. As shown in Fig 8, both in the scattered plot and the distribution plot, the amount of precise estimations has increased. Since the color bar range indicates the density of data in the diagram and it includes a greater range of numbers than the Decision Tree algorithm. We conclude that the Random Forest algorithm has better accuracy. This fact is also presented in terms of statistical parameters showing the accuracy in Table 2 such as the standard deviation.

Table 2. Analytical overview of statistical parameters for the Random Forest algorithm for two ranges of redshifts z≤7 and z≤2.

Parameters	Random Forest (z≤7)	Random Forest (z≤2)
Accuracy	81.02%	91.00%
Max Depth	25	13
Number of Trees	600	600
Median Difference	0.0164	0.0154
$\overline{\Delta Z}_{\rm norm}$	0.013	0.005
$\sigma_{\Delta z}$	0.23	0.12

5. Conclusion and Remarks

The current research addresses two leading ML regression algorithms namely the Decision Tree and the Random Forest, that were structured for estimating the redshifts of distant objects such as galaxies and quasars. Since there exist vital limitations in obtaining spectroscopic measurements, the photometric optical band data are widely investigated in this realm. This paper uses the 16 Data Release of the SDSS, where photometric colors are used as input features of the mentioned models. After developing the Decision tree and the Random Forest algorithms and evaluating the final results, it was concluded that the Random Forest algorithm will significantly perform better in this case (Table 3). The Random Forest algorithm leads to much better accuracy and marginally better standard deviation and median difference as seen in Table 3.

Another noteworthy improvement was filtering the dataset to redshifts below value 2. The significant effect of redshift splitting was illustrated in section 4.3 and we extensively discussed about all the possible reasons behind this effect.

Table 3. Comparison between statistical parameters of the Decision Tree and the Random forest algorithms for z≤2.

Parameters	Decision Tree (z≤2)	Random Forest (z≤2)
Accuracy	85.26%	91.00%
Median Difference	0.0156	0.0154
$\overline{\Delta Z}_{\rm norm}$	0.005	0.005
$\sigma_{\Delta z}$	0.16	0.12

A few recent attempts for redshift estimation applying similar developed ML algorithms are addressed in Table 4. The crucial factor affecting their evaluations is the amount of data in the training sets. Remarkably, in this work taking 400000

Table 4. Comparison among results obtained using similar methodologies by different collaborations and our results in this work.

Refrence Articles	Data Release	Training Set	$\overline{\Delta Z}_{\rm norm}$	ML Algorithm
Beck(2016)	12	1,976,978	5.84×10^{-5}	Local Linear Regression
Paul(2018)[1]	12	20,000	2×10^{-3}	Random-Forest
Baldeschi(2021)[12]	16	1,251,249	1×10^{-3}	Random-Forest
This work	16	320,000	5×10^{-3}	Random-Forest

data into consideration for the training set, we achieved nearly equivalent accuracy to the previous works.

Our results show the great potential of the ML methods for redshift estimation of distant sources using color index features. It is worth mentioning that applying ML methods is unavoidable when a large number of astrophysical data will be obtained from the next generation of sky surveys as the era of big data has started.

In view of increasing data volume of existing and upcoming telescopes/detectors we here apply the 1–dimensional convolutional neural network (CNN) to estimate the redshift of (high-)redshifts quasars in Sloan Digital Sky Survey IV (SDSS-IV) quasar catalog from DR16 of eBOSS. Our CNN takes the flux of the quasars as an array and their redshift as labels. We here evidence that new structure of the network, and augmenting the training set, provide a high precision result in estimating the redshift of quasars.

Keywords: Quasar, Deep learning, CNN, SDSS

1. Introduction

Quasars are the most luminous active galactic nuclei(AGN) which are powered by accretion disk around supermassive black holes at centers of their host galaxies. Thanks to their high luminosity, they can be observed across the universe in wide range of redshift from z = 0 to z ∼ 7. Thus, quasars give us important information about the early universe, the structure formation and evolution.[1,2]

Nowadays, astronomy and astrophysics have been brought into the big data era through the construction and development of ground-based and space telescope. Since huge amount of data, ranging from gamma-ray, x-ray, ultraviolet, optical,

infrared and radio bands of quasars is available in sky surveys, various challenges and opportunities are created for scientific discoveries.[3,6]

In recent years, machine learning (ML) and deep learning (DL) have been utilized in astronomy and astrophysics in order to deal with the big data surveys and as well extract the new physical understanding. The goal in ML and DL is to diagnose, by optimization, common characteristics and features in data.[10] These interesting branch of computer science have been used in estimating the physical parameters and classification of celestial objects; for example the morphological classification of galaxies,[15,16,20] estimation of photometric redshift,[12,25,33,34] classification of star/galaxy,[4,27,32] spectral classification of stars.[5,7,17,35]

This article is mainly dedicated to train a CNN to predict the redshift of Quasi-stellar radio source (quasars) or quasi stellar objects (QSO) in Sloan Digital Sky Survey IV (SDSS-IV) quasar catalog from Data Release 16 (DR16) of the extended Baryon Oscillation Spectroscopic Survey (eBOSS), which is the most comprehensive catalog of spectroscopically collected quasars to date.[26]

2. Dataset

In this paper, we exploit dataset from the quasar spectra obtained by the Sloan Digital Sky Survey-4(SDSS-4). They are provided by the Sixteenth Data Release (DR16) of SDSS extended Baryon Oscillation Spectroscopic Survey (eBOSS).[14] According to the technical details of eBOSS, namely the wavelength coverage in range of 361nm$-$1014nm with the resolution $R = 2000$, where $R = \frac{\lambda}{\Delta\lambda}$, more than 700,000 quasar spectra have been detected in the redshift range $0 \leq z \leq 7.1$.

The distributions of detected quasars redshift in the DR16 catalog is shown in Fig. 1. As can be seen, the number of quasars reaches its maximum around $z \approx 2.5$; at earlier epochs i.e., higher redshifts, they are comparatively rare.

2.1. *Redshift*

The observed quasar spectra contain broad emission lines, often time-variable flux both in the continuum and in the emission lines and UV flux; see e.g.[11] The shift and deformation of the various lines and specific characteristic of different fluxes in the spectra of quasars, due to the cosmological redshift, makes quasars a proper tool to invest the deep learning method and extract the common features hidden in their spectra (flux).

In DR16Q catalog, redshifts obtained for quasars by different methods, such as principal component analysis (PCA) and QuasarNET are reported. In this work we use "*primary*" redshift or best redshift for quasars which has been selected from the available visual inspection redshifts,[8] or, alternatively, the SDSS automated pipeline redshift;, see[23,24] and references therein for more information. The best option is exploiting only the visual inspection redshifts which will be presented in the forthcoming papers.

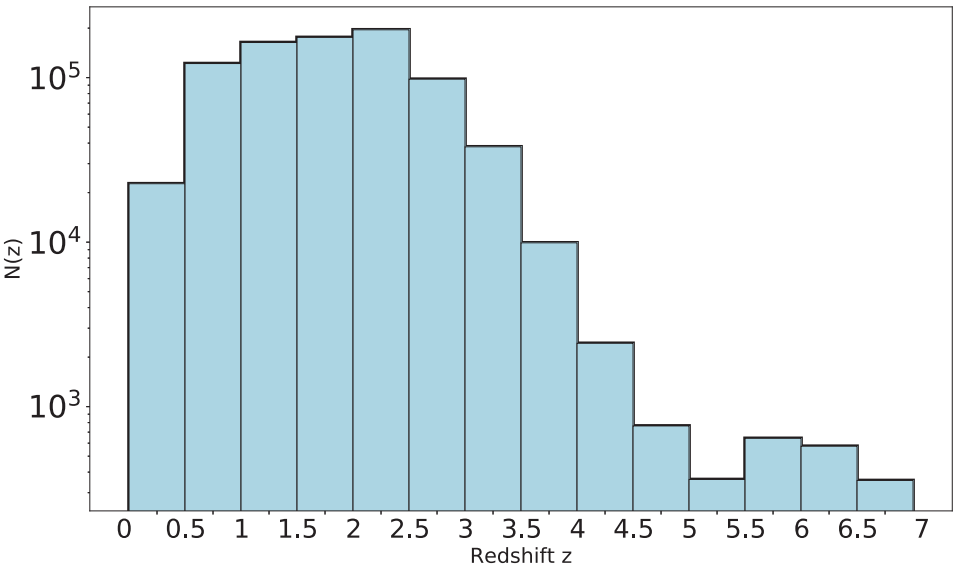

Fig. 1. The distributions of "*primary*" redshift of quasars in the DR16 catalog.

3. Convolutional neural network (CNN)

3.1. *CNN architecture*

Since the spectra of quasars are represented by flux versus the wavelength, namely 1+1 dimensional set of data, they can be considered as as time-series. For this reason, the neural network model in this work is designed to be a 1-dimensional CNN. It operates like a combination of some mathematical functions, which optimizes through several filters, and transforms the input data; here flux of quasars, to the output data, here redshift of quasars, by extracting the hidden features from the quasars' fluxes.

The physical information, such as redshift are hidden in the observed flux, and CNNs, as a regressor, are supposed to estimate the redshift through the training process. The CNN in the current work is a combination of convolutional and fully-connected layers. The convolutional layers are initialized with He Normal initializer.[22] If the model requires to access the non-linear modes in data he Rectified Linear Unit (ReLU) activation function is implemented.[36]

The filters in each convolutional layer scans each row (flux) and extract the prominent features from the raw input for the specific redshift. The feature-extraction layers have a repeating pattern of the convolutional layers whereas the pooling layers reduce the dimensions and concentrate only on the most prominent features. This process recognizes the non-linear correlation within the dataset. Finally, the fully-connected feed-forward layers connect and assign the extracted

features to the output layer (redshift). All free parameters in the model change dynamically as the algorithm finds the best solution, achieved by the back-propagation learning algorithm.

Many free parameters, such as the number of layers, layer specifications, and their arrangement can be changed while one constructs a neural network model; known as model architecture. The architecture selection affects optimization and quality of the performance; this process is called hyperparameter optimization.[18] The hyper-parameter optimization process is necessary in order to ensure that neither underfits nor overfits of the training set happens.

In the hyper-parameter optimization process, the number and length of filters of convolutional layers, the number of nodes in fully-connected layers, and the kernel size of the Maxpooling layer are considered and finally the "Mean Squared Error" (MSE), as the loss function, is utilized in our CNN.

We also use Adam optimizer to optimize the loss function, which is an algorithm for the first-order gradient-based optimization of stochastic objective functions. We here set the learning rate as 0.0001 and the coefficients for computing the averages of gradient and its square as 0.5 and 0.9, the weight decay of L2 penalty is set as 0.[28, 29]

Figure 2 demonstrates the CNN pipeline of this work. It takes a quasar spectrum as a 1-dimensional array and predicts the redshift. We have tested different samples of training set, and the addition of more layers to this configuration does not enhance the prediction accuracy presented in this paper for different redshift intervals.

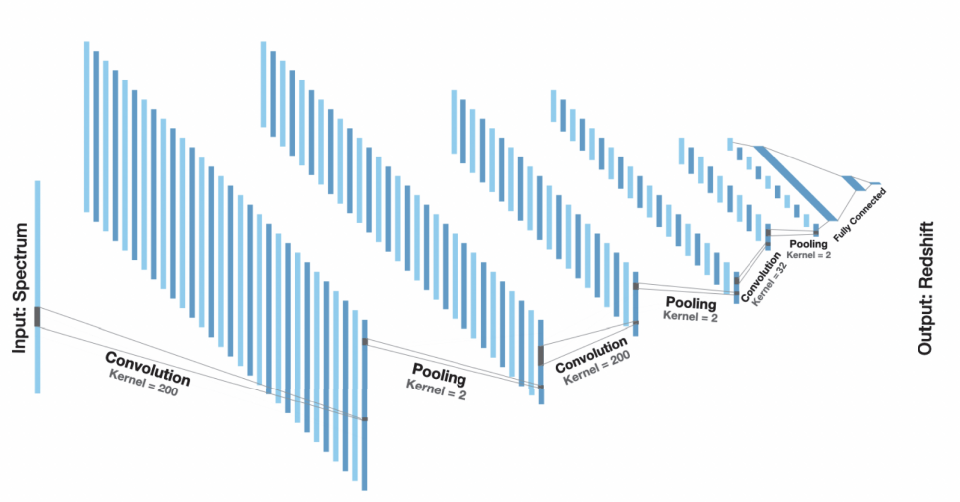

Fig. 2. Structure of 1-dimensional CNN developed in this work to learn higher-order features hidden in the input spectrum. The CNN goes through the spectrum via a convolutional layer of kernel size = 200, 200, 32, respectively in order to search for the global and local pattern. The fully connected layers output the redshift.

3.2. *Pre-processing the data*

Data pre–processing is crucial in two aspects: (1) to provide an understandable dataset for DL networks, and (2) to increase the speed and accuracy of processing. As the first step of the pr–eprocessing procedure in the present work, a two-dimensional matrix of the dataset is created. In the matrix each row represents the quasar flux and each column relates to a flux a certain wavelength. At the second step, the flux of every spectrum is normalized via the Zero-Mean Normalization method. Moreover, the normalized fluxes are stored in a Numpy array and applied as features dataset, their corresponding redshifts are collected for labels dataset as well.

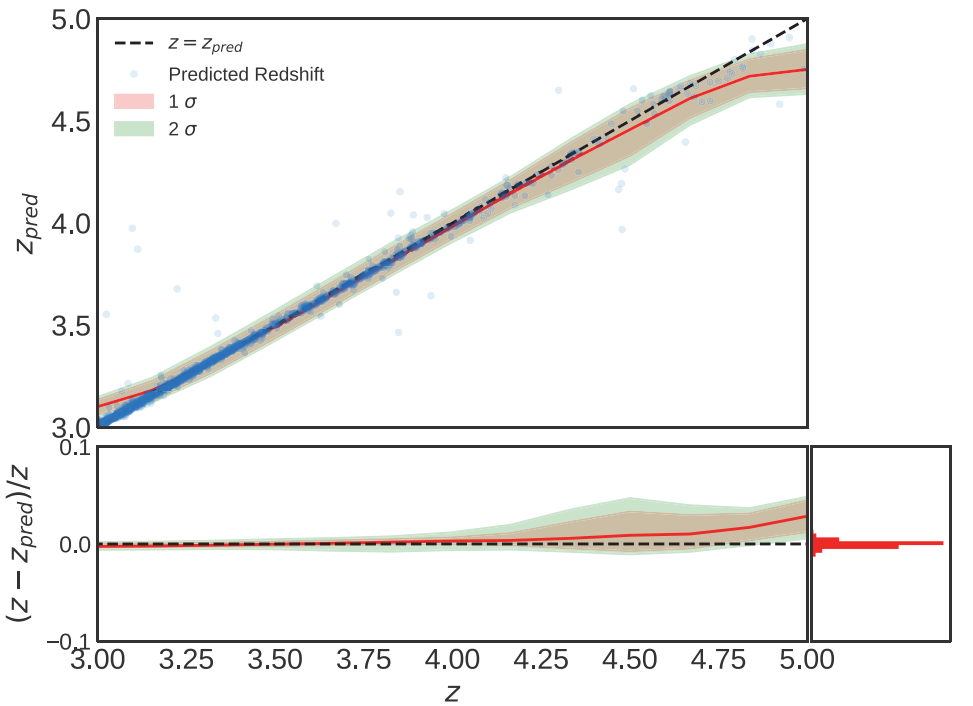

Fig. 3. Redshift predicted by our CNN for $3 \leq z \leq 5$. Top: The predicted redshift vs. the redshift reported in the DR catalog. Bottom: The relative error and their distribution. As it can be seen the distribution of relative error follows a Gaussian distribution with mean, $\mu = 0.0042$ and a standard deviation of $\sigma = 0.014$.

4. Prediction in the $3 \leq z \leq 5$ interval

As an example, we use the quasars in the $3 \leq z \leq 5$ interval as sources to test our CNN. In general, there are $51,100$ quasars in this interval,75% of them, namely 38832 spectra are taken as the sample in order to train our CNN (training set) and

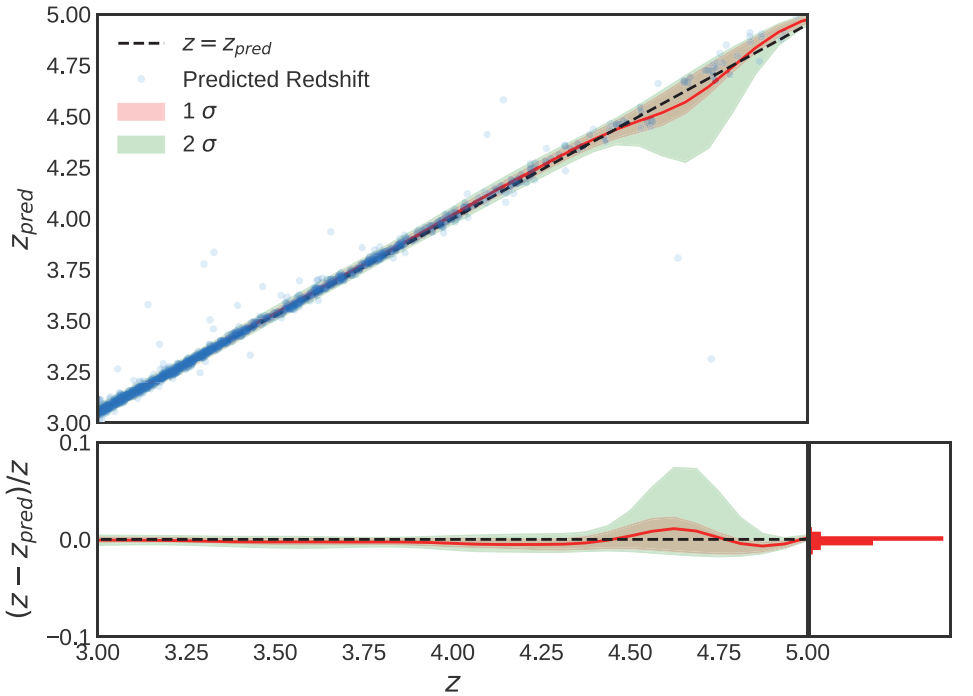

Fig. 4. Redshift predicted by our CNN for $3 \leq z \leq 5$ with training set in $2.9 \leq z \leq 5.2$ interval. Top: The predicted redshift vs. the redshift reported in the DR catalog. Bottom: The relative error and their distribution. The distribution of relative error follows a Gaussian distribution with mean, $\mu = 0.0038$ and a standard deviation of $\sigma = 0.012$.

25%, namely 12776 as sources to testify our CNN (test set). In the whole paper, the test set has not been used to train the CNN. Moreover, no limit on the S/N ratio of spectra is imposed.

The predicted redshift by our CNN for $3 \leq z \leq 5$ together with their relative errors distribution and the best fit is shown in Fig. 3. The distribution of relative error, RE,

$$\mathrm{RE} \equiv \frac{\mathrm{z} - \mathrm{z}_{\mathrm{pred}}}{\mathrm{z}}, \tag{1}$$

which z is the redshift reported by SDSS and z_{pred} is the redshift predicted by our CNN, follows a Gaussian distribution with mean, $\mu = 0.0042$ and a standard deviation of $\sigma = 0.014$. The method used for smoothing the scatterplot is locally weighted regression (LWR).[13]

As it can be seen in Fig. 3, the fit in the lower and upper edges of the prediction, namely $4.5 \lesssim z \leq 5$ and $3 \lesssim z \leq 3.1$ intervals, is not as significant as other time intervals.

This problem can be due to:

(1) the lack of data in $z < 3$ and $z > 5$ and consequently the failed LWR in the aforementioned intervals.
(2) the deficiency of training sample in $4.5 \lesssim z \leq 5$.

In order to solve the first issue, we extend our training set to $2.9 \leq z \leq 5.2$. By adding this extra data to the train set we make sure that there is no bias in the LWR fitting presented in Fig. 3 at its lower and upper part; see Fig. 4.

In order to accommodate the second issue and increase the number of spectra of the training set in $4.5 \lesssim z \leq 5$ we first convert the observed spectra in $4 \leq z \leq 4.5$ interval, where there are enough spectra to produce a reliable training set, into their cosmological rest-frame by dividing their wavelength by 1+z then we convert data set to $4.5 \leq z \leq 5$ by multiplying the wavelengths by a factor of 1+z+0.5.

Figure 5 represents the results when extra samples from $2.9 \leq z \leq 3$ and $5 \leq z \leq 5.2$ as well as the redshifted sample from $4 \leq z \leq 4.5$ to $4.5 \leq z \leq 5$ have been added to the original training set. The distribution of relative error follows a

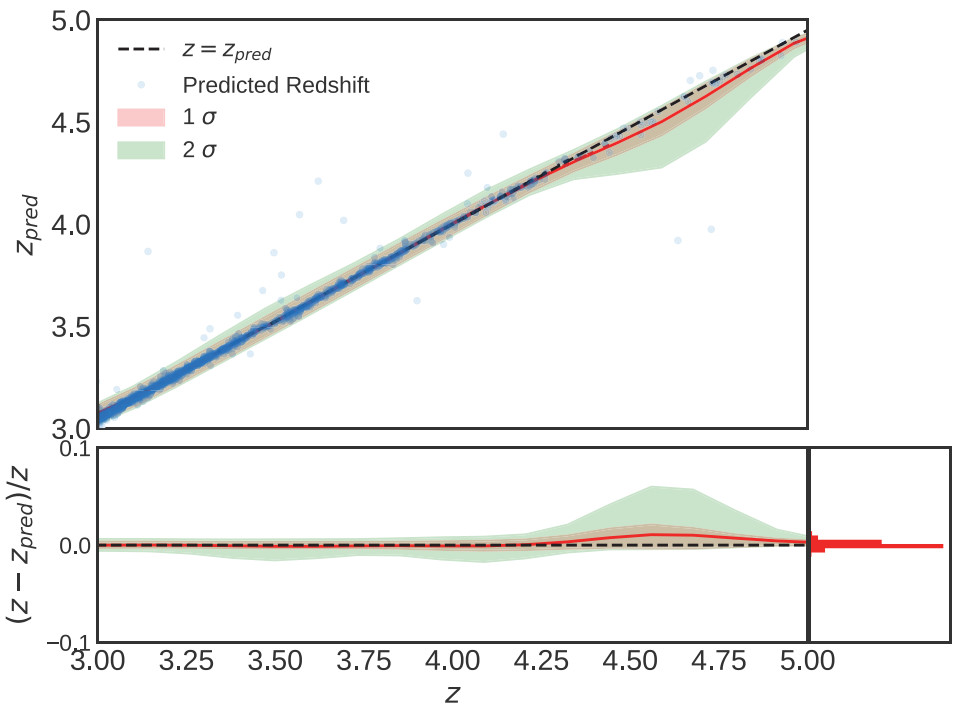

Fig. 5. Redshift predicted by our CNN for $3 \leq z \leq 5$ with training set in $2.9 \leq z \leq 5.2$ interval together with the converted observed spectra in $4 \leq z \leq 4.5$ interval into $4.5 \leq z \leq 5$. Top: The predicted redshift vs. the redshift reported in the DR catalog. Bottom: The relative error and its distribution which follows a Gaussian distribution with mean, $\mu = 0.0030$ and a standard deviation of $\sigma = 0.010$.

Gaussian distribution with mean, $\mu = 0.003$ and a standard deviation of $\sigma = 0.01$. The prediction is clearly improved in $4.5 \leq z \leq 5$ comparing to initial result shown in Fig. 3.

5. Conclusions

Deep learning, especially CNN[31, 37] is promising in the future Astrophysical studies. CNN can be utilized, owing to its several convolutional and fully connected layers to find the common deep hidden patterns in the spectrum, in provision for improving our astrophysical knowledge of distant objects. In this regard, we showed that exploiting a CNN leads to a statistically significant prediction of the redshift of quasars. We also showed that augmentation of dataset, which depends on the statistical and physical features of samples improves the prediction of redshift. Since CNN finds the physical characteristics of the spectra and these characteristics are deformed by the cosmological redshift the results presented here can be extended to the other energy bands like, X-ray, Infrared, UV, Gamma-ray and etc.

Two major challenges in modern cosmology involve understanding the origin and growth of Cosmic structure and the progenitors of Gravitational Waves. Both scenarios currently require heavy computational resources to perform simulations and inference. In this work, we adopt simple Machine Learning methods to alleviate these requirements, to enable significantly faster sampling and inference. We show that using Dimensionality Reduction and simple Supervised Learning methods, it is possible to generate high-precision emulations of density fields given a set of parameters (such as the Dark Matter density parameter and redshift). Our method provides orders of magnitude improvement of CPU run times and much less computational resources when compared with N-Body simulations or more complex supervised learning approaches. We also show that it is possible to generate fast inference of gravitational wave parameters (such as the Chirp Mass) from Binary Black Hole systems using the same method. This method provides a promising approach to fast emulation and parameter inference to further explore in the context of upcoming large surveys like Euclid, LSST/Rubin, and LISA.

Keywords: N-body Simulations, Gravitational Waves, Supervised Machine Learning, Dimensionality Reduction, Emulation, Inference.

1. Introduction

Two main challenges in modern Cosmology involve understanding the origin and growth of Large Scale Structure (LSS) and the physics behind the progenitors of Gravitational Waves (GW). To study these phenomena, usual approaches rely on the generation of mock data for comparison with observations and consequent inference of parameters concerning the underlying preferred models.

Regarding Structure Formation, mock data is usually generated with N-body simulations, which are the most powerful method to study the non-linear evolution of large scale structure, within a huge variety of cosmological scenarios. With upcoming surveys like Euclid,[1] the urgency to generate large databases of these simulations for statistical analysis becomes even higher. One serious limitation is that simulations take large amounts of computational resources and time, making unfeasible their direct adoption in tasks that require the realization of multiple simulations and wide explorations of parameter spaces. To overcome these limitations, we propose the application of simple Machine Learning methods to generate high accuracy emulations of N-body density fields in a minimal amount of time, given a chosen set of cosmological parameters, more specifically the Dark Matter Density (Ω_{dm}) and redshift (z).

Similarly to the N-body case, current approaches for parameter inference from gravitational waveforms also rely on computationally heavy and sometimes model-dependent methods. With GW detectors like LIGO[2] and the upcoming LISA[3] mission there is also the urgency for the development of methods that can efficiently extract information from this type of data. Consequently, we aim at generalizing our proposed N-body approach to enable fast and accurate inferences of astrophysical parameters of the waveforms progenitors, namely, the Chirp Mass (M_{chirp}).

To achieve both goals we combine a simple data projection method called Principal Component Analysis (PCA)[4–6] with Supervised Machine Learning techniques, requiring only an initial dataset of N-body simulations and approximated waveforms. PCA enables us to take advantage of the redundancy intrinsic to the data by compressing the dimensional size of input features before providing them as an input to the Machine Learning methods, which learn the relationship between the compressed representation, i.e. the Principal Component coefficients, and the desired cosmological/astrophysical parameters for emulation/inference.

After convergence is achieved, we can use the models to infer or emulate previously unknown regions of the parameter space, which can be compared with ground truth examples not included in the training data, to gauge the performance of the methods. To test different approaches and discriminate which was more appropriate for our analysis we explored four different machine learning algorithms, Random Forest,[7] Extremely Randomized Trees,[8] Support Vector Machine[9] and Neural Networks.[10] Additionally, we also explore the possibility of using *Functional Principal Component Analysis* (FPCA) to perform the emulation of N-body density fields, a method that combines the capabilities of both the PCA and the Supervised Learning approach, providing better accuracy at the cost of higher computational memory.

2. Methodology

This Section presents the method that we developed and the approaches that we used to generate our training and test data sets. To ensure that our methods are effective even in infrastructures with limited resources, all work presented here was created, run, and tested on a regular desktop computer with an Intel Core i5-4460

(4 cores, 4 threads), with 16Gb RAM at 2400 Mhz, running the Linux Ubuntu 18.04LTS operating system, without discrete high-performance GPU cards.

The whole pipeline includes codes in different programming languages. These include `Fortran`, for generation the N-body simulations and power spectrum computation from 3-dimensional density volumes; `Python`,[11] to generate GW waveforms, noise models, and to compute density field bispectra; and, finally, the `R` programming language[12] for the new statistical learning pipeline that we propose. This also includes R libraries for dimensionality reduction, regression models and parameter estimation, that are written in `C`, `C++` and `Fortran`.

In the following Sections, we provide a detailed description of our pipelines.

2.1. *Adopted Machine Learning Algorithms and Optimization*

To build our pipeline, we tested four classical machine learning algorithms, Random Forest,[7] Extremely Randomized Trees,[8] Support Vector Machine[9] and Neural Networks.[10] Each algorithm is governed by a set of hyper-parameters that define the properties of the learning process and the structure of the model. Consequently, we optimized the combination of these hyper-parameters using three different optimization approaches, Grid-Search, Bootstrap and K-fold Cross-Validation, ultimately choosing the one which provided the best results.

For the Random Forest algorithm we used the `randomForest` package,[13] while optimizing the number of trees in the ensemble (`ntree`), the number of features tried at each split (`mtry`) and the minimum size of the terminal nodes (`nodesize`).

For the Extremely Randomized Trees, our implementation used the package `extraTrees` while optimizing the number of random cuts at each split (`numRandomCuts`) and similarly to the previous case, the number of trees in the ensemble and features tried at each split.

The Support Vector Machine models were built using the package `e1078`[14] and the hyper-parameters optimized were the kernel `kernel`, the margin/error `cost` and the amount of curvature allowed in the decision boundary of the Gaussian Radial Basis Function Kernel (`gamma`).

Finally, for the Neural Networks, our implementation used the package `nnet`,[15] and we optimized the number of perceptrons in the single layer (`size`) and the decay of the weights (`decay`).

For the particular case of Gravitational Wave parameter inference, since the Principal Components are used as independent variables, they were also optimized. Here we used a simple Grid-Search.

2.2. *The N-body Emulation Pipeline*

In the first half of our work, we attempted to estimate N-body dark matter density fields using our proposed compression-based machine learning methods.

We consider two scenarios. In the first scenario, we attempt to estimate the density fields considering just one cosmological parameter as the independent variable

used to build the regression models, the Dark Matter density (Ω_{dm}). In the second scenario, we extend the pipeline to include the redshift (z) as a second cosmological variable and attempt to use both as independent variables to estimate the density field for different values of Ω_{dm} and at a continuous range of z.

2.2.1. *Generation of the Training and Test Datasets*

We generated the N-body simulations using a public version of the Hydra code,[16] which solves the Newtonian equations for a set of mass particles of Dark Matter. Every simulation has the same initial conditions, starting from the first snapshot at $z = 49$ until reaching $z = 0$, summing up to a total of 10 snapshots. We generated the fields for 160^3 particles of dark matter initially positioned on a regular cubic grid of comoving length $L = 100\ h^{-1}$Mpc on the side, and every snapshot contains positions and velocities for each one of them.

The cosmological model assumed was the Λ-*CDM* model with $\Omega_k = 0$, $\Omega_m = 1 - \Omega_\Lambda$, $\sigma_8 = 0.809$, and $h = 0.7$, where σ_8 the stardand deviation of density fluctuations when convoluted with a Kernel at a scale of $8\ h^{-1}$Mpc and h is the Hubble parameter (i.e. $h = \mathrm{H}_0/100$).

After calculating the positions and velocities for each particle using the Hydra code, the data is compiled by another code called *darkdens* which calculates the densities of the particles using the *Smooth Particle Hydrodynamics* (SPH) formalism.[17] Finally, the data goes through yet another fundamental piece of code which computes the density field in 128^3 cubic voxels, in units of $10^{27}\ Kg\ m^{-3}$.

In the first scenario of emulation from a single free-parameter, as a demonstration of the validity of our method, it was enough to generate a small set of 24 simulations, setting one of them apart to evaluate the performance of the models. The 23 simulations in the training set were generated with Ω_m varying in the interval $\Omega_m \in [0.05, 0.6]$ with $\Delta\Omega_m = 0.025$, while our test simulation was generated with the density value from the Planck collaboration 2015,[18] corresponding to $\Omega_m = 0.309$.

For the scenario of multiple parameter (Ω, z) density field emulation, the training set we adopted in this work comprises 23 Ω_m density fields spanning four redshifts, $z = [0, 0.25, 0.75, 1]$, while $z = 0.5$ for $\Omega_m = 0.309$ was held for testing. Consequently, the final training dataset will consist of a total of 92 density cubes.

2.2.2. *The Density Field Emulation*

After creating the N-body simulations, we then proceed to load our training set into a matrix to perform dimensionality reduction using PCA, while forcing the data to be scaled and centered, and apply it to our training matrix in its logarithmic form. For that purpose we use the function `prcomp` from the package `stats`.

As a result of the PCA analysis, we have five objects. A vector containing the standard deviations of each Principal Component. Two vectors containing respectively the values used in the centring and scaling of our original data matrix. The

matrix containing the *loadings* (in each column), holding the correlations between the original data and the PCs. And the scores matrix containing the PC scores, or in other words, our data projected in the principal directions. If we consider the loading and scores matrices to be given by $\mathbf{L}$ and $\mathbf{S}$, the scale and centre vectors to be given by $\mathbf{s}$ and $\mathbf{c}$, to obtain our original data representation the scores must be matrix multiplied by the loadings with a posterior sum of the centre vector and multiplication of the scaling one, yielding:

$$\boldsymbol{M_{orig}} = 10^{(\boldsymbol{SL^T s^T + c^T})} \tag{1}$$

Once we have our projected quantities, we use them to optimize and train the regression models. Since we aim to estimate the field itself, in the case of single free-parameter emulations the training is performed using the PCs as dependent variables and Ω_m's as independent ones. Once trained, the models are used to predict the new set of PCs for $\Omega_m = 0.309$ (or any other Ω_m), which can be de-projected into the final estimated cube. To achieve this, we created an iteration loop wherein each iteration our four different algorithms build a regression model accounting for that specific PC and the same set of Ω_m values.

To obtain the final PC predictions using these models, we rely on the function `predict` from the R package `stats`. This function accepts as inputs the regression model and the predictor variables, which in this case correspond to one of the four algorithms and $\Omega_m = 0.309$, respectively.

For the case of the two free-parameter regressions, it is just a matter of adding the redshift as a second independent variable, providing the correspondent training redshift vector to the supervised learning algorithms and the new test redshift (z=0.5) plus the trained models to the `predict` function. Keep in mind that in this case, we are training with 4 distinct redshifts, and thus 4×23 simulations, as mentioned in the previous section. After having the new PCs, the four final estimated cubes are obtained, by de-projecting them using Eq. 1.

2.2.3. *Testing the Models*

To test the emulation performance of our methods we need to define an appropriate metric for comparison against the ground-truth N-body simulation. Consequently we chose to use both the Power Spectrum and Bispectrum for this comparison.

The power spectrum corresponds to the Fourier Transform of the two-point correlation function defined by:

$$\xi(r,t) = \frac{V}{(2\pi)^3} \int \langle |\delta_k(\vec{k},t)|^2 \rangle e^{-i\vec{k}\cdot\vec{r}} d^3k \tag{2}$$

where V is the considered volume and $\delta_k(\vec{k},t)$ corresponds to the over-density field. Thus the power spectrum yields:

$$P(k,t) = \langle |\delta_k(\vec{k},t)|^2 \rangle = \frac{1}{V} \int \xi(r,t) e^{i\vec{k}\cdot\vec{r}} d^3r \tag{3}$$

this quantity gives a complete statistical description of a Gaussian Field. The Bispectrum corresponds to the Fourier Transform of the three-point correlation function and, as an higher order correlation function, it is sensitive to departures from Gaussianity. It is usually defined as B, yielding:

$$\langle \delta_{\vec{k}_1} \delta_{\vec{k}_3} \delta_{\vec{k}_3} \rangle = \delta_D(\vec{k}_1 + \vec{k}_2 + \vec{k}_3) B(k_1, k_2, k_3) \tag{4}$$

where δ_D is the Kronecker delta function.

Since Dark Matter density contrast fields are considered to be well approximated by Gaussian Random Fields at the extreme of large scales (linear regime), and as we travel to smaller scales we begin to observe departures from Gaussianity (non-linear regime), this two quantities are quite appropriate to be used as testing metrics in the context of this work.

During the optimization process, each explored range and optimization scheme will provide us a different optimal model, in order to discriminate between the different models we compared their estimated outputs against our test simulation using the following quantity:

$$PSD_{RD} = \sum_{i=1}^{n} \left| 1 - \frac{y^i_{est}}{y^i_{sim}} \right| \tag{5}$$

where $\mathbf{y_{est}}$ and $\mathbf{y_{sim}}$ are the power spectrum vector of our estimated field and the ground truth, respectively, n corresponds to the power spectrum vector size, y^i_{est} and y^i_{sim} are the ith power spectrum vector cell value for both the estimated and simulated vectors.

Consequently, to have an estimation as close to the ground truth as possible, we need this quantity as close to zero as possible, and thus, given a set of different optimal models, the best performing will be the one with a minimal PSD_{RD}.

2.2.4. *FPCA: An Alternative Approach*

In an attempt to increase the efficiency of our pipeline and explore less traditional approaches, we also demonstrated an application of *Functional Principal Component Analysis*, in the single free-parameter emulation context.

This method provides a continuous function relating the Principal Components with our desired free-parameter, thus combining the compression capabilities of PCA with the predictive usefulness of the Machine Learning methods, and consequently, enabling us to perform a "short-cut" in our pipeline by discarding the Supervised Machine Learning step. Here we adopt the R package `fda`[19] in a process divided into three steps, as follows.

In the first step we build a *Functional Data Object* from the training data. To do so we first need to specify the set of basis functions used to compute the FPCA. To follow our application of standard PCA, we defined 23 b-spline basis functions.

After having the basis functions, we use them to convert the training data (in logarithmic scaling) into the final *Functional Data Object* where the harmonics/FPCA's will be evaluated.

Once the harmonics are obtained, we apply them to compute the Principal Components (PCs) for $\Omega_{dm} = 0.309$, following the de-projection into the original density cube by multiplying each PC by each column of the scores matrix returned by the FPCA decomposition.

One important remark is that this method is highly expensive in terms of memory. Thus, we evaluated it in lower-resolution simulations of 64^3 density cells, instead of the 128^3 density cell simulations used in the previously other pipelines.

2.3. *The Gravitational Wave Inference Pipeline*

In this Section, we describe the methodology we adopted for the Gravitational Wave parameter inference. We demonstrate our implementation in Frequency Domain waveforms. To probe the generalization capabilities of our pipeline, all algorithms were trained in waveforms *without noise* but tested for Chirp Mass inferences in a dataset of waveforms *imbued with noise*, with decreasing S/N ratios.

In the following Subsections, we will be describing the process of waveform and noise generation, the GW parameter inference pipeline and finally, the performance evaluation of our pipeline.

2.3.1. *Generation of the Training and Test Datasets*

We generated a training set of 256 waveforms and a test set of 255 waveforms, varying the chirp mass in the ranges $M_{chirp} = [9.13; 25.80]\ M_{\odot}$ and $M_{chirp} = [9.19; 21.79]\ M_{\odot}$, respectively.

One crucial aspect of our work is that we tweak the S/N ratio by varying the distance to the source, consequently we generated 3 different test sets for the mentioned test Chirp Mass range, while only varying the distance parameter (eg. 1 Mpc, 100 Mpc and 1 Gpc).

Apart from the distance and masses, it is also necessary to provide high and low frequency cutoffs, the frequency resolution, and the frequency domain waveform approximator. To follow the LIGO detector parameters, the low and high frequency cutoffs were chosen to be, respectively, 10 Hz and 10kHz. Finally, we set the frequency resolution to $\Delta f = \frac{1}{16}$, and choose the *TaylorF2*[20] approximant to generate the simulated waveforms.

2.3.2. *Noise Generation and Data Pre-Processing*

To colour the waveforms with noise, we need to generate an analytical power spectral distribution (PSD) following the expectations for the Advanced Ligo detector. To do so, we use an analytical Gaussian Noise simulation, as implemented by the function `analytical.aLIGOZeroDetHighPower` from the package `pycbc.psd`. We

set the length of the PSD (l_{PSD}), the frequency resolution ($\Delta f = \frac{1}{16}$) and the low-frequency cutoff ($f_{low} = 10\ Hz$).

The noise is then generated from the defined PSD using the `pycbc.noise` package and its `frequency_noise_from_psd` function. After obtaining the noise vector, we add it to the strain obtained as from the waveform generation.

Finally, we resize the simulated waves by cropping all the strain values for frequencies above 51 Hz, which corresponds to the limiting frequency domain of the shortest wave. Thus, each frequency domain waveform results into 656 data points.

2.3.3. *The Inference Pipeline*

Once we generate all waveforms, they are organized to form a training matrix composed of 256 instances and a test matrix with 255 instances, each corresponding to a matrix row. Similarly to the cosmological density fields case, the next step consists of performing dimensionality reduction. This data projection results into a compact representation, where each waveform is represented by 256 PCs.

In this case we are dealing with smaller matrices than in the N-body case. Thus the PCA projection step is significantly faster. However, as now a higher number of instances is considered (e.g 256 instead of 23), the final projection will result in a higher number of Principal Components.

After producing the compressed data representation, we proceed to the machine learning regressions. Different from the N-body emulation scenario, here we are not attempting to emulate waveforms, but we are instead attempting to infer parameters concerning those waveforms given their strain vectors.

Consequently, instead of using the PCs as dependent variables, now they are used as independent variables, while the chirp masses are the dependent variables for prediction. That implies a large simplification in our pipeline since we are not forced to build a regression model for every single PC.

Also, in this part of the work, we excluded the neural networks. Since in this scenario we have 256 dimensions/independent variables, as opposed to the N-body context where we have a maximum of 2 independent variables (e.g Ω_m and z), here the single-layer neural network is expected to highly under-perform.

After we train and optimize the models using the training set, they are used to infeer the parameters for the not previously seen waveforms. To do so we need to first project the test waveforms in the PC basis of the training set, were the same centering and scaling vectors as learnt from the training set are used, obtaining the PC vector for a specific waveform as:

$$\boldsymbol{PC_{new}} = \boldsymbol{L^T}\left(\frac{\boldsymbol{t_{wf}} - \boldsymbol{c}}{\boldsymbol{s}}\right) \tag{6}$$

where, as in the Density fields case, $\boldsymbol{L^T}$ corresponds to the loadings (or rotation) matrix provided by the PCA, $\boldsymbol{s}$ the PCA scaling vector, $\boldsymbol{c}$ the PCA centering vector and $\boldsymbol{t_{WF}}$ to the test waveform vector for chirp mass inference.

After having our 255 inferred chirp masses we proceed to evaluate the algorithms.

2.3.4. *Testing the Models*

In this case of Chirp Mass inferences, since we are dealing with discrete instances represented by a real number, our choice for evaluation metric was the simple Root Mean Squared Error, given by:

$$RMSE = \sqrt{\sum_{i=1}^{n} \frac{(\hat{y_i} - y_i)^2}{n}} \tag{7}$$

where $\hat{y_i}$ and y_i correspond, respectively, to the ith estimated and ground-truth chirp masses and n is the total number of instances.

Here, we use this metric to discriminate between the different models generated in the optimization process and also as the final evaluation measure, used to discriminate between the different algorithms explored in this approach.

3. Results

In this Section, we present the results of our work. We first show the results concerning the N-body dark density field estimations, and following that, the results regarding the GW parameter inference.

We present our final optimized regressions, and compare the performance of the algorithms against the ground-truth using the evaluation metrics described in the previous section.

3.1. *N-body Density Fields*

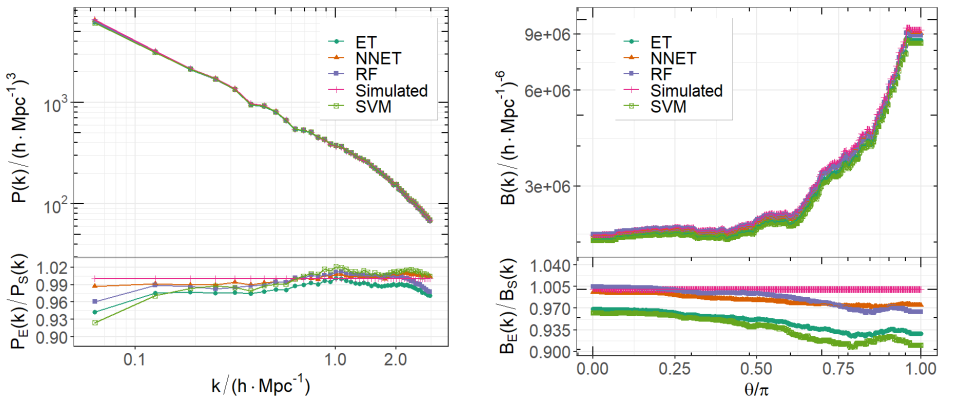
We begin by showing the results concerning our N-body Density Field Emulations.

First we present the results concerning our main pipeline, coupling PCA with the four supervised learning methods in the two emulation scenarios, with one and two free parameters. Lastly, we show the results regarding the FPCA emulations, implemented in the reduced size dataset.

3.1.1. Ω_{dm} *Emulations*

In Figure 1 we show the main results from the four supervised learning emulations. On the top panels, left-hand side we see the Power Spectra of our estimators against the ground-truth while on the right-hand side we see the Bispectra. The lower panels show the ratio between the spectra of the emulations and the ground-truth.

Regarding the Power Spectra, we achieved an accuracy within 99% throughout all of the k domain using the Single-Layered Neural Network, which was the best performing algorithm. This is impressive, because these results show that it is possible to attain very low errors even at extreme scales as $k \geq 2$ hMpc^{-1} and nearing $k \sim 0.3$ hMpc^{-1}, while using one of the most simple types of neural networks, a single-layer network. We note, however, that this is only possible because of the compression step that was adopted here.



(a) (b)

Fig. 1. Results for the single free-parameter emulation scenario implemented at z=0. (a) Power Spectrum Comparison. (b) Bispectrum Comparison.

Looking at the lower panel, it is possible to observe that generally, the algorithms seem to have a sharp decrease in their performance at the large scale extreme ($k \leq 0.2$ hMpc^{-1}), which can be attributed to the lack of independent modes in the training dataset.

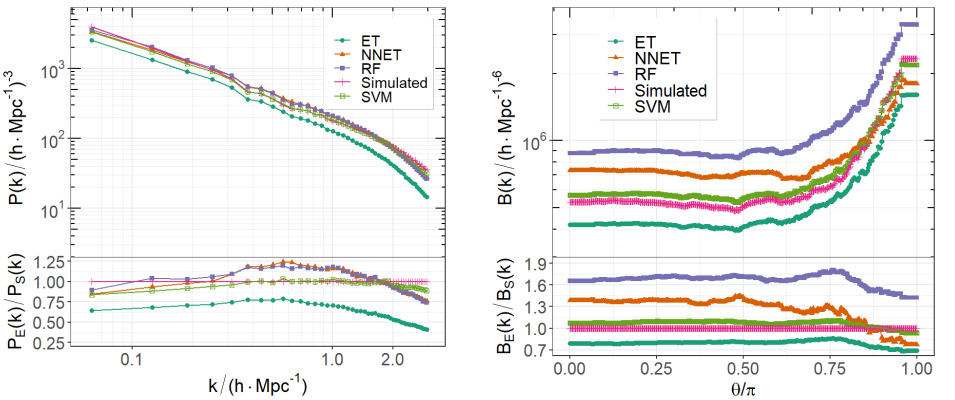
On the opposing small scale extreme, we can also observe a slight decrease in performance, this time due to leakage of the Nyquist modes, as we approach the resolution limit of the simulations.

Regarding the Bispectra, we obtained an accuracy within 97% throughout all of the θ domain using the Neural Networks. Here we see Random Forest excelling at lower θ's ($\frac{\theta}{\pi} \leq 0.75$), but its accuracy eventually falls below 97% at the large θ extreme. The reason why we observe such an overall decrease in performance in the Bispectra case, compared to the Power Spectra can be attributed to the fact that the Bispectrum is non-linear in nature, giving a description of departures from Gaussianity, as opposed to the Power Spectrum. Since the Bispectrum deals with the non-linear aspects of the density fields, we should expect an higher challenge in reproducing it faithfully, since the non-linear features should be harder to compress via a simple PCA method and thus, later to predict via Supervised Learning. Non-linear compression methods would allow these results to be improved significantly.

3.1.2. (Ω_{dm}, z) *Emulations*

Figure 2 shows the results for the two-free parameter emulation scenario.

In the case of the two-free parameter emulation scenario we observe a decrease in the performance of the algorithms from the previous scenario. This can be expected, as now an increased dimensionality is faced. Also, the simple neural network is no



(a) (b)

Fig. 2. Results for the two free-parameter emulation scenario. (a) Power Spectrum Comparison. (b) Bispectrum Comparison.

longer the best performing algorithm, and its adoption results in errors reaching 25% at around $k = 0.6$ hMpc^{-1}.

It is however remarkable how well the SVM method performed in this scenario. Here, the SVM achieves an accuracy of more than 95% for $0.3 \leq k \leq 2$ hMpc^{-1}, decreasing to about 90% at the low scale extreme and $\sim 85\%$ at the large scale one.

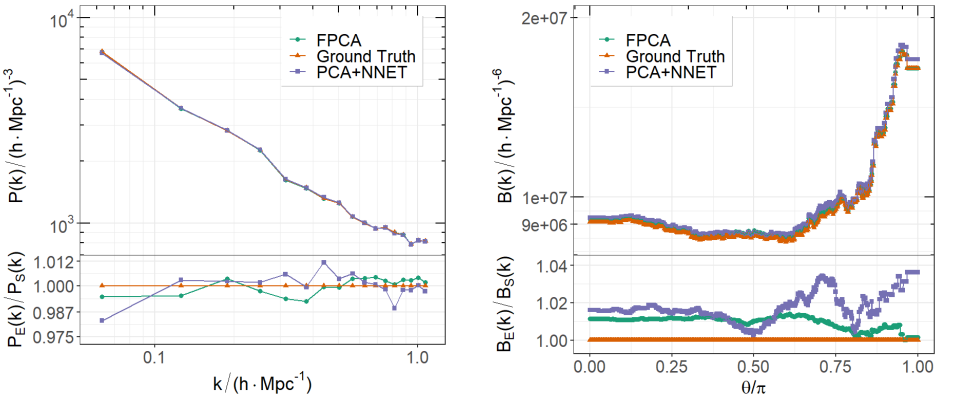
Finally, the observed decrease in overall accuracy between the previous scenario to the present, multidimensional one, can be explained due to the so-called *Curse of Dimensionality*. To reach similar performances compared to lower-dimensional cases, a required increase in the size of the training set can be exponential, when the number of dimensions in the feature space increases.

Regarding the Bispectrum, the results further indicate that SVMs are the best method among those studied in this work, since as we can see, even looking at higher order correlations it still out-performs the remaining algorithms. It is the only algorithm able to maintain an accuracy below 15% for the entire θ domain.

Finally, one additional interesting feature we see in this result, is the fact that the relation between the error and the θ domain seems to be inverted. While in previous, one dimensional case, the errors tend to increase for larger angles (corresponding to larger scales), here they tend to decrease. This could possibly be due to the increased size of our training dataset. By increasing the amount of full simulations in our training data we are effectively increasing the number of large scale modes, and consequently, improving the predictions of the algorithms at such scales.

3.1.3. *FPCA Results*

Finally, we close the N-body section by showing the results regarding our FPCA demonstration. The Power Spectra and Bispectra are shown in Figure 3,



(a) (b)

Fig. 3. FPCA emulation results at z=0. (a) Power Spectrum Results. (b) Bispectrum Results.

compared against an optimized Single-Layered Neural Network and the ground-truth simulation.

We can observe from Figure 3 that even when compared against the best performing algorithm of our previous results, FPCA seems to attain an slightly better performance, particularly at the large scale regime, indicating a strong capacity of the algorithm for generalization.

Additionally, FPCA seems to be more stable than the neural network, in the sense that we do not observe the frequent oscillations in the power ratio that we can observe in the neural network case. This could be due to the smoothing process of the b-spline basis functions that takes place within the FPCA.

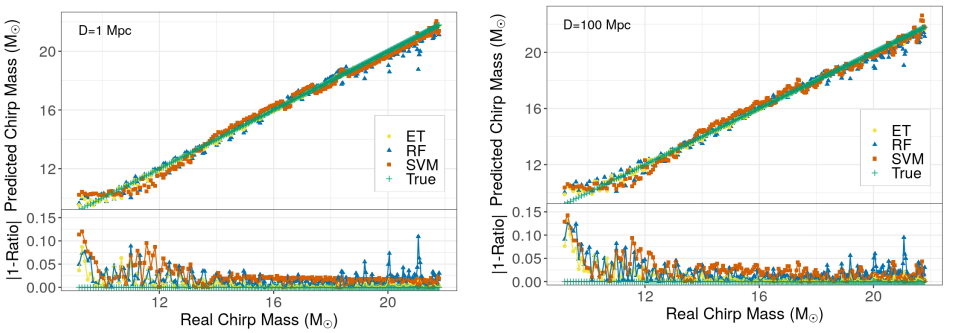
Finally, one interesting thing to notice when looking at the error in terms of overestimation and underestimation of the power is the fact that the neural network and the FPCA seem to roughly exchange roles. When one underestimates, the other overestimates. This suggest that it would be possible to further improve the results by merging these two methods into an ensemble or a stacked generalization.[21] Since, roughly, their average results seem to overlap with the simulated Power Spectrum.

3.2. *Gravitational Waves*

Here we present the results from our Gravitational Wave inference pipeline. We show results concerning 255 Chirp Mass inferences from waveforms emitted at increasing distances and consequently, decreasing signal-to-noise ratios.

3.2.1. *Frequency Domain Inferences*

In Figure 4 we can see the results regarding inferences from waveforms emitted at 1 Mpc (left hand-side) and 100 Mpc (right hand-side). The top panels show our



(a) (b)

Fig. 4. Comparison between the estimated chirp masses and the ground truth in Frequency Domain. (a) For waveforms emitted at 1 Mpc (b) For waveforms emitted at 100 Mpc.

predictions against the ground-truth while the lower panels show a measure of the ratios.

These results show that up to 100 Mpc and for $M_{chirp} \geq 14$ we are able to obtain an accuracy within 98% using our best performing model which in this context was the Extremely Randomized Trees.

The Support Vector Machine also manages to obtain stable results throughout the mentioned domain, with an accuracy within 97%. On the other side, Random Forest was the worst performing algorithm, with its accuracy falling below 95%, even in this expected well behaved region of the Chirp Mass domain.

The large increase in error observed at the lower Chirp Mass extreme ($M_{chirp} < 14$) is a consequence of the fact that lower chirp masses result in lower amplitude Strains, which get highly diluted in the noise.

Turning our attention now to inferences in very low signal to noise ratio regimes, Figure 5 represent the results for inferences from waveforms emitted at much higher distances, at 1 Gpc.

Here we see a decrease in the quality of the results, with the previous best performing algorithm (Extremely Randomized Trees) having its accuracy falling to values close to 85% in the interval $14 \leq M_{chirp} \geq 16$ and to 90% for $16 \leq M_chirp \geq 20$.

We can also observe a shift in the "well behaved" domain, now $M_{chirp} > 16$, which is a natural consequence of increasing the distance to the progenitors of the waveforms, translating in a generalized decrease in the signal to noise ratio.

On the other side, the Support Vector Machine manages to excel compared to the other algorithms, achieving an accuracy $\sim 95\%$ for $M_{chirp} > 16$. The results from these simulated experiments reinforce the strong generalization capabilities of SVMs, and are particularly impressive considering that the algorithms were trained in a dataset of waveforms without noise while they are being tested on noisy ones. In part this is due to the data compression step, since by its very nature, it is also working as a denoising procedure.

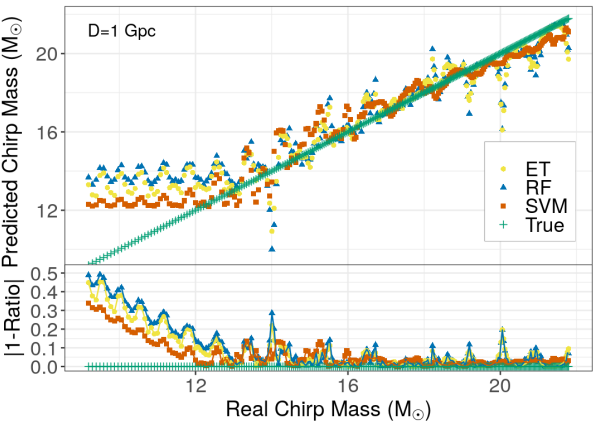


Fig. 5. Comparison between the estimated chirp masses and the ground truth in Frequency Domain for waveforms emitted at 1 Gpc.

4. Discussion

We showed that combining PCA with simple supervised learning methods allows fast and accurate estimation (regression) of cosmological density fields. We also demonstrated that the same method can be used, in the inverse way, to perform parameter inference, applied to the problem of GW source parameter determination.

Indeed, the fast increase in the demand for larger and more diverse sets of cosmological simulations, to study large-scale structure mechanisms and their dependence on Cosmology, demands fast and accurate methods to produce multiple realizations of density volumes. Our results show that our approach achieves this objective. On the other hand, our results demonstrate that our proposed method also provides a fast way of performing GW parameter inference without requiring additional prior assumptions on top of those that were already adopted to build the set of approximated waveforms.

Here we discuss the main results of our work. We comment on the relevance of our method for further developments in these fields, addressing its gains of performance and potential to explore other situations of interest. We also address the method's present constraints and discuss ways to mitigate them, proposing solutions for future implementation.

4.1. *Efficiency*

Here we focus on the efficiency of our method. In other words, we will discuss the amount of CPU time and computational resources required to produce a final result. We begin by showing the CPU run times for the N-body emulations, in both scenarios of single and two free-parameter emulation, and following that we show

the CPU run times for the GW inference pipelines in both low and high signal to noise ratio regimes.

4.1.1. *Cosmological Density Fields*

In Table 1, we show the total time in order to perform the emulations. The first row regards the single free-parameter emulation scenario, where our best performing algorithm was the Neural Network (NNET), while the second row regards the two free-parameter emulation scenario, where the best performing algorithm was the Support Vector Machine (SVM).

Table 1. CPU run times for the N-body Emulation Case.

Emulation	**PC Estimation**	**De-Projection**	**Total Emulation Time**
$\boldsymbol{\Omega_{dm}}$	0.077 s	0.719 s	**0.796 s**
$\boldsymbol{(\Omega_{dm}, z)}$	0.082 s	4.380 s	**4.462 s**

We managed to achieve an high accuracy for the density field estimation, in a total of ~ 0.796 s for the one-dimensional case and ~ 4.462 s for the two-dimensional case. As a comparison, it takes ~ 84 min to perform an N-body simulation of the same scale. Our results, thus, correspond to an improvement of three orders of magnitude in the time required to generate the density field. Moreover, the computational resources required to implement our pipeline are far smaller than those required to perform the N-body simulations. Additionally, these emulations reproduced the real Power Spectra to less than a 1% (NNET in Figure 1 at $0.4 \leq k \leq 3$ and SVM in Figure 2 at $0.4 \leq k \leq 2$).

Finally, with respect to our work on Gravitational Wave inferences, we present the CPU running times of our pipeline in Table 2. The first row regards the high signal-to-noise ratio regime, where the best performing algorithm was the Extremely Randomized Trees (ET), while the second row regards the low signal-to-noise ratio regime, where the best performing algorithm was the Support Vector Machine (SVM).

Table 2. CPU run times for the GW Inference Case.

GW Inference (FD)	**Projections into the PC Basis**	**Inferences**	**Total Time**
D=1 Mpc	0.142 s	0.041 s	**0.182 s**
D=1 Gpc	0.252 s	0.004 s	**0.256 s**

Once again, we achieve a highly significant efficiency in inferring the Chirp Mass of the waveforms, obtain inference times down to 0.183 s for high signal-to-noise

ratio regime. These results are particularly appealing, considering this is the time required to perform 255 simultaneous waveform projections and M_{chirp} inferences.

5. Conclusions

In this work, we presented a simple and computationally light methodology to enable fast sampling and inference of datasets in two gravity dominated contexts, Structure Formation and Gravitational Waves. To achieve that we implemented supervised Machine Learning methods coupled with Principal Component Analysis, on training datasets of full 3D N-body simulations and approximated Gravitational Waveforms.

In the context of structure formation, we provided contributions to the field using our methodology for fast and accurate emulations of full N-body dark matter density fields of 128^3 density cells in a box of 100 h^{-1} Mpc, given a choice of cosmological parameters. We applied four supervised Machine Learning Algorithms, Random Forest, Extremely Randomized Trees, Support Vector Machine and Neural Networks, in two different emulation scenarios. In the first scenario, we performed emulations solely based on the Dark Matter Density (Ω_{dm}) parameter. We managed to reproduce the Power Spectrum of the corresponding simulated field to a less than a 1% difference for $k > 0.3$ hMpc^{-1} in all redshifts, and reproducing the Bispectrum for all θ domain to less than a 3% difference for $z = 0$ and less than a 2% difference for the remaining redshifts, using the best-performing algorithm (Neural Networks). We additionally studied Functional Principal Component Analysis in the context of structure formation. We achieved even better results than the supervised methods for a reduced size dataset of simulations with 64^3 density cells, managing to reproduce the Power Spectrum and Bispectrum to less than a 2% and 5% difference from the ground truth, at all redshifts. In this scenario we trained our algorithms with 23 N-body simulations in the range $\Omega_{dm} = [0.05; 0.6]$ with $\Delta\Omega_{dm} = 0.025$, and tested the emulations for $\Omega_{dm} = 0.309$.

In the second scenario, we introduced an additional dimension, adding the redshift as free-parameter. Using the best-performing algorithm in this scenario (Support Vector Machine), we managed to reproduce the Power Spectrum to less than a 5% difference for $0.3 \leq k \leq 2$ hMpc^{-1} and the Bispectrum to less than a 15% difference in all θ domain. Here we trained the algorithms with simulations in the same Ω_{dm} range as in the first scenario, but in four distinct redshift snapshots ($z = 0$, $z = 0.25$, $z = 1$, $z = 10$), increasing the training dataset by a factor of four. We tested the emulations against an $\Omega_{dm} = 0.309$ simulation at redshift $z = 0.5$, although the emulator can be used for any value of Ω_{dm} and z.

We thus demonstrate that percent level accuracies can be reached using these emulators, and that moreover emulations can be performed in 0.796 s in the first scenario and in 4.462 s for the second scenario. This corresponds to an improvement of three orders of magnitude when compared to the time required to perform an N-body simulation of the same scale.

In the context of Gravitational Waves, we inverted the pipeline to perform inference of the Chirp Masses for a set of Frequency Domain simulated waveforms. We managed to achieve a high generalization capacity in our models by training them with 256 denoised waveforms, and testing on 255 waveforms imbued in theoretical LIGO detector noise, for three different datasets at decreasing signal-to-noise ratios. In this case we achieved differences in the inferences of around 2% for the higher signal-to-noise contexts and for $M_{chirp} > 14\ M_{\odot}$, while around 5% for lower signal-to-noise ratio contexts and for $M_{chirp} > 16\ M_{\odot}$. For both high and low signal-to-noise ratios, the parallel inference of 255 independent waveforms is performed in less than 0.3 seconds. The main success in these Gravitational Wave parameter inference results, however, reside in the generalization capabilities of our proposed methodology, since while it was trained on noise-free training sets, it was tested on highly noisy test sets.

Galaxy Clusters are essential to study galaxy evolution and are sensitive probes of cosmology and the dynamics of the Dark sector. Large galaxy surveys, such as Euclid, DES, LSST/Rubin will detect many new clusters. For example, the Euclid mission survey may reveal more than 6×10^4 clusters with S/N>3 up to $z \sim 2$, representing a whole new era for cluster cosmology. A large fraction of these clusters will be unknown high-redshift cluster candidates, lacking spectroscopic information. Thus, a major challenge for cluster detection is the identification of possible member galaxies from photometry alone, and ideally without strong assumptions of what a cluster is. Here we present the first results for the detection of galaxy clusters of a modified version of the UPMASK (Unsupervised Photometric Membership Assignment) method. The method, created to study star clusters, uses heuristics and statistical analysis to separate cluster candidate galaxies from other field galaxies without assuming cluster profiles or any strong theoretical cluster priors. We show that the method operates in a fully unsupervised way and it can even work with minimal amounts of astrometry and photometry information, using Euclid-like galaxy survey simulations. We then use Pan-STARRS data to assess the performance of the method to identify Planck clusters and present possible detections of optical counterparts for cluster candidates in the second PlanckSZ data release catalog. Finally, we compare our findings with other Planck cluster candidate follow-up efforts.

Keywords: Methods: data analysis, methods: statistical, galaxies: clusters: general.

1. Introduction

The distribution of galaxies in the Universe is not uniform. They permeate an immense cosmic web that has evolved from an initial density field, continuously sculpted by gravity and cosmological expansion, where galaxy groups and clusters emerge at the interceptions of filamentary structures. The study of these objects, their abundance, and spatial correlations provides unique ways to test cosmological

models, including those featuring dark matter, dark energy, or modified gravity theories (see e.g. Refs. 1, 2). Regarding clusters, their use as cosmological probes in galaxy surveys critically depends on the definition of "cluster" and the separation of their member galaxies from other galaxies in the field. Spectroscopic information can significantly improve cluster identification, but present and near-future surveys lack spectroscopic information for a large fraction of detected objects. Additionally, most cluster identification methods adopt strong *a priori* models and explicitly search for the existence of a Red Sequence (see e.g. Ref. 3). Moreover, some of these *a priori* assumptions provide only the expected behavior of idealized systems, which are sometimes poor approximations to a more complex reality.

2. The method

UPMASK[4] is a method designed to study stellar clusters, that was successfully applied to discover multiple new objects of this type.[5,6] This method was created considering only the availability of minimal data, like photometry and astrometry. However it is also possible to use any other input feature that can help to discriminate objects. The method uses processes like the Principal Component Analysis[7] (PCA), clustering algorithms, Kernel Density Estimation[8,9] (KDE), data resampling, and an iterative process. In this proceeding we report our testings of UPMASK for a membership study in galaxy clusters. We also report on tests done with modified versions of the method (see Sec. 3), aiming at improving the processing speed of the original version, and looking towards the development of a future galaxy cluster search application for large datasets.

The method will firstly re-sample the measured data according to their error distributions and then apply PCA to the photometric parameters. It will cluster the data with k-means[10] in the space defined by the Principal Components. Each mathematical cluster is analyzed in the astrometric space with a KDE and then compared with the KDEs of a uniform random distribution. The method eliminates the KDEs compatible with those of a uniform distribution KDE and iterates. This way, UPMASK can discern clustered objects from field objects, by purifying the cluster data at each iteration. Finally, running this routine multiple times, UPMASK accounts for observational errors/uncertainties, and provides a score (equivalent to a frequentist membership probability) for each object in the dataset.

3. Modifying UPMASK

This method, in particular the KDE step, is computationally time-consuming. Thus, its application to large areas of the sky requires significant computational resources. We studied alternatives to replace the KDE step of the method. We have used tools such as the Voronoi tesselation, Anderson-Darling test and regression functions, as described next.

3.1. *Voronoi selection procedure with Anderson-Darling Test*

Here we apply a Voronoi[11] diagram to the K-means clusters in the astrometry space and then compare the polygon areas distributions of these objects with those obtained from a random uniform distribution. For an illustration of the method, we show in Fig. 1 the Voronoi Tesselations and the distribution of sky areas of the polygons of a random normal distribution and a random uniform distribution. Note that the first is naturally clustered at the center, whereas the latter shows a typical uniform distribution of points. The type of point distribution, therefore, affects the distribution of the areas of the Voronoi polygons. We have adopted a two-sample Anderson-Darling test[12] to perform the comparison between the resulting distributions of polygon areas. We use this test twice: testing the area distribution of the k-mean mathematical cluster against the area distribution of a random uniform realization, and testing the area distribution of random uniform realizations against each other – the later test has performed a maximum of 100 times to account for statistical fluctuations. Each test gives us a p-value that is used to discern between the two cases. A K-means group is classified as a clustered group if

$$p_{kmeans-uniform} \leq \langle p_{uniform-uniform} \rangle - T \times \sigma_{uniform-uniform} \tag{1}$$

where $p_{kmeans-uniform}$ is the p-value of the Anderson-Darling test between the distribution of Voronoi areas of the k-means cluster and the distribution of areas of a random uniform realization, $p_{uniform-uniform}$ is the mean p-value of the Anderson-Darling test of two distributions of areas between 2 random uniform realizations, $\sigma_{uniform-uniform}$ is the standard deviation of p-values from the latter case and T is a threshold level. We have set $T = 3$ as default, but one can modify this parameter as desired. We improve the computational processing speed of this step by including a lookup table for quantities that can be pre-computed before running the method.

3.2. *Voronoi selection procedure with simple statistic comparison*

We have studied another modification, also using Voronoi diagrams. This alternative has a simple statistical comparison between tesselation area distributions instead of the Anderson-Darling Test. As in the previous section, Voronoi tessellation is performed on the K-means clustering points to compute the mean of the distribution of tessellation areas. The same thing is done for a set of random uniform realizations in identical conditions (same total area and number of points) and an average and standard deviation of polygon areas are also obtained. The K-means mathematical group is then assigned as an identified cluster if:

$$\langle N_{kmeans} \rangle > \langle N_{uniform} \rangle + T \times \sigma_{uniform} \tag{2}$$

in which $\langle N_{kmeans} \rangle$ is the mean of the density of the polygons from the Voronoi Tesselation applied to the K-means group, $\langle N_{uniform} \rangle$ is the mean of all the uniform realizations average density of the polygons from the Voronoi Tesselation, $\sigma_{uniform}$

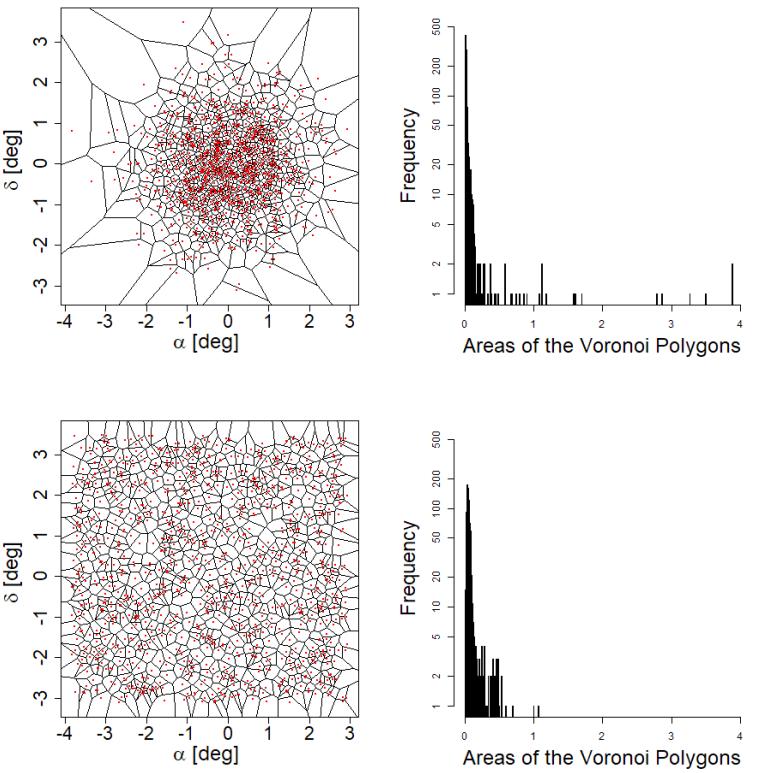

Fig. 1. Top: Left - Voronoi Tesselation (black lines) of a random normal distribution (red points). Right - Histogram of the distribution of polygon areas that resulted from the Voronoi Tesselation on the left. Bottom: Left - Voronoi Tesselation (black lines) of a random uniform distribution (red points). Right - Histogram of the distribution of polygon areas that resulted from the Voronoi Tesselation on the left.

is the standard deviation of all the uniform realizations average density of the polygons from the Voronoi Tesselation and T is a threshold level that can be adjusted by the user. As in the previous subsection, $T = 3$ is chosen to be the default case.

3.3. *Grid selection procedure*

Another approach to replace the KDE part in UPMASK is to create a new version of the method, implementing a "contingency table" as a very simplistic and discrete approximation of the KDE. This approach works as follows. Silverman's rule of thumb[13] is used to provide the width of grid divisions to distribute the K-means cluster points in the astrometry space. Then, a squared grid is generated and the number of points that fall inside each grid cell is counted. The counts are interpreted as a non-normalized frequency. Next, the method computes the distance between the maximum and the mean frequency, normalized to the standard deviation of the count distribution. This is then compared with the average of the same quantity

for multiple random uniform realizations, using the same expression in the original UPMASK version (second equation in section 2 of Ref 4).

3.4. *Grid selection procedure with fast thresholding*

The computation of statistics for the random uniform distributions only depends on the number of points of the realizations and therefore does not depend directly on the input data. As such, and to reduce iteration times, we have applied regression methods to pre-compute a function that provides the threshold according to the number of K-means clustering points. This is obtained by performing 1000 random uniform realizations and computing threshold levels as a function of size as in subsection 3.3. The number, n, of considered points is in the range 1 – 1000 and are more concentrated between 1 – 100, motivated on one hand by the traditional galaxy cluster definition in which a cluster is expected to have more than 50 members and on the other hand by the fact that the data will be divided by the k-means into subsamples. The longer interval accounts for possible group samples that fall inside the 1–100 range. The generated threshold values are represented in Figure 2 and can be fitted by the following, two-branch, polynomial regression function:

$$f(x) = \begin{cases} a_0 + a_1 x + a_2 x^2 & n < 90 \\ b_0 + b_1 x + b_2 x^2 + b_3 x^3 + b_4 x^4 + b_5 x^5 + b_6 x^6 + b_7 x^7 & n \geq 90 \end{cases} \tag{3}$$

The function coefficient values are presented in Table 1. It is worth adding that the creation of this function and its points were generated outside the UPMASK method. As such, the kernel will simply use this function and it does not need to compute the values needed, improving the computational time.

Table 1. Fitting function coefficients of Eq. (3) for the Grid method.

a_0	1.149227	a_1	0.200402	a_2	-0.001189		
b_0	1.351×10	b_1	-7.293×10^{-2}	b_2	4.462×10^{-4}	b_3	-1.443×10^{-6}
b_4	2.529×10^{-9}	b_5	-2.422×10^{-12}	b_6	1.187×10^{-15}	b_7	-2.315×10^{-19}

3.5. *KDE selection procedure with a fitting function*

Following the same procedure and reasoning as in subsection 3.4, we have replaced the KDE random uniform part with a regression function created based on the KDE random uniform realization threshold output for the same range of n used in subsection 3.4. The generated threshold values are represented in Fig. 2, and can be fitted by the following regression function:

$$f(x) = \begin{cases} c_0 + c_1 x + c_2 x^2 + c_3 x^3 & n < 40 \\ d_0 + d_1 x + d_2 x^2 + d_3 x^3 & n \geq 40 \end{cases} \tag{4}$$

where the polynomial coefficients are listed in Table 2.

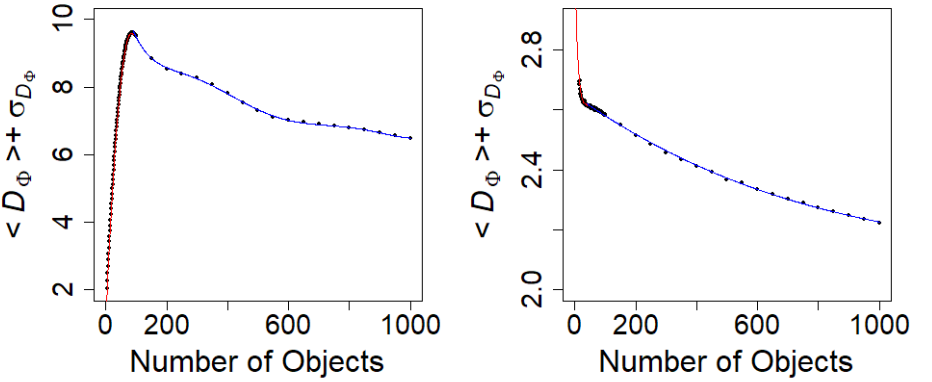

Fig. 2. Fitting function for the Grid (left) and KDE (right) method. In both cases, the red line corresponds to the first branch of the function and the blue line corresponds to the second branch.

Table 2. Fitting function coefficients of Eq. (4) for the KDE method.

c_0	3.0532634	c_1	-0.0381186	c_2	0.0011377	c_3	-0.0000115
d_0	2.648	d_1	-7.205×10^{-4}	d_2	3.781×10^{-7}	d_3	-7.897×10^{-11}

To validate UPMASK and all the proposed modifications of the method, we adopted state-of-the-art galaxy mock catalogues from N-body simulations. The simulated catalogue contains photometric information and is described in the following section. The study performed is presented in Sec. 5.

4. Data

In this section we describe the data that was used in this project. First, we applied UPMASK and its modifications (Refs Sec. 2 and Sec. 3) to simulated data, to validate and inspect their performance. Afterwards, we applied the method to real data, looking to re-identify the PLANCKSZ2 clusters from Pan-STARRS data.

4.1. *Simulated data*

We used simulated galaxy survey catalogues that contain estimated photometry for DES[14] and Euclid[15] bands to test the application of UPMASK and its modifications in the context of galaxy clusters. We used the MICE catalogue version 2,[16–20] obtained from the CosmoHub portal.[21,22] This data was obtained by selecting the most massive cluster that was present inside a one square degree area ($30.5° \leq \delta \leq 31.5°$, $0.5° \leq \alpha \leq 1.5°$) and its surrounding objects. The resulting

subset contained a total of 8774 galaxies, 171 belonging to the most massive cluster that lies at $z = 1.09$. We selected the following catalogue entries: the DES[14] filters g, r, i, z, y, the Euclid[15] filters RIZ, Y, J and H, astrometry (α, δ), redshift, halo identifier and mass, and the galaxy identifier. In Sec. 5 we present the performance of UPMASK and its aforementioned modified versions using only this subset of galaxies and entries from the MICE catalogue.

4.2. *Planck 2nd Sunyaev-Zel'dovich source catalogue*

Many clusters that were detected via the Sunyaev-Zel'dovich (SZ) effect are still lacking optical counterparts as of the present time. After testing UPMASK and modifications with simulations, we search for the optical counterparts of Planck detected clusters. PLANCKSZ2 - Planck 2nd Sunyaev-Zel'dovich Source Catalogue[23] contains detections of galaxy clusters candidates, obtained during 29 months of observations. 1653 of the total objects in this catalogue, 1203 ($\approx 73\%$) are confirmed clusters. Here we use PLANCKSZ2 sources that were detected by the three detection methods in Ref. 23. We used the object identifier, the astrometric information, position errors and the integrated SZ intensity distortion, Y_{5R500}, from this catalogue. With this data we searched for galaxy clusters with UPMASK, in the PanSTARRS[24] catalogue as described below.

4.3. *Pan-STARRS*

As mentioned in the previous subsection, we decided to use the recent observations from the Pan-STARRS Panoramic Survey Telescope and Rapid Response System) survey[24] as the input to re-detect the PLANCKSZ2 galaxy cluster candidates. We used the second data release of the Pan-STARRS catalogue[25] published in 2019. Our method is as follows. Around each PLANCKSZ2 object, we extracted the following astrometric (α, δ) and photometric information: the mean PSF (Point Spread Function) magnitude of each filter (g - $486.6\,nm$, r - $621.5\,nm$, i - $754.5\,nm$, z - $867.9\,nm$ and y - $963.3\,nm$) and its standard deviation, and the mean Kron magnitude[26] of each filter and its standard deviation. We tailored the area queried for each PLANCKSZ2 catalogue entry using the sky coordinates and the position uncertainty – the latter used to determine the radius of the Pan-STARRS query. Thus we obtain multiple subsets, each containing the field that corresponds to the PLANCKSZ2 cluster coordinates. This catalogue contains mostly stars and galaxies, however, no flag is provided to discern between the two. To perform a simple separation, we adopted the difference between the PSF magnitude and the Kron magnitude of a filter (e.g. see Ref 27). To obtain a final galaxy catalogue we selected the objects that have a PSF-Kron magnitude > 0.05 in all of the selected filters. Finally, we applied UPMASK. We describe our findings in Sec. 6.

5. Validation of the method

This section is dedicated to a viability study of applying UPMASK to detect optical counterparts of galaxy clusters in photometric galaxy surveys. The validation process was carried out using state-of-the-art N-body simulations containing photometric and galaxy-dark-matter halo membership information that allows determining which galaxies are part of true cluster halos or are field galaxies. These simulations are described in Sec. 4. Below we present a detailed description of the tests and method yields for all versions of UPMASK under investigation, followed by a discussion of how the different modifications work and compare when varying method parameters.

5.1. *UPMASK and its modifications*

We applied the original UPMASK method as well as its modifications to the subset of simulated galaxies described in the previous section, using Euclid filters RIZ, Y, J, and H and also their respective colors, as well as the astrometry information. To compare performances between different method versions, we choose to set the number of runs equal to 10, *nruns*= 10, in all versions. This choice is a good compromise between having relatively short CPU running times and a fair membership frequentist probability, with a 10% resolution for all method versions. To perform a quantitative comparison, we compute the completeness and purity metrics as:

$$\text{Purity} = \frac{N_{UPMASK,cluster}}{N_{UPMASK,detec}}, \tag{5}$$

$$\text{Completeness} = \frac{N_{UPMASK,cluster}}{N_{cluster}}, \tag{6}$$

where $N_{UPMASK,cluster}$ is the number of known objects belonging to the cluster above a certain UPMASK probability threshold; $N_{cluster}$ is the number of known objects belonging to the simulated cluster and $N_{UPMASK,detec}$ is the number of objects above a certain UPMASK probability threshold. The results of this test are represented in Fig. 3, and their resulting CPU running times are shown in Table 3.

Table 3. CPU running times for the different UPMASK versions. The last column shows the relative CPU running time percentage of each version with respect to the original UPMASK method.

UPMASK Version	CPU running time (s)	%
KDE	274	100
KDE + Fitting Function	262	96
Voronoi + Anderson-Darling Test	190	69
Voronoi + Mean Comparison	148	54
Grid	303	110
Grid + Fitting Function	289	105

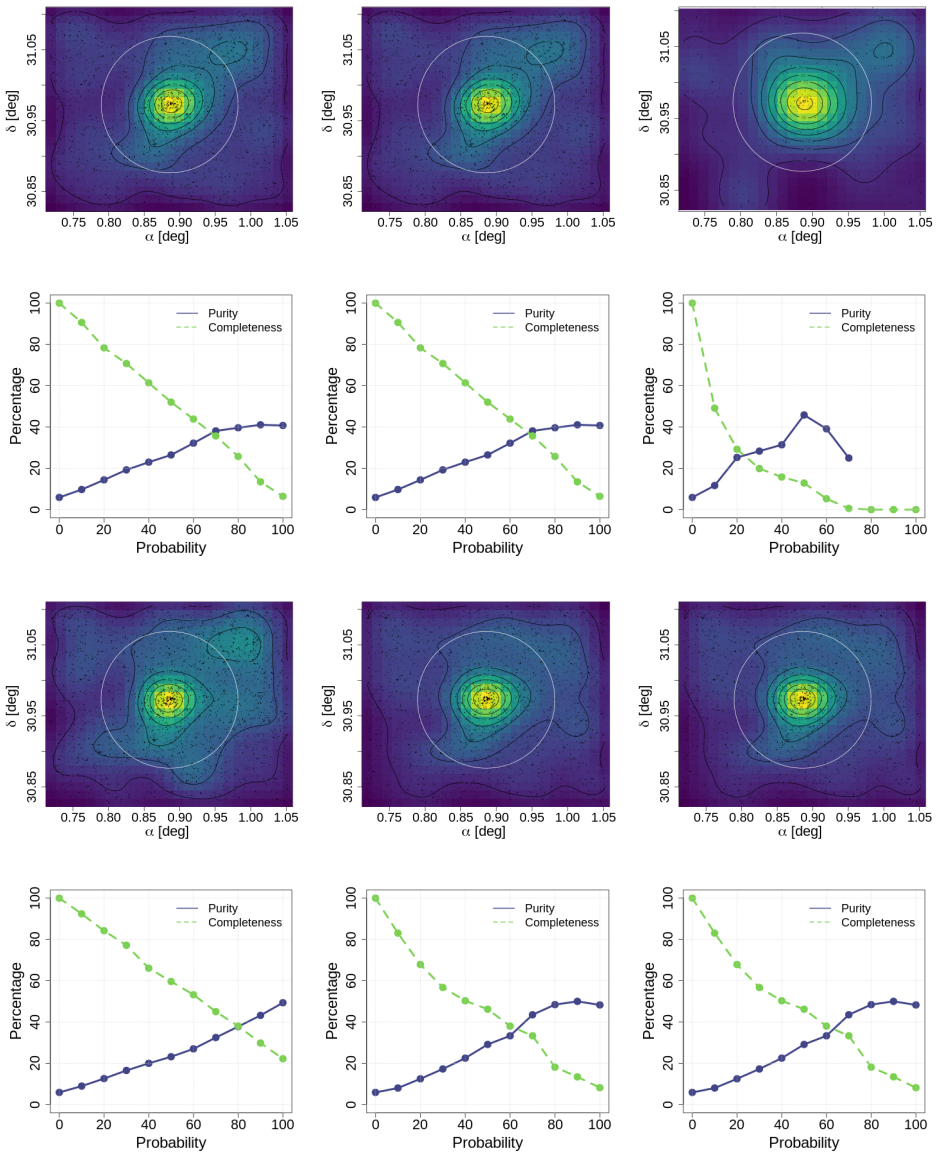

Fig. 3. The detection results for the original and all modified UPMASK versions. The results are displayed in groups of two rows, with each column corresponding to a version. The first and third rows show the density maps of UPMASK detected galaxies for the following versions: KDE, KDE + Fitting Function, Voronoi + Anderson-Darling Test, Voronoi + Mean Comparison, Grid, and Grid + Fitting Function. The color scale was set the same for all the field panels, with a color scheme where lower (higher) densities are in blue (yellow). The white circles indicate the cluster dark-matter halo radius. The second and fourth rows show the Completeness (green dashed) and Purity (blue solid) functions obtained from the unsupervised UPMASK classification, corresponding to the field above each case.

As expected when analyzing Fig. 3 and Table 3, the fitting function versions give the same results and improved in processing time, when comparing to their base UPMASK version. Voronoi+Anderson-Darling implementation is the one that improved the CPU time the most ($\sim 30\%$). However, the application of this version results in a less concentrated field (when comparing with KDE), as well as a more incomplete sample. This is due to the fact that the Anderson-Darling test is a stricter test since it compares the whole distribution of two samples, while the other implementations depend only on simple statistical calculations as the mean and standard deviation. When the Anderson-Darling test is replaced by a comparison of the mean of the Voronoi distributions. we were able to improve the completeness. On the other hand, the Grid implementation looks overall similar to the KDE version, although it results in a slightly purer sample when comparing to the latter. It is however unclear why the grid versions take more time to run than a KDE implementation, as the latter needs to perform more CPU-heavy tasks. We hypothesize that this difference is purely due to the implementation of the prototype code adopted here.

In the following subsections, we study the impact of the UPMASK parameters – number of Principal Components, number of objects per K-means cluster and threshold level T – have on the results, namely in the purity and completeness.

Table 4. Principal Components of the photometric information using simulated data (Sec. 4) and the Standard Deviation for each PC

Principal Component	Standard Deviation
PC_1	2.604481
PC_2	1.792770
PC_3	9.108574×10^{-1}
PC_4	3.631163×10^{-1}
PC_5	2.028331×10^{-1}
PC_6	4.036392×10^{-15}
PC_7	2.559386×10^{-15}
PC_8	2.356076×10^{-15}
PC_9	1.541463×10^{-15}
PC_{10}	1.157850×10^{-15}
PC_{11}	7.081957×10^{-16}

5.2. *Dependency in the number of principal components*

Here we show how the number of principal components affects the purity and completeness of the sample, as well as the UPMASK method run times. Principal components are ordered according to the variance of the original data projected on the PCA basis. Thus, by selecting the first few n principal components, one can grasp the most important information about the data. UPMASK calculates each PC from the provided photometry and colors. The standard deviation of each PC is shown in Table 4. This shows that the first five principal components are those that

contribute the most to the data representation and all the others can be neglected. We have studied the case of using 2, 3, 4, or 5 PCs. For each of these scenarios, we show purity and completeness curves represented in Fig. 4, and the CPU run times in Table 5.

Table 5. CPU run time as a function of the number of Principal Components used in UPMASK.

Nº of Principal Components	2	3	4	5
Time (s)	1073	1193	1224	1249

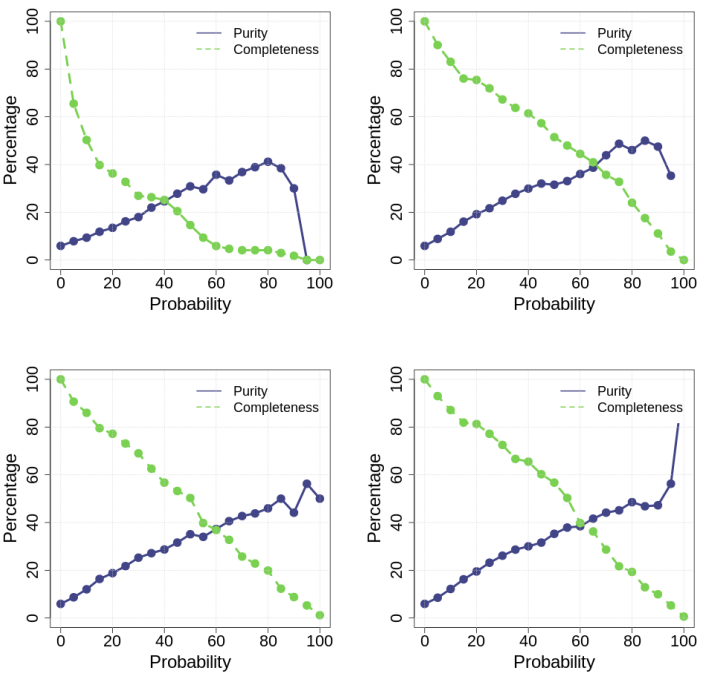

Fig. 4. Completeness (green dashed) and Purity (blue solid) of the unsupervised UPMASK classification (applied to the simulated data of Sec. 4) for different number of PCs being used in the method: 2 PCs (top left), 3 PCs (top right), 4 PCs (bottom left) and 5 PCs (bottom right).

Taking into account the completeness and purity in Fig. 4 as well as the computational time in Table 5, we have chosen to use the first 4 principal components for all of the applications below. The usage of 5 principal components includes more information, however, it is not significant when comparing with the study with 4 principal components. As such, it does not justify the additional run time.

5.3. *Dependency on the number of k-means objects "N"*

The next step is to test how the number of k-means objects "N" affect the results of the method, in all versions. We have performed this study for 20, 35, 50, 65, 80, 95, 110, 125, 140, 165, and 180 objects per K-means cluster. In Fig. 5 we show only some of the results, due to economy of space. For a complete grasp, we refer the reader to the appendix A of Ref 28.

Changing "N" impacts completeness and purity. Figure 5 shows that the completeness is increasing with the number of objects being clustered by k-means. On the other hand, the purity has the contrary behavior and decreases. This is because including more objects, these are not ignored by the method and the completeness will naturally increase. However, we are also contaminating more and as such, the purity is seen to be decreasing as expected.

5.4. *Dependency on the threshold level "T"*

Next, we study the impact of changing the threshold level T in UPMASK. This is a parameter that controls the detection limit comparison between the data and the uniform realization distributions. T can be adjusted in all method versions, except for those with thresholds provided by the fitting function procedures described earlier. We applied UPMASK and its modifications, testing different values for T, $T = \{0.5, 1, 1.5, 2, 2.5, 3\}$. The completeness and purity curves are shown in Fig. 6 for $T = \{0.5, 1.5, 3\}$. For complete results, we refer the reader to the Appendix A of Ref 28. From Fig. 6, we see a general behavior – a higher T leads to higher purity, but lower completeness. When increasing this value, the k-means cluster needs to achieve a higher threshold to be classified as a cluster. Thus, more groups will happen to be classified as following a uniform distribution and the completeness will decrease. On the other hand, k-means clusters that are without a doubt clustered, will be classified as such and kept in the UPMASK kernel.

Finally, the original implementation of the method seems to be a promising alternative for membership determination in galaxy clusters and cluster finding, as well as the newly implemented versions although there is room for accelerating UPMASK methodology, specially when making stronger assumptions about the cluster member distributions.[29]

6. Optical identification of Planck clusters with UPMASK

In this section, we apply UPMASK to search for optical counterparts of the PLANCKSZ2 cluster candidates in the Pan-STARRS catalogue. We are particularly interested in clusters not yet confirmed by other surveys. For each subset (which were obtained as described in Sec. 4) we applied UPMASK using the coordinates and the photometric data of each object. Taking into account the discussion in Sec. 5, here we used 4PCs. Some fields have a small number of objects after the star-galaxy separation, therefore we used 10 objects per k-means cluster for all the

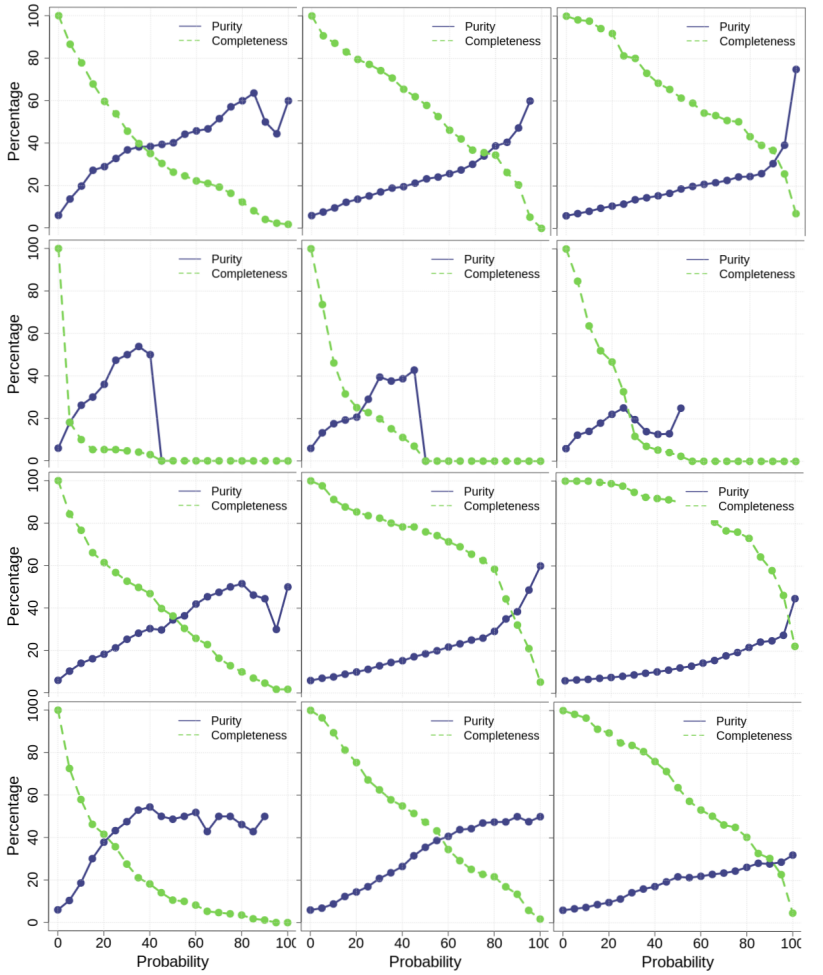

Fig. 5. Completeness (green dashed) and purity (blue solid) of UPMASK classification, applied to the simulated data of Sec. 4 for different N. We change this value along the lines ($N = \{20, 60, 140\}$), for the different methods. The lines are an application of the KDE version (original), Voronoi+Anderson-Darling, Voronoi+Mean and finally the Grid version.

fields. Since we are only interested in detect clusters with optical parameters, a resolution of 10% in the UPMASK score (frequentist probability) is a reasonable choice. The classification of a cluster is entirely up to the user of the method. Ours will depend on the number of objects each field has, above a certain probability. In Fig. 7 we show how this classification behaves when changing the cut in probability.

Thus, for the rest of this proceeding, we have chosen to classify a cluster as the field that has more than 10 members above 50% frequentist membership probability. In Fig. 8 we show the dependency of our findings with the redshift. The first plot shows the dependency of the measured SZ flux with the redshift. The figure

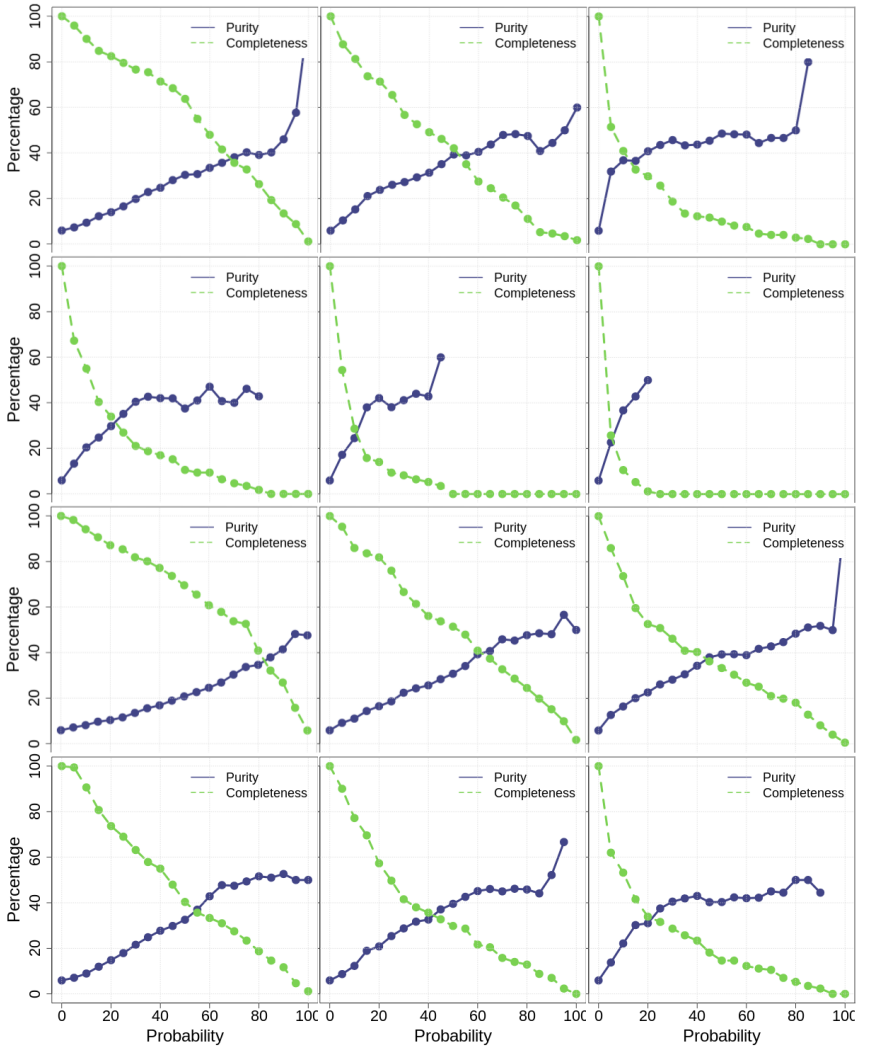

Fig. 6. Completeness (green dashed) and purity (blue solid) of UPMASK classification, applied to the simulated data of Sec. 4 for different T. We change this value along the lines ($T = \{0.5, 1.5, 3.0\}$), for the different methods. The lines are an application of the KDE version (original), Voronoi+Anderson-Darling, Voronoi+Mean and finally the Grid version.

shows three distributions: all PSZ2 sources (grey points), PSZ2 sources inside the Pan-STARRS sky-coverage (blue circles) and finally the UPMASK detections (blue dots). One can conclude that the detections do not seem to depend on the redshift (the dependency is only present due to the Planck selection function). In the second plot, we show the count dependency on the redshift for the same distributions described previously. Finally, the third plot shows the ratio of the detected objects over the total PSZ2 sources present in the Pan-STARRS sky coverage. This

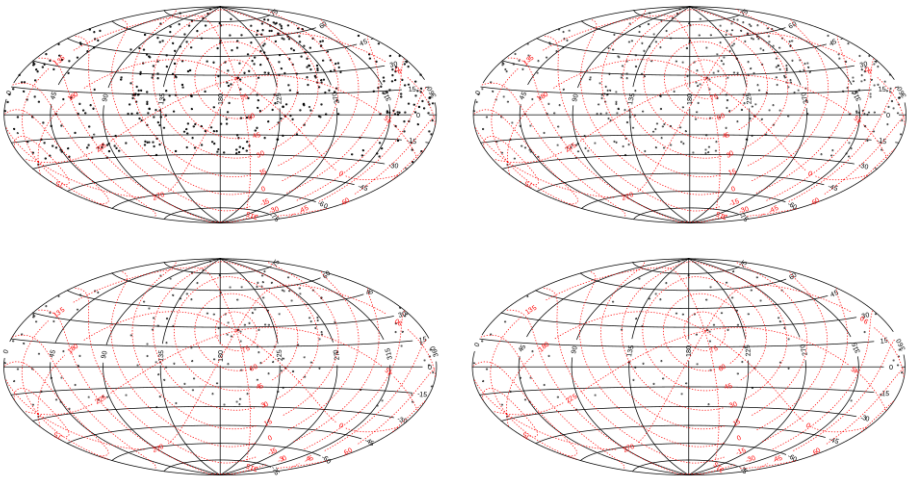

Fig. 7. Projection of the distribution of Planck Clusters in the sky detected by UPMASK for Clusters that have more than 10 objects with probability above of 50, 70, 90 and 100% (Left to right, top to bottom). Each point indicates one galaxy cluster from the PLANCKSZ2 catalogue. The red lines are the Galactic coordinate lines.

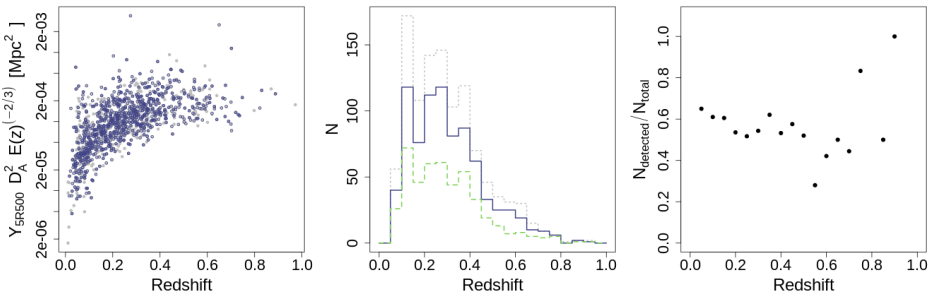

Fig. 8. Variation of PSZ2 sources properties with redshift. Left panel - Dependency of the measured Planck SZ flux with redshift. The grey points represent all the PSZ2 sources, the blue circles represent the PSZ2 sources that are included in the Pan-STARRS sky coverage and the blue points represent the sources that UPMASK detected (here, we established the detection criteria as the fields that contain more than 10 members above 50% membership probability. This detection criterion is the same in all panels of the figure). Center panel - Variation of PS2 source counts with redshift, for all sources (dotted grey), for sources included in the Pan-STARRS sky coverage (solid blue), and for the UPMASK detections (dashed green). Right panel - Fraction of the detected sources as a function redshift.

distribution shows a very weak dependency until redshift 0.5. Above this redshift, the ratio fluctuates significantly due to the small number of objects.

It is also particularly interesting to look for clusters in the PLANCKSZ2 survey catalogue that were not confirmed by an external counterpart at the moment of the

Table 6. Comparison table between the results of Refs 30 and 31 and UPMASK. The "True" and "False" fields are the unconfirmed PSZ2 sources that were found or not by the respective methods. The results are normalized to the total number of unconfirmed sources in the Pan-STARRS sky coverage.

	Streblyanska et al., Barahona et al. False	Streblyanska et al., Barahona et al. True
UPMASK False	36 (12%)	49 (16%)
UPMASK True	78 (26%)	138 (46%)

Table 7. Comparison table between the results of UPMASK and other authors (see Refs. 30–35). Here we used SIMBAD[36] to investigate which among the 216 UPMASK clusters had previous optical counterparts.

	Found (Other Authors)	Not Found (Other Authors)
UPMASK Found	67	149

release of the PLANCKSZ2 catalogue. Following the same classification, out of the 301 galaxy cluster candidates with no external validation, UPMASK was able to rediscover 72% (216) clusters with optical information. Furthermore, we have compared our results with other works in the literature (see Refs 30 and 31) in Table 6. The authors report that there are some spurious detections (ie, no obvious cluster observed in the photometric data) and therefore we have not included these detections in this table. The "False" and "True" fields refer to the fields that were not found in the list of PSZ2 sources without an optical counterpart, and those that are a clear detection, respectively. Overall we have a general accordance with the results from the aforementioned articles, while our method shows a more optimistic result (26% UPMASK clusters when compared with the "False" results). This optimistic behavior emerges naturally from the fact that UPMASK makes no assumptions about the cluster model, or requires direct redshift information from the galaxies in the data. However, more fortuitous detections might also be returned from the method in these conditions, and this should not be considered a drawback since any selected candidate still need to be spectroscopically confirmed. Here we were especially interested in the UPMASK candidates that were not previously confirmed by other authors, Refs. 30–35. In Table 7 we show that we found 67 cluster candidates in other recent efforts but without present optical confirmation. Fig. 9 shows an example of 4 of these detected clusters by UPMASK. Each panel is a KDE image with iso-contours obtained from the spatial distribution of galaxies that have membership probabilities $\geq 50\%$. Our forthcoming work will be dedicated to perform follow-up spectroscopy observations aiming to confirm or rule-out some of these new galaxy cluster candidates.

7. Conclusion

The study and characterization of galaxy clusters requires their detection and the identification of their member galaxies. In this proceeding, we modified and applied

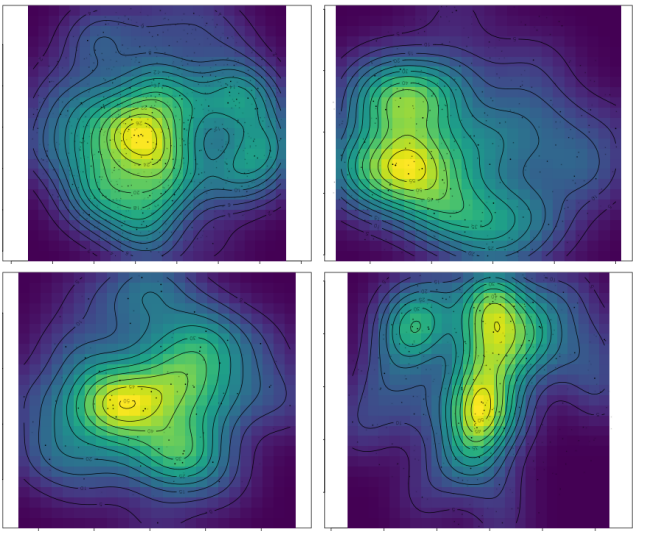

Fig. 9. Examples of UPMASK detections in Pan-STARRS fields around PSZ2 sources. The plots show a KDE image representation with iso-contours (color map: the brighter, the denser) of the most likely members (members with a probability above 50%)

UPMASK, a method originally designed to analyse stars in stellar clusters, to galaxy clusters. We show that the method is effective in this context, adopting only photometric and astrometric data as expected from upcoming surveys. Additionally, our study suggests that the performance of the method seems to be redshift independent.

In section Sec. 3 we describe the modifications proposed in this work: KDE+Fitting Function; Voronoi+Anderson-Darling test; Voronoi+Mean Comparison; Grid; Grid+Fitting Function. These modifications and the method itself were validated in Sec. 5, with simulated data from the MICE version 2 galaxy survey catalogue. In that same section we studied how the results behave with varying parameters, as the number of objects per K-means group, the number of Principal Components, and the threshold level. We conclude that the fastest modification is the Voronoi+Mean Comparison. On the other hand, the Grid implementation is the method that provided the highest improvement in purity. We also studied the optimal number of principal components to use. Overall, we were able to reduce dimensionality to 4 Principal Components. This number was chosen because additional components result in similar outcomes, with the penalty of increasing CPU time. Moreover, we have seen that using more objects per K-means cluster, results into higher completeness, while decreased purity. Also, when using a smaller threshold level, the completeness decreases, while the purity has an ascending behavior. In the end, we conclude that the UPMASK modifications and this parameter study shows that this is a very versatile tool for galaxy cluster cosmology, as the user can adjust the method and the parameters according to their goals: to use the method to quickly find galaxy cluster candidates or, to obtain membership probabilities.

In Sec. 6 we look for optical counterparts of Planck SZ clusters. We start with a list of candidates from the 2nd Sunyaev-Zel'dovich cluster catalogue (PSZ2) and the data from the Pan-STARRS catalogue collected from the Pan-STARRS survey. For each field obtained from Pan-STARRS, which corresponds to a certain PSZ2 candidate, we apply UPMASK. We show in this work (Fig. 8) that UPMASK can detect clusters independently of redshift. Additionally, we were also able to discover optical counterparts for about 72% of the 301 clusters without previous external validation. In the future, it can be interesting to apply the methods developed here to search for the new clusters directly from deep optical surveys, as the Rubin/Large Synoptic Survey Telescope and the Euclid space mission. For the cluster candidates detected in this work, we now plan to perform dedicated spectroscopic observation to determine their redshifts and to confirm or rule-out their physical existence.

Finally, thanks to the methods we developed here and to the adoption of the most modern optical surveys, we performed the detection of the optical counterparts for 67 galaxy cluster candidates previously identified by the ESA Planck space mission. This builds up the evidence for the reality of these candidates, which are at the backbones of the large-scale structure of the Universe.

The recent associations of neutrino events with blazars (e.g. TXS 0506+056, 3HSP J095507.9+355101) provided a unique opportunity to study the possible physical connection between the multiwavelength electromagnetic and neutrino emissions. We present *SOPRANO*, a new conservative implicit kinetic code which follows the time evolution of the isotropic distribution functions of protons, neutrons and the secondaries produced in photo-pion and photo-pair interactions, alongside with the evolution of photon and electron/positron distribution functions. In the current work, we apply *SOPRANO* to model the broadband spectrum of TXS 0506+056, 3HSP J095507.9+355101 and 3C 279 blazars. It was possible to constrain main physical parameters within both a pure hadronic and lepto-hadronic scenarios.

Keywords: Radiation mechanisms; non-thermal–quasars; individual; TXS 0506+056, 3HSP J095507.9+355101 and 3C 279 – galaxies; jets – gamma-rays; galaxies

1. Introduction

In recent years, the discovery of very high energy neutrinos of astrophysical origin by the IceCube experiment[1–3] has opened a new window on very high energy sources such as gamma-ray bursts (hereafter GRBs), active galactic nuclei (AGNs) and tidal disruption events (TDEs). In 2017, the very high energy neutrino IceCube 170922A[4] and its further association (confidence level of 3.5σ) with the blazar TXS 0506+056[5] made clear that high energy protons, neutron and even possibly nucleons have an important role to play in the dynamics and the radiation of relativistic jets.[6–8]

In the forthcoming years, it is expected that many more crucial data will become available for high energy sources at all wavelengths, but more importantly at very high energy. For instance, the MAGIC collaboration recently reported the first observations of a GRB at energies above TeV with its observation of 190114C,[9] and several more are expected to be observed with CTA.[10,11] In addition, upgrades of existing neutrino facilities, with e.g. IceCube-Gen2,[12] as well as new experiments such as P-one,[13] KM3Net[14] and the Baikal-GVD,[15] will allow for increasingly more

*Current address.

sensitive searches of the origin of very high energy neutrinos.[16] Those experiments should also help to establish more firm coincidental observations of neutrino bursts with identified electromagnetic counterparts, thus allowing for models to be tested, constrained, challenged and eventually ruled out.

In order to understand observations and constrain models of emission able to explain very high energy neutrinos, it is necessary to perform self-consistent simulations of the time evolution of hadrons distribution functions, together with following the evolution of the photon and lepton distribution functions. This is a challenging task since 1- the number of distributions is much larger (from two to fourteen although some are trivial), 2- all equations describing the time evolution of particle distribution functions are coupled in a non-trivial (and non-linear) way by many complex processes that 3- have different time scales, requiring an implicit time discretization. The high number of distribution functions comes from the fact that we also wish to follow the cooling and emission of charged secondaries (pion and muons), preventing us from using semi-analytical expressions for the production rate of neutrinos, see *e.g.*[17]

Over the years, several groups have developed numerical models to estimate leptons, hadron and photon distribution functions in order to make predictions to explain observations, either under the steady state approximation[18–21] or for the fully time dependent equations either for leptons only[22] or adding protons.[23–28] In this paper, we present our approach to the problem: a modular code solving the time dependent isotropic kinetic equations which preserves the total energy of the system as well as the number of particles where needed. The code structure is modular such that processes can be added easily (or removed). It is also implicit so numerical stability is achieved at all time.

The paper is organised as follows. In Section 2, we detail the processes included in our numerical code and the associated kinetic equation. In Section 3, we provide elements of the numerical discretizations in energy and time. In Section 4 we present examples of the theoretical modelings obtained by *SOPRANO*. In particular, we model the spectra of TSX 0506+056, 3HSP J095507.9+355101 and of 3C 279. The conclusion follows.

2. *SOPRANO*: Simulator of Processes in Relativistic AstroNomical Objects

In its current version, the code evolves in time the isotropic kinetic equations for photons, electrons and positrons (considered as one species, see below), protons, neutrons, charged and neutral pions, muons, neutrino and anti-neutrino of all flavors. We summarize here all terms appearing in the kinetic equation for all particle species. For the cross-sections used in SOPRANO see.[29] In the photon distribution function, we assign $n_{\rm ph}$ to be the number of photons per unit volume per hertz. We further define $N_{\rm i}$ to be the number of particles of species i per unit volume per unit Lorentz factor of particle i. Here i can be all leptons and all hadrons. Then, we

define N_{ν_i} the number of neutrinos of flavour i per units volume per GeV. Finally, for the sink and source terms we assign Q and S, respectively. The contribution of inverse Compton scattering is noted R_{IC} for the photons and is a cooling term for the leptons.

- *Photons :* they are created by synchrotron radiation from all charged particles, and by π_0 decay. They are absorbed by pair production and redistributed in energy by inverse Compton scattering. We neglect the absorption of photons in the photo-pion and photo-pair processes. The resulting kinetic equation takes the form

$$\frac{\partial n_{\rm ph}}{\partial t} = -S_{\gamma\gamma\to e^+e^-} + Q_{\pi_0} + R_{\rm IC} + \sum_i Q^i_{\rm synch} \tag{1}$$

- *Leptons :* electron and positrons are considered a single species. They are created by muon decay μ, by photo-pair production and photon pair production. The also undergo synchrotron cooling such that the final kinetic equation reads

$$\frac{\partial N_{\rm e^\pm}}{\partial t} = Q_\mu + Q_{p\gamma\to e^+e^-} + Q_{\gamma\gamma\to e^+e^-} C_{\rm IC} + C_{\rm synch} \tag{2}$$

- *Protons :* protons undergo cooling via synchrotron emission, Bethe-Heitler photo-pair production and via photo-pair production. They are produced by photo-pair interaction with neutron, and disappear for a fraction of photo-pair interaction. The kinetic equation takes the form

$$\frac{\partial N_p}{\partial t} = C_{p\gamma\to p\pi} + C_{p\gamma\to e^+e^-} + C_{\rm synch} - S_{\gamma p\to n\pi} + Q_{\gamma n\to p\pi} \tag{3}$$

- *Neutron :* Neutron are produced in photo-pion production and disappear in photo-pion interactions. The kinetic equation takes the form

$$\frac{\partial N_n}{\partial t} = -S_{n\gamma\to p\pi} + Q_{p\gamma\to n\pi} + C_{n\gamma\to n\pi} \tag{4}$$

- *Charged pions :* π_+ and π_- are produced by photo-pair production. Then, they cool via synchrotron emission and decay. The kinetic equation for both species takes the form

$$\frac{\partial N_{\pi_\pm}}{\partial t} = Q_{p\gamma\to\pi} + Q_{n\gamma\to\pi} - S_\pi + C_{\rm synch} \tag{5}$$

  We note that we solve the kinetic equation independently for both species, since the branching ratio in photo-pion production are different for negative and positive pions.
- *Neutral pions :* the π_0 kinetic equation is similar to that of charged pions but without synchrotron cooling.

- *Muons :* Muons are produced by the decay of charged pions. They are also cooled by the synchrotron process and they decay. Therefore, the kinetic equation is

$$\frac{\partial N_\mu}{\partial t} = Q_{\pi_\pm} - S_\mu + C_{\text{synch}} \tag{6}$$

- *Neutrinos and anti-neutrinos:* neutrinos and anti-neutrinos are produced in the decay of pions and of muons. We consider all 2 flavours ζ

$$\frac{\partial N_{\nu,\zeta}}{\partial t} = Q_{\pi_\pm} + Q_\mu \tag{7}$$

3. Numerical Discretization

The SOPRANO follows the evolution of distribution functions as a function of time under the following simplificative assumptions: i) space is infinite and homogeneous, ii) distribution functions are isotropic. For disretization, SOPRANO uses a flavour of finite volume approximation based on the discontinuous Galerkin method. This method fits nicely for solving integro-differential equations.

3.1. *Energy discretization*

In order to numerically solve the kinetic equations presented in Section 2, a numerical grid for the energy of all particles is introduced. The grid element are equally space in logarithmic of the energy.[a] The grid characteristics for each types of particle are given by Table 1. We use the approach of the discontinuous Galerkin method. On each energy cell I, we approximate the distribution function by a polynomial. In the current version we restraint to first order and consider the Legendre polynomial as basis function. Therefore, on each energy cell I, the distribution function is approximated by

$$N_{\text{i}}^I(x) = N_{\text{i},0}^I L_0^I(x) \tag{8}$$

where the first order Legendre polynomial on the energy cell I is

$$L_0^I = \frac{1}{\sqrt{x_{I+\frac{1}{2}} - x_{I-\frac{1}{2}}}} \equiv \frac{1}{\sqrt{||I||}} \tag{9}$$

Here $x_{I\pm(1/2)}$ are the boundaries of energy cell I and where we introduced the additional notation $||I|| = (x_{I+1/2} - x_{I-1/2})$. An important properly of the Legendre polynomial is that

$$\int_I L_0^I dx = 1. \tag{10}$$

[a]Note that our numerical method do not require to have a uniform grid. Because it is based on finite volume, we can refine the grid in one or several energy bands of interest. In this way, we can provide more detailed results in those specific bands, while the rest of the domain is coarse for faster numerical estimation.

Table 1. Characteristics of the numerical grids used by SOPRANO for the numerical models of this work. The cells are equally space in logarithmic scale.

Particle	Number of cells	Minimum energy	Maximum energy
Photons	150	$\nu = 10^{-2}$Hz	$\nu = 10^{30}$ Hz
Leptons	130	$\gamma_{e\pm} = 1.2$	$\gamma_{e\pm} = 5 \times 10^{13}$
Hadrons	100	$\gamma_h = 1.2$	$\gamma_h = 10^{11}$
Neutrinos	100	$E_\nu = 10^{-3}$ GeV	$E_\nu = 10^{11}$ Gev

In the following we will use interchangeably $N_i^I \equiv N_{i,0}^I$. We seek the weak formulation of all kinetic equations presented below on all energy interval I. For this, we multiply both sides of the equation by L_0 and integrate over I. After simplification, we obtain a system of differential equations for all $N_{i,0}^I$. This specific discretization and the structure of the kinetic equation allows us to retrieve a numerical method which conserves energy and the number of particles when they are conserved.

3.2. *Temporal discretization*

Before discussing the temporal discretization, we note that the equation are non-linear in the distribution function for Compton scattering, pair production, photo-pion and photo-pair processes. We have decided to linearize the kinetic equation of photo-pion and photo-pair processes by assuming that the target photon-field is equal to the one at the previous time step, effectively making those process linear in the distribution function. For all leptonic processes,[b] we preserve the non-linearity of the kinetic equations and solve at each time step a non-linear system via Newton-Raphson iteration. The temporal evolution of the distribution function is performed with the implicit Euler.

The computation of one time step is done in the following form

(1) solve the linear kinetic equation for the protons since for photo-pion and photo-pair processes the photon distribution function is assumed to be known and given by its value at time t. The pairs created in the photo-pair processes are saved to be use as a source term in the leptonic computation.
(2) compute the decay and cooling (when required) of pions and muons. The pairs and photons created in the muon and pion decay are used as source terms in the leptonic computation.
(3) perform the fully implicit leptonic computation with the source term computed in the two previous steps.

4. Modeling of Blazar SEDs

The code *SOPRANO*, described in Section 2, is used to model the multiwavelength SEDs of TXS 0506+056, 3HSP J095507.9+355101 and 3C 279. Two of these sources,

[b]This is true for all process but synchrotron which is linear in the distribution function.

TXS 0506+056 and 3HSP J095507.9+355101, coincide in space and time with the IceCube 170922A[4] and IceCube 200107A[30] events, respectively. The other source, 3C 279, shows a prominent flare in the γ-ray band. In all modelings, the emission region assumed to be a sphere with a radius of R' which is moving with a bulk Lorentz factor of $\Gamma \sim \delta$, carries a magnetic field with an intensity of B' and a population of relativistic particles. The magnetic jet luminosity is defined as

$$L_{\rm B} = \pi c R'^2 \delta^2 \frac{B'^2}{8\pi}, \tag{11}$$

while for protons and electrons as follows:

$$L_{\rm p} = \pi R'^2 \delta^2 m_{\rm p} c^3 \int \gamma_{\rm p} Q'_{\rm p}(\gamma_{\rm p}) \gamma_{\rm p}, \tag{12}$$

$$L_{\rm e} = \pi R'^2 \delta^2 m_{\rm e} c^3 \int \gamma_{\rm e}\, Q'_{\rm e}(\gamma_{\rm e})\, d\gamma_{\rm e}, \tag{13}$$

where c is the speed of light, $m_{\rm p}$ and $m_{\rm e}$ are the proton and electron masses, while $Q'_{\rm p}$ and $Q'_{\rm e}$ refer to proton and electron injection spectra, with the following forms:

$$Q'_{\rm p}(\gamma_{\rm p}) = Q'_{0,p} \gamma_{\rm p}^{-\alpha_{\rm p}} \qquad \gamma_{\rm p} < \gamma_{\rm p,max}. \tag{14}$$

$$Q'_{\rm e}(\gamma_{\rm e}) = \begin{cases} Q'_0 \gamma_{\rm e}^{-\alpha_{\rm e}} \exp\left(-\dfrac{\gamma_{\rm e}}{\gamma_{\rm e,cut}}\right) & \gamma_{\rm e,min} \le \gamma_{\rm e} \le \gamma_{\rm e,max}, \\ 0 & \text{otherwise}, \end{cases} \tag{15}$$

where $\gamma_{\rm e,min}$ is the minimum injection Lorentz factor. All primed quantities refer to the comoving frame. The distribution functions of protons and electrons evolve via cooling and via interaction with photons, producing different signatures in the broadband spectrum. Our aim is to identify those signatures and use them to constrain the emission mechanism within the framework of different scenarios. We also assume that the injection power-law indexes are such that $\alpha_{\rm e} = \alpha_{\rm p}$. Once injected in the emitting region, particles interact with the magnetic field and with the photons, producing secondary particles, which themselves interact, radiate and decay, shaping the broadband SED. The low energy component is interpreted as the synchrotron emission of the primary electrons while the HE component is modelled either within a pure hadronic model(hereafter HM) or a hybrid lepto-hadronic (hereafter hybrid) model e.g.[31,32] For the HM, the high energy peak on SED is formed due to the proton synchrotron emission, however in the hybrid model, the high energy peak is explained by leptonic processes and proton synchrotron emission is required to be subdominant. The proton content is obtained by maximizing the neutrino flux at PeV energies, which is constrained by the radiation from the secondaries produced by the Bethe-Heithler and photo-pion processes. Indeed, it has long been speculated that efficient neutrino production is associated with efficient Bethe-Heithler process, creating a population of HE pairs, which can over-shine the tight constraints in the X-ray band e.g., order of minutes.[33] The system of kinetic equations is evolved for

one dynamical time scale $t'_{\rm dyn} \sim R'/c$ considering the magnetic field to be constant, and taking into account all relevant processes for particles interactions. Having estimated the model parameters of each blazar SEDs, the corresponding neutrino flux can be derived. The flux of muon neutrino, $F_{\nu_\mu}(E_{\nu_\mu})$, in all considered scenarios is shown by the light blue line in Figures 1-3. When available, the neutrino flux is compared with the limit imposed by the IceCube detector. This flux can be transformed to the expected observed number of neutrinos in the IceCube detector using its averaged effective area $A_{\rm eff}(\mathrm{E}_\mu)$, which is mostly a function of the incident neutrino energy. For 3HSP J095507.9+355101 and 3C 279, the average area from[34] was considered, while for TXS 0506+056 we used the area released after the observation of IceCube-170922A.[c] The effective area increases with energy and reaches its maximal value for energies above several hundreds of PeV. The expected number of muon neutrinos and anti-neutrinos is computed through

$$N_{\nu_\mu+\bar{\nu}_\mu} = t_{\rm exp} \int_{E_{\rm min,\nu_\mu}}^{E_{\rm max,\nu_\mu}} F_{\nu_\mu}(E_{\nu_\mu})\, A_{\rm eff}(\mathrm{E}_{\nu_\mu})\, dE_{\nu_\mu} \tag{16}$$

where the minimum and maximum energy of the neutrinos are $E_{\rm min,\nu_\mu} = 100$ GeV and $E_{\rm max,\nu_\mu} = 10^9$ GeV, respectively, chosen to correspond the limits for the effective area. The expected number of neutrino events depends on the duration of the source activity, $t_{\rm exp}$, over which the neutrinos are emitted. The neutrino oscillation, within the quasi-two neutrino oscillation assumption, is taken into account by

$$N^{obs}_{\nu_\mu} = 0.575 N_{\nu_\mu} + 0.425 N_{\nu_e}, \tag{17}$$

where $N^{obs}_{\nu_\mu}$ is the observable distribution of muon neutrinos, while, N_{ν_μ} and N_{ν_e} are the emitted muon and electron neutrino distributions.[35]

5. Results

The results of the SEDs modeling are shown in Fig. 1-3 with the Table 2 and 3.

TXS 0506+056: Two different periods are chosen for modelling: the single neutrino detection period,[4] and the historical neutrino flaring period.[5] The modeling results are shown in Figure 1 and Table 2. Panels a) and b) of Figure 1 represent the modeling of SED of the single neutrino event period, while panel c) and d) show flare for historical neutrino flare SED modelings. The multiwavelength data from[4] are modeled within a HM scenario in panel a). The corresponding model parameters are given in Table 2. The sum of all components, represented by the blue line in the top left panel of Figure 1, satisfactorily explains the observed data. The model overpredicts the radio data, but by taking into account the synchrotron self-absorption effect,[29] the model is in agreement with the data. The modeling parameters given in the first column of Table 1 are in the range of similar estimations for blazars in general and for TXS 0506+056 in particular. A Doppler factor $\delta = 20$ and a radius

[c] https://icecube.wisc.edu/science/data-releases/

$R' = 2.5 \times 10^{15}$ cm were used in our modeling. This is in agreement with the limits on the variability time of 10^5s presented in.[36] We note that when $\delta = 10$ or 15, the data can also be well reproduced by the model. The initial injection power-law index of the emitting electrons is $\alpha_e = 2.1$, a value that can be formed by shock accelerations, *e.g.*[37] Due to the high magnetic field, $B = 80$ G, electrons are in the fast cooling regime and their distribution function is a power-law with index $\alpha_e + 1$. The initial electron distribution extends up to $\gamma_{\rm cut} = 2.4 \times 10^3$ (~ 1 GeV) which is representative of the acceleration and cooling time scales. Instead, protons cool less efficiently and they could be accelerated up to much higher energies, *i.e.* $\gamma_{\rm max} = 10^9$ (9.4×10^{17} eV), see.[29]

As an alternative model to HM or leptonic models, the hybrid model is also applied to the SED of TXS 0506+056, shown in panel b) of Figure 1. The model parameters are given in the second column of Table 2. The blue dashed lines represent the time evolution of the spectrum in selected numerical steps, which builds and forms the overall SED, represented by the solid blue line after one dynamical time scale. The synchrotron component peaking between 1-10 eV is up-scattered by the relativistic electrons to produce the HE and VHE component. In contrast to HM scenario, the magnetic field in the emitting region is $B = 0.57$G significantly lower, therefore, electrons with Lorentz factor $\gamma_{\rm e,min} = 10^3$ are not substantially cooled within one dynamical time scale. For this hybrid model, protons do not directly contribute to the observed SED, instead the contribution of secondary electron-positrons dominates in the X-ray band, which puts constraints on the proton luminosity and as a consequence the neutrino luminosity. For example, if one increases by 1.5 times the proton luminosity, the model would overshoot the X-ray data, as shown by the dotted-dashed blue line in panel b) of Figure 1.

Further the results of the SED modeling obtained during the historical neutrino flare of TXS 0506+056 is presented. Unfortunately, when 13 ± 5 neutrinos were observed between October 2014 and March 2015,[5] the multiwavelength coverage is scarce. Yet, the flux upper limit of $F < 9.12 \times 10^{-12}$erg cm^{-2} s^{-1} derived from Swift BAT observations[38] introduces substantial difficulties for a one-zone modeling. Indeed, the predicted number of neutrino events cannot be matched to the IceCube observations[38] and[39] have shown that only few neutrino events could be detected under different optimistic considerations for the emitting region and for the target photon field (internal or external to the jet). Matching together the observed multiwavelength data and the neutrino data seems to require two zone models with more free parameters.[38,39]

To accommodate the X-ray limit and try to account for the neutrino flux during this flare, two different assumptions on the proton distribution function are made. On the one hand, radiation from the secondaries can be constrained to be dominant in the MeV band, in which there are no observational constraint. On the other hand, radiation from the secondaries could be dominant in the GeV band and produce the second HE hump. The SEDs of these two models are respectively shown in panels c) and d) of Figure 1, with data from.[39] Those two models lead to two very

different sets of parameters for the emitting region, see column 3 and 4 of Table 2. The first model requires a large radius $R' = 10^{17}$cm and a slowly moving jet with Doppler factor $\delta = 10$, while the second model necessitates those parameters to be $R' = 10^{15}$cm and $\delta = 15$. The required magnetic field also significantly differs between these two models with $B = 35$G for the first model, to be compared to $B = 0.65$G for the second one. The first model tends to reproduce the neutrino flux, albeit produces the peak at lower energies. The second model puts the neutrino peak at larger energy, but is not able to reproduce the observed neutrino number. In both interpretations, it is clear that the upper limit in the X-ray band imposes strong constraints on the photon spectrum, which in turn limits the proton content in the jet. Considering larger proton luminosity would lead to over-estimate both the observed γ-ray flux and the X-ray upper limit.

Table 2. Parameter sets used for modeling the SEDs of TXS 0506+056, observed in 2017 and during the neutrino flare in 2014-2015. The electon, proton and magnetic luminosities are also given.

	TXS 0506+056: 2017		TXS 0506+056: 2014-2015	
	Hadronic	Lepto-hadronic	Hadronic	Lepto-hadronic
δ	20	20	15	10
$R/10^{15}$ cm	2.5	10	1	100
$B[G]$	80	0.57	35	0.65
$\gamma_{\rm e,min}$	100	1000	2×10^2	9×10^3
$\gamma_{\rm e,cut}$	2.4×10^3	4.5×10^4	10^4	$=\gamma_{\rm e,max}$
$\gamma_{\rm e,max}$	3×10^4	6×10^4	8×10^4	8×10^4
$\alpha_{\rm e}$	2.1	2.0	2.0	2.0
$\alpha_{\rm p} = \alpha_{\rm e}$	2.1	2.0	2.0	2.0
$\gamma_{\rm p,min}$	1	1	1	1
$\gamma_{\rm p,max}$	10^9	10^6	2×10^8	1.2×10^5
$L_{\rm e}$ (erg s^{-1})	2.2×10^{44}	9.3×10^{44}	2.8×10^{44}	5.3×10^{44}
$L_{\rm B}$ (erg s^{-1})	6.0×10^{46}	4.9×10^{43}	10^{45}	1.6×10^{45}
$L_{\rm p}$ (erg s^{-1})	2.1×10^{47}	2.6×10^{50}	3.4×10^{47}	4.9×10^{52}

From the jet energetic perspective, the total jet luminosity in the case of TXS 0506+056, for the proton synchrotron model, shown on panel a) of Figure 1, is $L_{\rm tot} = L_{\rm p} + L_{\rm e} + L_{\rm B} = 2.7 \times 10^{47}\,{\rm erg\,s^{-1}}$, which exceeds by one order of magnitude the Eddington luminosity of $\simeq 4 \times 10^{46}{\rm erg\,s^{-1}}$ for a black hole mass of $3 \times 10^8\,M_\odot$, as estimated for TXS 0506+056 using the absolute R-band magnitude.[40] This is in agreement with previous studies suggesting that in the case of proton synchrotron models or models producing a high neutrino flux, the required jet luminosity exceeds that of the Eddington limit.[41] Within the hybrid model, matching the neutrino flux with the neutrino event of TXS 0506+056, displayed on panel b) of Figure 1, requires the jet luminosity to be $\sim 10^{50}\,{\rm erg\,s^{-1}}$, significantly exceeding that of the Eddington luminosity. Although the Eddington luminosity is not a strict limit and super-Eddington luminosities were previously reported,[42] this value is extremely large. On the other hand, for the neutrino flare in 2014-2015, when assuming that

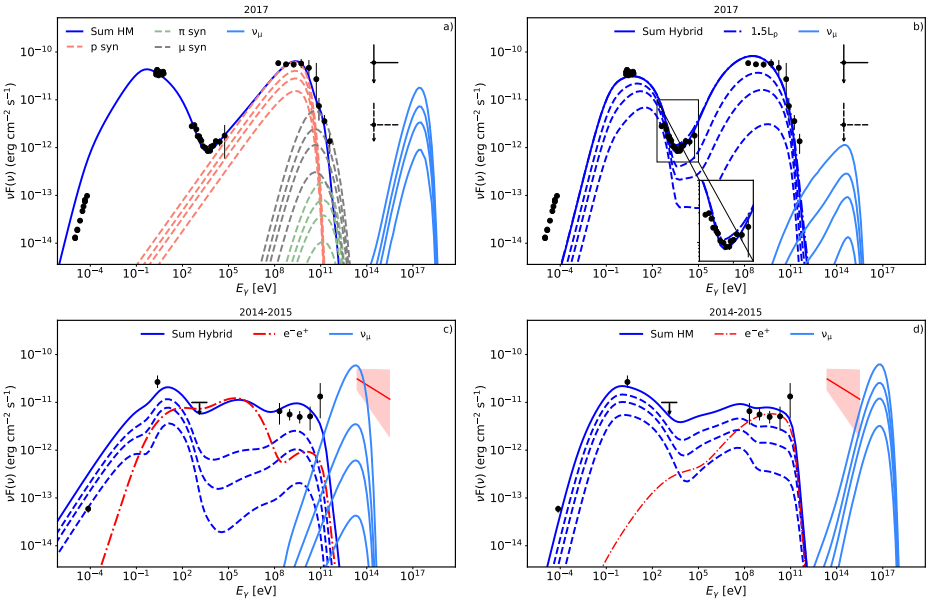

Fig. 1. The multiwavelength SED of TXS 0506+056 during the neutrino emission in 2017 (upper panels) and during the neutrino flare in 2014-2015 (lower panels) modeled within the hadronic and lepto-hadronic hybrid scenarios. The solid blue line in all plots represents the sum of all components which has been corrected for EBL absorption considering the model of.[43]

the emission from the secondary pairs solely dominates in the X-ray and γ-ray bands, an unrealistically high luminosity of $\sim 10^{52}$erg s^{-1} is obtained. Indeed, matching the high neutrino flux with the large radius (10^{17} cm) imposed by the modeling in this case, requires a large protons density, hence the too large proton luminosity. In the alternative interpretation, when the emission from the secondary pairs dominates in the GeV band, a modest luminosity of 3.4×10^{47} erg s^{-1} is estimated.

The expected numbers of neutrinos during the 6 months flare of TXS 0506+056 are 0.43 and 0.23 for the hadronic and hybrid scenarios, respectively. During the 2014-2015 neutrino flare, our most optimistic models predict 3.0-3.3 neutrinos for a 6 months exposure time (note however that the IceCube observational window was $\sim$ 110 days). Our results are in agreement with previous estimations for TXS 0506+056 and confirm that within a one-zone scenarios, 13 ± 5 events from the direction of TXS 0506+056 cannot be explained.[38,39]

3HSP J095507.9+355101: It is the first time that the jet of an extreme blazar is associated with a neutrino event,[30] straightening the assumption that the jets of this blazar type are potential sites for cosmic rays and even ultra-high energy cosmic ray acceleration.[44]

The SED of 3HSP J095507.9+355101 is shown in Figure 2, where the multiwavelength data are from.[45] Optical, UV and X-ray data were acquired on the 8$^{\text{th}}$, 10$^{\text{th}}$ and 11$^{\text{th}}$ of January. However, since the data taken on the 8$^{\text{th}}$ and 11$^{\text{th}}$ of January

seem to have the same flux and spectral shape,[46] we only model the data from the $8^{\rm th}$. The lack of available multiwavelength data does not allow to constrain the low and high energy peaks, which hardens the estimation of the model free parameters. A hint of a $20-30$ minutes variability has been found in the NICER and NuSTAR data, but only at the $\sim 3.5\,\sigma$ level.[47] Therefore, the compactness of the emitting region cannot be constrained. In order to keep the generality, the SED of 3HSP J095507.9+355101 is modeled for two different parameter configurations. For the HM, we consider $R' = 3\times10^{14}$ cm and $\delta = 15$, while for the hybrid model we assume $R' \simeq 10^{16}$ cm and $\delta = 30$. The all estimated parameters are shown in Table 3.

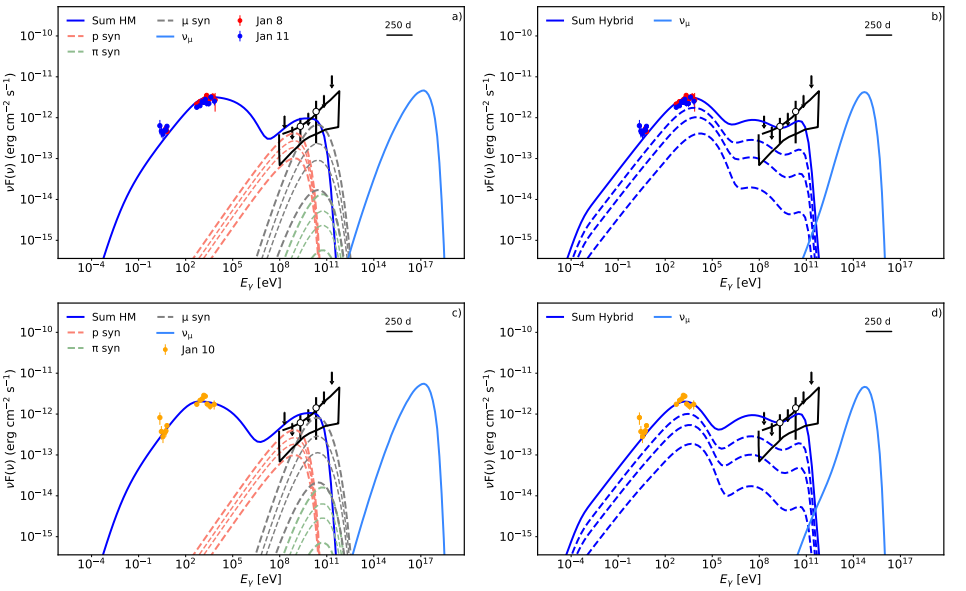

Fig. 2. The multiwavelength SEDs of 3HSP J095507.9+355101 on the the $8^{\rm th}$ and the $11^{\rm th}$ of January (panels a) and b) on the top raw) and on the $10^{\rm th}$ of January (panels c) and d) on the bottom raw). The data are taken from.[45,46] The observed spectrum including all processes is shown by the solid blue line. All models (solid blue lines) have been corrected for EBL absorption considering the model of.[43]

The estimated muon neutrino rate for 3HSP J095507.9+355101, is within $6\times10^{-4} - 4.8\times10^{-3}$ per day. This implies that under this rate of emission, the expected number of neutrinos to be detected by IceCube in a time corresponding to the duration of the flare is very low. Such low neutrino estimation was obtained also by the authors of,[46] where they concluded that in the most promising scenarios, there is a $\sim 1\%$ to $\sim 3\%$ to observe one neutrino over the time characteristic of the long-term emission of 3HSP J095507.9+355101 (years).

3C 279: The broadband emission from the powerful FSRQs 3C 279 at redshift $z = 0.536$ has characterized by high amplitude variability almost in all energy

bands e.g., order of minutes,[48] and in particular in the HE γ-ray band, which present the fastest variability. On the 16$^{\rm th}$ of June 2015, Fermi LAT observations showed that 3C 279 was in an exceptionally bright state. The flux increased up to 3.6×10^{-5} photon cm^{-2} s^{-1} with a flux doubling time on the order of 5 minutes.[49] IceCube performed a time-dependent neutrino signal search correlated with this γ-ray flare but no evidence for a signal was found.[50] We apply *SOPRANO* to model the SED of 3C 279 during its flare in the framework of the HM, when the second peak dominates by proton synchrotron emission. The parameters of our modeling are given in Table 3. Figure 3 shows the multiwavelength SED of 3C 279 taken from,[51] alongside with the results of our modeling. During the brightening, the X-ray emission of the source appears with a hard photon index < 1.50, smoothly connecting with the INTEGRAL data, described by a power-law with index 1.08.[51] In the HE γ-ray band, the spectrum presents a power-law with photon index 2.21 with a turn over.[52] We make the hypothesis that the HE component is produced from a single mechanism. In our modeling it is interpreted as proton synchrotron emission, represented by the red dashed lines in Figure 3. This interpretation requires that protons are accelerated up to $\gamma_{\rm p,max} = 2.1 \times 10^8$, see Table 3.

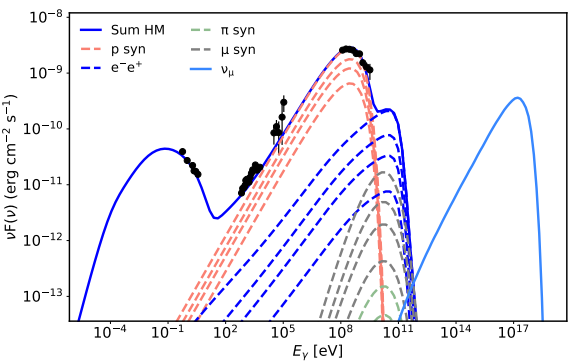

Fig. 3. The multiwavelength SED of 3C 279 during the exceptional flaring activity in 2015. The contribution of different particle emission is shown by dashed lines whereas the thick solid line represents the observed spectrum, corrected for EBL absorption considering the model of.[43]

The compactness of the emitting region implies a high efficiency for photo-pion and photo-pair interactions, which inject energetic secondary pairs. The contribution of these pairs dominates above ~ 10 GeV and peak at ~ 100 GeV, as can be seen by the blue dashed line in Figure 3. The synchrotron radiation of the primary electrons peaks at ~ 0.1 eV and its HE tail accounts for the observed optical/UV data. These data constrain the cut-off energy to be relatively low, $\gamma_{\rm e,cut} = 2.4 \times 10^2$, otherwise, for $B = 70$ G and $\delta = 55$, the synchrotron radiation would overshoot the observed flux in optical and UV bands. A similar hadronic modeling for this flare is presented in[51] and in.[53] The neutrino rate for the considered flaring period

is as high as 0.15 per day is estimated. However, for a relatively short period of the source activity, from minutes to one day, no neutrino events in the IceCube detector are expected, in agreement with.[50]

Table 3. Parameters used to model the multiwavelength SEDs of 3HSP J095507.9+355101 and 3C 279. The electron, proton and magnetic luminosity is also displayed.

6. Conclusion

We have presented a new kinetic model of photo-hadronic and leptonic interactions aiming at studying the emission of optically thin (for Compton scattering) scenarios of relativistic sources (e.g., AGNs and GRBs). Our numerical solution of the kinetic equations for protons, neutrons, pions, muons, neutrinos, pairs, and photons conserves the total energy of the system as well as the number of particles where required. The code takes as an input the spectral injection rate of the particles (e.g., electrons and/or protons), and compute the time evolution of all relevant particles, including the secondaries, as they interact and cool, allowing the computation of the broadband emission spectrum at any given period. In this paper, we have applied *SOPRANO* to model the SEDs of three blazars, two of which are potentially associated to neutrino emission observed by IceCube. We have assumed different models for the production of the HE component and compute in all cases the expected number of muon neutrinos. The time-dependent nature of the code allowed to follow the evolution of all particles in one dynamical time scale and then assess the proton content in the jet by using the radiative spectrum of either secondaries or initial particles. This is necessary for the estimation of the expected number of neutrinos. Such time-dependent treatment of the particle evolution enabled us to constrain different scenarios of neutrino production by using the limits imposed by the observations in different bands.

Multiwavelength study of high-redshift blazars

G. Harutyunyan and D. Israyelyan
ICRANet Armenia, Marshall Baghramian Avenue 24a, Yerevan 0019, Republic of Armenia

High-redshift blazars are among the most powerful objects in the Universe. The spectral and temporal properties of 33 distant blazars ($z > 2.5$) detected in the high-energy γ-ray band are discussed using *Fermi*-LAT and *Swift* Ultraviolet and Optical Telescope/X-ray Telescope (UVOT/XRT) data accumulated during 2008-2018. The properties of the jets of these blazar obtained by modeling the multiwavelength spectral energy distributions within a one-zone leptonic scenario are presented and discussed.

Keywords: Galaxies; active –Gamma rays; galaxies–radiation mechanisms; non-thermal.

1. Introduction

Blazars are a type of active galactic nuclei(AGN) which have relativistic jet that is directed towards to the Earth.[1] Blazars characteristic features are high degree of polarization, short and strong non-thermal emission variations both in time and amplitude. Based on the absence or presence of emission lines in their optical spectra blazars are divided in two large classes, namely FSRQs and BL Lacs.For FSRQs the equivalent width of emission line is >5 $\mathring{A}$ meanwhile BL Lacs have weak emission lines <5 $\mathring{A}$.[1]

The spectral energy distribution (SED) of blazars has a double-peaked structure. Low energy peak, from radio to X-ray is due to synchrotron radiation of relativistic electrons. Instead, the high energy peak is most probably due to the Inverse Compton scattering of either synchrotron photons(Synchrotron-Self Compton(SSC)[2–4]) or photons field external to the jet (external Inverse Compton).[5–7] The external target fields can be photons of the accretion disc, broad-line region and dusty torus.

The dominant class of extragalactic γ-ray sources are blazars. During its ten year survey, Fermi-LAT has observed $\sim$ 5000 sources in γ-ray band from which more than 2863 are AGNs detected above the 5σ.[8] Only 33(1.18%) out of 2863 are distant blazars $z > 2.5$ (Table 1) from which 26 are FSRQs, 2 are BL Lacs and 5 are blazar candidate sources. Studying of these sources can shed light on some questions such as, cosmological evolution of blazars and black holes, evolution of relativistic jets across different cosmic epochs, accretion disc-jet connection, extragalactic Background Light density limit, etc.[9]

In this paper were investigated multiwavelength emissions from high red shift blazars($z > 2.5$) using data accumulated by *Fermi*-LAT and Swift telescopes.

Table 1. List of γ-ray emitting blazars at $z > 2.5$. The results of observation of distant blazars from August 4, 2008, to August 4, 2018 by *Fermi*-LAT are presented in the right part of the table.

2. Fermi LAT analysis

To investigate considered sources in the γ-ray band the data accumulated by *Fermi*-LAT were used. In the current paper, the 100 MeV to 500 GeV data from the region with 12° radius were downloaded and analysed. The data had been accumulated during ten years since launch of *Fermi*-LAT (4 August 2008 to 4 August 2018). *gtselect* and *gtmktime* tools were applied to select good time intervals when data were valid. The maximum zenith angle was 90° to avoid γ-rays which are due to Earth's limb. Events were binned into 16.9×16.9 ROI (region of interest) and 37 equal logarithmically spaced energy bins using *gtbin* tool. The model file of each source includes all the 4FGL sources falling within the ROI+5° region and it was generated using 4FGL-DR2 catalog which is the second release of 4FGL (based on ten years operation). For galactic and extragalactic diffuse emission components *gll_iem_v07* and *iso_P8R3_SOURCE_V2_v1* models were used. With the *gtlike* tool spectral analysis of considered sources using binned maximum likelihood method was performed. The spectral parameters of sources located within the ROI are set to free. Detection significance of the sources estimated using TS (Test Statistic)[10] which is defined as $TS{=}2 \times (logL_1 - logL_0)$ where L_1 is the likelihood of the data with a point source at the given position and L_0 without the source. For each source the same γ-ray spectral model as in 4FGL catalog was used and additionally analysis was performed using power-law spectral model. SEDs of the sources were created by running *gtlike* for smaller energy intervals equal in logarithmic space. The γ-ray light curves were computed with *gtlike* tool applying unbinned likelihood analysis method which is suitable for shorter periods. The spectra of the considered source was modeled using a power-law which provide good results for small interval. The normalization and photon index of the chosen sources are free to vary except photon index of all sources which are lying within the ROI. For the fitting the events

with energy 0.1-300 GeV were considered. To investigate γ-ray variability initially we calculated 30 day bins light curves for all the sources. There are statistically significant ($\geq 5\sigma$) sources in the sample which have flaring periods and for that periods the light curves with small bins such as day or week were calculated. For some powerful sources such as B3 1343+451, PKS 0537-286, PKS 0347-211, PKS 0451-28 additionally the adaptively binned method has been applied to generate the light curves. In this method time intervals are adapt to provide bins with constant flux uncertainty(with 15%) above the E_0 which is a powerful method to study flux variation in γ-ray band.[11–17]

3. Swift observations

In the current paper the data from the two of the instruments onboard Swift XRT[18] and UVOT[19] have been analysed. Although the primary scientific goal of the Swift telescope is the observation of GRBs,[20] also, due to its wide frequency coverage, it is suitable for studies of blazars. Except 4 sources from the Table 1 the rest of the sources at least once have been observed by Swift, some of them (e.g. B2 0743+25, PKS 0438-43, TXS 0222+185, TXS 1448+093, PMN J0226+0937, TXS 1616+517 and PKS 2107-105) had been observed more than ten times. The Swift XRT data analysis was available for twenty-two sources, and only twenty-six sources were detected in at least one of the optical-UV Swift-UVOT filters (see Table 3).

The Swift UVOT performs measurements at 6 wavelengths: UVW2 (188 nm), UVM2 (217 nm), UVW1 (251 nm), U (345 nm), B (439 nm), and V (544 nm). The photometry analysis of the sample was performed using the standard UVOT software distributed within the HEAsoft package (v6.25) and the calibration included in the CALDB (v.20170922). The source counts were extracted from a circular region with a 5″ radius around the source, while the background one is a region with 20″ radius not being contaminated with any signal from the nearby sources. If in the observation data from the different filters exists, the same models were used, after checking background region contamination by nearby sources. For converting source counts to magnitudes *uvotsource* tool and the conversion factors provided by[21] was used. The fluxes were corrected for extinction using the reddening coefficient $E(B-V)$ from the Infrared Science Archive[a].

In the X-ray band the Swift XRT data observed both in photon counting and window timing modes were used. The data were analyzed with the standard XRTDAS tool distributed within the HEAsoft package (v6.25), applying standard procedures, filtering, and screening criteria. As a source region was selected a circular region with a 20-pixel (47″) centered on the coordinates of each source, while as a background region was selected an annulus, with the same center as the source region and inner and outer radii of 51 (120″) and 85 pixels (200″), respectively. For fitting the 0.3-10 kev X-ray spectrum was used XSPEC12.10.1 tool, adopting

an absorbed power-law model with a neutral hydrogen column density fixed to its Galactic value in each direction.

As these sources are not observed with the Swift XRT instrument too long, for most of the sources the count rates were below 20, which would prevent spectral fitting, some cases several observations of the same source were merged if they were available for increasing the photon statistics. The merging was performed using the tool available from the UK Swift Science Data Center[b].[22] Again for the fitting of the 0.3-10 keV spectrum XSPEC was used, applying both the absorbed power-law and log-parabola models. Also, light curves have been generated for the investigation of the flux variation in each band.

4. Results of data analysis

In Table 1 the results of γ-ray data analysis(γ-ray flux, index, TS, etc.) obtained after power-law fitting are presented. Detection significance(TS) for all sources was TS $>$ 34.05, only S4 2015+65 detected with TS=23.77.Also, fit with log-parabola spectral model was performed for sources which spectral model is log-parabola in 4FGL(Table 2). Results show that fluxes estimated using log-parabola spectral model are not much different from corresponding fluxes estimated from the power-law fitting. The results presented in Table 1 are shown in Fig. 1. The γ-ray photon index versus flux is shown in he upper left panel.The photon index estimated in the 0.1-500 GeV ranges from 1.71 to 3.05 with a mean of 2.54. The flux of considered sources ranges from 4.84×10^{-10} to $1.5 \times 10^{-7} photon\ cm^{-2}s^{-1}$. The two BL Lacs, 87 GB 214302.1+095227 and MG1 J154930+1708, have the lowest flux $(4.84 \pm 1.37) \times 10^{-10} photon\ cm^{-2}s^{-1}$ and $(1.66 \pm 0.79) \times 10^{-9} photon\ cm^{-2}s^{-1}$. The γ-ray flux of BCUs included in the sample ranges from 2.19×10^{-9} to $1.46 \times 10^{-8} photon\ cm^{-2}s^{-1}$ with Γ_γ within 2.20-2.84. The FSRQs occupy the region of high flux $\geq 3.89 \times 10^{-9} photon\ cm^{-2}s^{-1}$ with a mean $2.11 \times 10^{-8} photon\ cm^{-2}s^{-1}$. The highest γ-ray flux of $1.50 \times 10^{-7} photon\ cm^{-2}s^{-1}$ was observed from the bright FSRQ B3 1343+451. The luminosity of each source was computed using the observed flux(F_γ) and photon index(Γ_γ). In upper right panel is shown the distribution of the considered sources in Γ_γ-L_γ plane. The γ-ray luminosity of the considered sources ranges from $1.01 \times 10^{47} erg\ s^{-1}$ to $5.54 \times 10^{48} erg\ s^{-1}$. The lowest luminosity of $1.01 \times 10^{47} erg\ s^{-1}$ has been estimated for CRATES J105433+392803 which is of the same order with that of the two BL Lacs included in the sample $(1.42 \pm 0.98) \times 10^{47} erg\ s^{-1}$ for 87GB 214302.1+095227 and $(1.24 \pm 0.59) \times 10^{47} erg\ s^{-1}$ for MG1 J154930+1708. The luminosity of these BL Lacs corresponds to the highest end of the luminosity distribution of BL Lacs included in the fourth catalog of AGNs detected by *Fermi*-LAT.[23] The γ-ray luminosity of PKS 0347-211, PKS 0451-28, PKS 0537-286 and B3 1343+451 $\geq 10^{48} erg\ s^{-1}$. X-ray data analysis results (Table 3) show that flux ranges from $\simeq 5 \times 10^{-14} erg\ cm^{-2}s^{-1}$ to

[b] `https://www.swift.ac.uk/user\_objects/`

$\simeq 10^{-14} erg\ cm^{-2} s^{-1}$, the highest flux of $(1.19 \pm 0.04) \times 10^{-11} erg\ cm^{-2} s^{-1}$ being observed for TXS 0222+185. In the lower left panel X-ray flux versus the photon index was plotted. Because of small number of detected counts flux and photon index were estimated with large uncertainties. X-ray photon indexes estimated for these sources is <2 which means that X-ray spectra has a rising shape. The hardest X-ray spectrum detected for B3 0908+416B with $\Gamma_x = 1.01 \pm 0.46$. PKS 0451-28, TXS 0222+185, PKS 0834-20, PKS 0537-286, TXS 0800+618, B2 0743+25 and PKS 0438-43 have a comparable high X-ray flux $\geq 2.13 \times 10^{-12} erg\ cm^{-2} s^{-1}$. In the lower right panel are compared γ-ray and X-ray fluxes. Sources which are bright in γ-ray band such as PKS 0537-286 and PKS 0451-28 appear to be,also a bright sources in X-ray band.

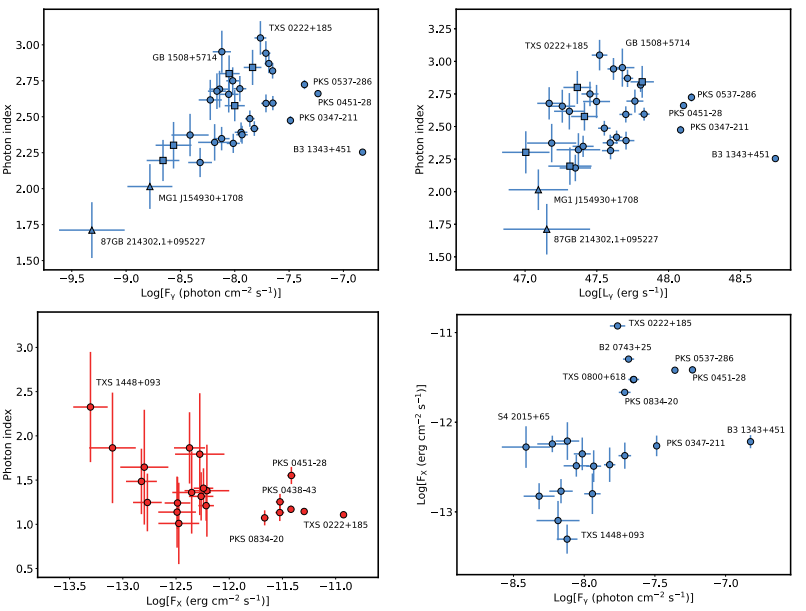

Fig. 1. The γ-ray flux (> 100 MeV) and luminosity of considered sources versus the photon index are shown in the upper panels. BL lacs, FSRQs and BCUs are shown with triangles, circles, and squares, respectively. *Lower left panel:* The X-ray flux ($0.3 - 10$ keV) versus the photon index. *Lower right panel:* Comparison of γ-ray and X-ray (if available) fluxes.

4.1. *Variability*

Multiple observations of some of these sources with the Swift telescope allow us to investigate their X-ray flux variability. After processing and analyzing data from each observation there were only eight objects with enough counts for constraining the flux and the photon index in a single observation. The results showed that the

X-ray emission from the considered sources was relatively constant except for PKS 0438-43, B2 0743+25, and TXS 0222+185.

The X-ray flux of TXS 0222+185 is mostly around $(0.96 - 1.1) \times 10^{-11}$ erg cm^{-2} s^{-1} which increased to $(1.62 \pm 0.13) \times 10^{-11}$ erg cm^{-2} s^{-1} and $(1.37 \pm 0.16) \times 10^{-11}$ erg cm^{-2} s^{-1} on 24 December 2014 and 31 July 2006, respectively. In case of PKS 0438-43, it was in a bright X-ray state on 15 December 2016 with a flux of $(1.09 \pm 0.16) \times 10^{-11}$ erg cm^{-2} s^{-1} as compared with the flux of $(1.30 \pm 0.31) \times 10^{-11}$ erg cm^{-2} s^{-1} in the quiescent state. Similarly, the X-ray flux of B2 0743+25 in the high state on 01 January 2006 was $(1.06 \pm 0.56) \times 10^{-11}$ erg cm^{-2} s^{-1}. The variation of the 0.3-10 keV X-ray flux of PKS 0438-43, B2 0743+25 and TXS 0222+185 is shown in Fig. 4. No variation of X-ray photon index was found, due to the large uncertainties in its estimation.

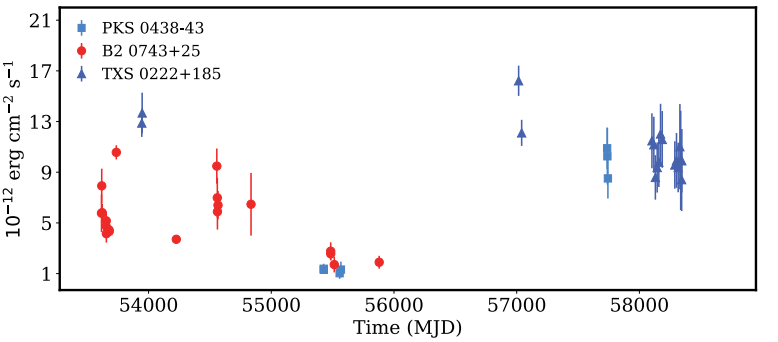

Fig. 2. The 0.3-10 keV X-ray fluxes of PKS 0438-43, B2 0743+25 and TXS 0222+185 measured by Swift-XRT.

A detailed investigation of γ-ray flux variation of the considered sources during the ten years was possible due to the continuous observation by *Fermi*-LAT. In some cases, when source detection significance is $< 10\sigma$, the data are not enough for variability searches in month scales, in these cases the variability has been checked for longer scales (6 to 12 months).[24] If the source detection significance is $> 37\,\sigma$, it is possible to use the adaptively binned intervals for computations. The adaptively binned light curves were possible to compute only for B3 1343+451, PKS 0451-28, PKS 0347-211 and PKS 0537-286, which are shown in Fig. 3. For the other sources included in Table 1 the variability on week and month scales are investigated.

The adaptively binned light curve of B3 1343+451, which is the brightest and the most variable source in the sample is shown in 3. During the bright γ-ray flaring periods: around MJD 55100, MJD 55890, MJD 56170, MJD 56640, and MJD 57060 the flux changes in sub-day scales. The width of 83 bins was shorter than 12 hours, which were observed during the flares around MJD 55890 (24 bins) and MJD 56170 (35 bins). There are about 200 bins with a width shorter than a day, and the

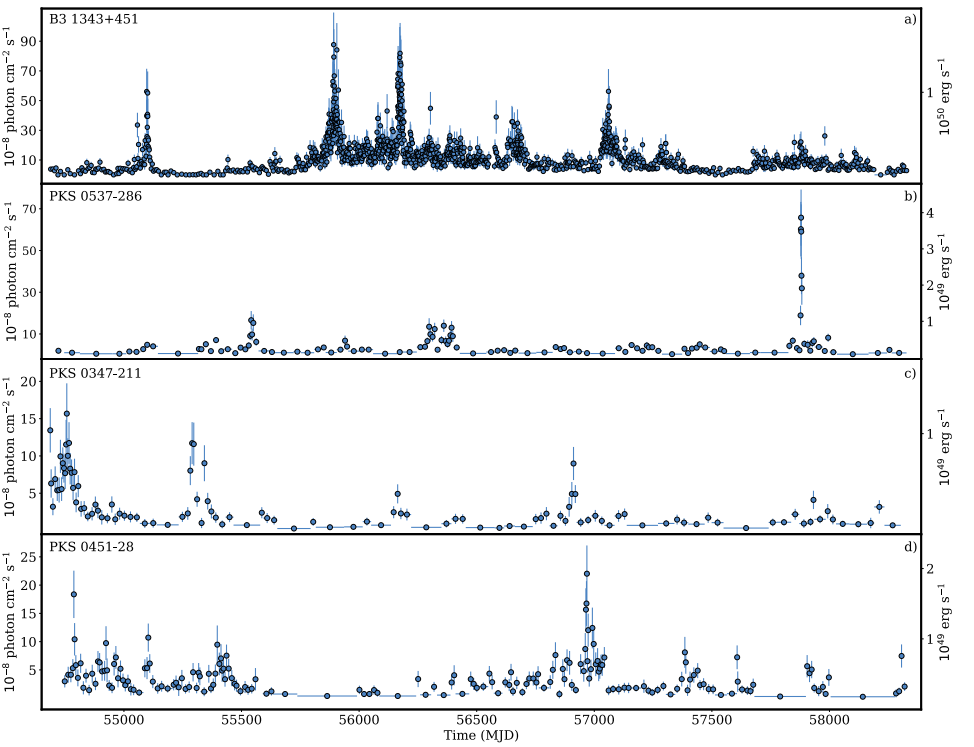

Fig. 3. γ-ray light curve of B3 1343+451, PKS 0537-286, PKS 0347-211, and PKS 0451-28 for the period from August 2008 to August 2018 calculated using adaptively-binned timescales.

minimum adaptively binned time width is 6.33 hours observed on MJD 56176.34 when the source flux was $(7.52\pm1.85)\times10^{-7}$photon cm^{-2} s^{-1}. In the quiescent state, the γ-ray flux of the source is $\simeq(1-5)\times10^{-8}$photon cm^{-2} s^{-1} with $\Gamma_\gamma = 2.48\pm0.29$ was observed on MJD 55891.7 with a detection significance of 9.1σ within a time bin having a width of 8.2 hours, which is 36.4 times higher than the γ-ray flux of the source in the quiescent state but the Γ_γ is within the uncertainties of the value given in Table 1. During the hardest γ-ray emission period, $\Gamma_\gamma = 1.45\pm0.21$ was detected on MJD 56432 with a significance of 7.2σ, which is unusual for this source.

PKS 0537-286 ($z = 3.10$) is the furthest source showing γ-ray flux variability in short time scales (Fig. 3b). The adaptive light curve showed variability in intra-day scales: 20.45, 15.96, and 18.90 hours. First about flaring activity of PKS 0537-286 was reported in[25] and the rapid γ-ray flux variations in.[24] γ-ray flux of PKS 0537-286 was increased from its 10 year average value, which was $(4.38\pm0.18)\times10^{-8}$ photon cm^{-2} s^{-1}, on MJD 55528-55553, MJD 56264-56400 and MJD 57878.0-57883.4, with the maximum value of $(6.58\pm1.35)\times10^{-7}$ photon cm^{-2} s^{-1} observed on MJD 57879.2 with a detection significance of 10.57σ. But in this periods the Γ_γ

is not significantly different from its average value in Table 1, which means that the emission is dominated by the MeV photons.

In the case of PKS 0347-211 and PKS 0451-28 (Fig. 3c and d) the adaptively binned light curves show several periods of γ-ray brightening. For example, for PKS 0347-211 the shortest γ-ray flux increase time interval is 2.65 days, and for PKS 0451-28 it is 1.56 days. The light curves of both sources show multiple periods when γ-ray flux increased. For example, on MJD 54757.04 ± 2.71 the γ-ray flux of PKS 0347-211 was $(1.57 \pm 0.41) \times 10^{-7}$ photon cm^{-2} s^{-1}. In the case of PKS 0451-28, the peak γ-ray flux of $(2.20 \pm 0.50) \times 10^{-7}$ photon cm^{-2} s^{-1} was observed on MJD 56968.60 ± 0.79 with 9.64σ. During this period, Γ_γ was 2.06 ± 0.19.

For finding out whether the γ-ray emission of other sources is variable or not,a simple $\chi 2$ test was performed;[26] the flux measured in each interval was fitted by a constant flux and the reduced $\chi 2$ and the probability of the flux being constant are computed. The $\chi 2$ fitting showed that the γ-ray emission variability of these sources varies from week to month scales. MG3 J163554+3629 at $z = 3.65$ is the most distant γ-ray flaring blazar; this source was reported to be in active state during May-July 2018: for example on July 7 2018 its daily averaged γ-ray flux peak value was $(6.4 \pm 1.15) \times 10^{-7}$ photon cm^{-2} s^{-1}.[27] During June-July 2018 this source was also bright and the maximum daily averaged γ-ray flux was observed $(1.18 \pm 0.23) \times 10^{-7}$ photon cm^{-2} s^{-1}.[27]

For the considered sources also investigated the γ-ray photon index evolution in time has been. This may reveal crucial information, because the photon index is defined by the processes responsible for particle acceleration and cooling and its changes are directly linked with the processes inside the jet. For the searching the photon index variation are used the γ-ray light curves produced in 30 and 7 days, in the case of B3 1343+451 3 day bins, and for escaping large uncertainties only those periods when the source detection was $TS > 25$ were considered, because adaptively binned light curves have narrow width, and photon indexes would be estimated with big uncertainties, which would would not allow to make definite conclusions. The $\chi 2$ test shows that the photon index of B3 1343+451, PKS 0451-28, B3 0908+416B and TXS 0907+230 only varies in time and the evolution was shown in Fig. 4 where the horizontal line corresponds to the averaged photon index estimated in ten years (Table 1).

The most interesting photon index variability has B3 1343+451, there are 60 periods when $\Gamma_\gamma < 2.0$. The hardest spectrum of B3 1343+451 was observed on 58089.16 ± 1.5 with $\Gamma_\gamma = 1.73 \pm 0.24$, also it is interesting, that the γ-ray spectrum was hard in a brightly γ-ray flaring state on MJD 56172.16 ± 1.5 with 1.95 ± 0.07. In the 30-day binned light curve of PKS 0451-28 are observed $\Gamma_\gamma = 2.06 \pm 0.07$ and $\Gamma_\gamma = 2.17 \pm 0.15$ on MJD 56977.66 ± 15 and 58297.66 ± 15, respectively. In the case of B3 0908+416B we can see remarkable hardening on MJD 57517.66 ± 15 when the Γ_γ changed to 1.84 ± 0.25 compared to the average of 10 years 2.42 ± 0.05. And in the case of the most distant object where γ-ray spectrum hardening was

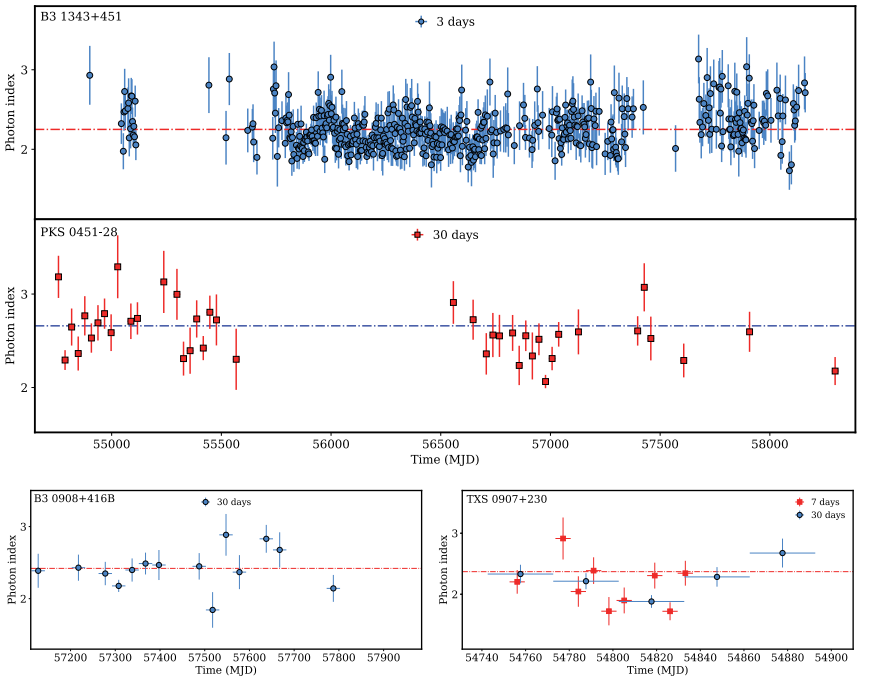

Fig. 4. The evolution of the γ-ray photon indexes of B3 1343+451, PKS 0451-28, B3 0908+416B and TXS 0907+230 in time.

observed is TXS 0907+230 with $z = 2.66$. It's 7 day γ-ray light curve shows that on MJD 54798.16 ± 3.5, 54805.16 ± 3.5 and 54826.16 ± 3.5 its γ-ray photon index appeared $\Gamma_\gamma = 1.72 \pm 0.23$, 1.90 ± 0.21 and 1.72 ± 0.15, respectively. Such a hard γ-ray spectrum is more typical for BL Lacs, but it has also been occasionally observed for the FSRQs during the flares.[12, 15, 28–31]

5. Theoretical modelling and results

The multiwavelength emission from blazars is due interaction of accelerated electrons[2–7] or protons[32–39] with magnetic and photon fields. The currently proposed models can not explain dynamical changes of the radiation and flares which are most likely caused by changes of radiating particles or the emission region.[40] Origin of flares can be investigated with contemporaneous multiwavelength data. From considered sources only for PKS 0438-43 and TXS 0800+618 are available contemporaneous Swift data. Our goal is to constrain the main physical parameters of distant blazars jets and because of lack of multiwavelength data in the modeling will be used only the averaged multiwavelength SEDs which presents the typical state of the source. To investigate broad band emission from considered sources we have used a one-zone leptonic model. The emission region is assumed to be a spherical blob with a radius of R which is filled with uniformly tangled magnetic field

B and with a homogeneous population of relativistic electrons. Non-thermal energy distribution of electrons is described by a power-law with exponential cut-off:

$$N(\gamma) \backsim \gamma^{-\alpha} exp(-\gamma/\gamma_{cut})\ \gamma > \gamma_{min}, \tag{1}$$

where γ is the Lorentz factor of electrons in the blob rest frame and α is the power-law index which defines the properties of acceleration mechanism.[41–44] γ_{min} and γ_{cut} are the minimum and cut-off energy of the electron in the emission region correspondingly. γ_{cut} allows constraining the cooling process of the particles and the state of plasma in the jet.[29,45] In a simple one zone leptonic model emitting region parameters are the radius, Doppler factor(Γ=δ), and magnetic field. Magnetic field is a free parameter and its density is $B^2/4\pi$. In the modeling it is assumed that from radio to optical/UV emission is due to synchrotron emission of relativistic electrons, meanwhile high energy peak is due to the Inverse Compton scattering of both internal[2–4] or external[5–7] photons.

The previous studies show that high energy peak is well explained when assumed external photons for Inverse Compton scattering.[15,46–49] Depending on the position of emission region(blob) in the jet different photon field can be assumed.[50] In case of these sources it is assumed that emission region is outside of broad-line region(BLR) and in this position dominant photon field is the infrared emission from dusty torus.[51] IR radiation from dusty torus has a black body spectrum which luminosity is $L_{IR} = 0.6L_{disc}$,[46] where L_{disc} is the accretion disc luminosity. Directly emission from accretion disk showing a UV excess in the SED and fitting of this excess allows us to estimate photons temperature and luminosity.[52] SEDs modeling results are shown in Table 3 and SEDs of sources for which were generated adaptively binned light curves are shown in Figure 4. The archival data from the Space Science Data Center are in gray, while the optical/UV, X-ray, and γ-ray data, obtained here, are shown in cyan, red, and blue, respectively. The radio data are not included in the SEDs fits, but are considered only as upper limits. The observed radio emission is assumed to originate from a different and extended region. The hard γ-ray emission spectra of B3 1343+451, PKS 0451-28 are in magenta, showing that the γ-ray flux increased and their spectra extend to higher energies.

The SEDs in Fig. 5 contain enough data from radio to HE γ-ray bands to shape both low and high energy peaks. The electron power-law index is defined by the X-ray data and depending on whether the SSC or EIC component is dominating in the X-ray band, different values for α are obtained. When the X-ray spectrum is hard and the SSC component is dominating, the energy distribution of the emitting electrons has a hard spectrum as well. For example for PKS 0537-286 $\alpha = 1.33 \pm 0.07$. The HE tails of both synchrotron and IC components are well defined by the optical/UV and γ-ray data, respectively, allowing precise estimation of $\gamma_{cut} = (1.01 - 15.73) \times 10^3$.$\gamma_{cut}$ strongly depends on α and its highest values is $(15.73 \pm 1.60) \times 10^3$ which was estimated when $\alpha = 2.80 \pm 0.04$. Meanwhile, when $\alpha = 2.2 - 2.5$, the highest γ_{cut} is $(1.01 - 15.73) \times 10^3$ for B3 1343+451. The estimated Doppler factor is from $\delta = 10.00$ to $\delta = 27.42$ with a mean of $\delta = 19.09$ which is higher

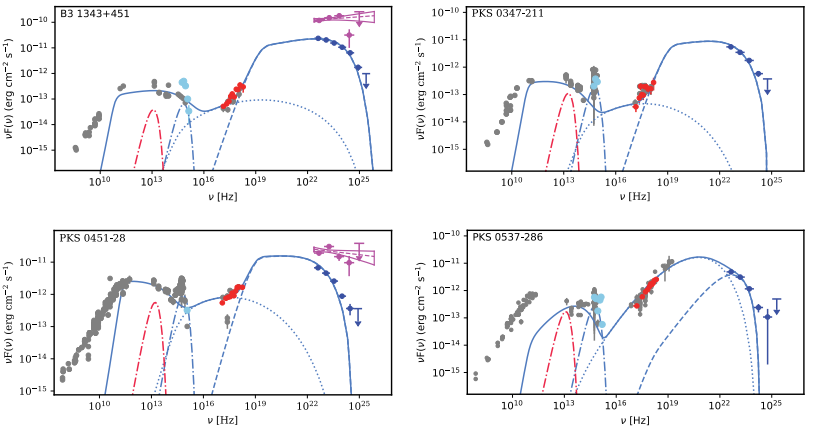

Fig. 5. The evolution of the γ-ray photon indexes of B3 1343+451, PKS 0347-211, PKS 0451-28, PKS 0537-286 in time.

than the average values estimated for FSRQs.[53,54] The emitting region size is within $R = (0.70-9.48)\times10^{16}$ cm. Results obtained for R suggest that the multiwavelength emission is produced in the sub-parsec scale regions of the jet. Modeling results allow us to estimate energetics of the considered sources. For seventeen sources out of thirty three was possible to estimate discs luminosity assuming that disc has a black body spectrum. Estimations shows that $L_d \simeq (1.09 - 10.94) \times 10^{46}$ erg s^{-1} and highest value estimated for PMN J0226+0937 is $L_d \simeq 1.09 \times 10^{47}$ erg s^{-1}. Jet power was calculated as

$$L = \pi R^2 c \Gamma^2 U_i \tag{2}$$

where U_i is electron or magnetic field energy density.Corresponding values from Table 4 show that $L_e \simeq (0.03 - 13.49) \times 10^{45}$ erg s^{-1} and $L_B \simeq (0.24 - 434.69) \times 10^{44}$ erg s^{-1}.

6. Summary

The main results after analysis of Fermi-LAT data, accumulated in 2008-2018 and Swift data, observed in fifteen years are summarized. The γ-ray photon index of all the considered sources is between 2.18-3.05 except for two BL Lacs. Swift XRT has detected significant X-ray emission only from FSRQs considered here and X-ray flux ranges from 5×10^{-14} erg cm^{-2} s^{-1} to 10^{-11} erg cm^{-2} s^{-1}. The γ-ray variability of the considered sources has shown emission on short and long time scales from sub day to month scales. During γ-ray flares the luminosity riches $(10^{49} - 10^{50})$ erg s^{-1}. The most luminous source in the sample is B3 1343+451 which luminosity during flare increases 36.4 times and corresponds to $L_\gamma = 1.5 \times 10^{50}$ erg s^{-1}. For SED modeling one zone leptonic model considering SSC of synchrotron and IC of dusty

torus photons was used. Magnetic field ranges from $0.10-1.74$ G and Doppler factor is within $10.00-27.42$. Estimated black hole masses are within $(1.69-5.35)\times10^9 M_\odot$.

In this review, we discuss a derivation of effective low energy quantum gravitational dynamics from thermodynamics. The derivation is based on the formalism developed in semiclassical thermodynamics of spacetime that allows to obtain Einstein equations from the proportionality of entropy to the area. We first introduce the relevant ingredients of semiclassical thermodynamics of spacetime, paying special attention to the various concepts of entropy involved and their relations. We then extend the semiclassical formalism by considering low energy quantum gravity effects which imply a modified entropy formula with an additional term logarithmic in the area. Upon discussing the derivation of effective gravitational dynamics from this modified entropy, we comment on the most important features of our proposal. Moreover, we show its physical implications on a simple cosmological model and show that it suggests the replacement of the Big Bang singularity by a regular bounce.

Keywords: Quantum gravity phenomenology, Thermodynamics of spacetime

1. Introduction

The search for a consistent theory unifying gravity and quantum physics has been an important direction of research in the last decades. While promising candidates have been put forward, none of them presently provides a complete and consistent final theory. In the absence of a fully developed theoretical framework, quantum gravitational phenomenology offers a way to gain information about possible low energy dynamical effects of quantum gravity.[1–5] Phenomenological models concerning strong gravitational fields are mainly available for physics in the vicinity of classical singularities.[6–10] However, these models face limitations coming from the simplicity of the studied geometries and their results cannot be directly applied in more general settings. Motivated by overcoming these issues, the authors have employed thermodynamics of spacetime to study quantum gravitational phenomenology and propose effective equations of motion applicable in generic spacetimes.[11] As we will see, thermodynamic methods allow us to look for model-independent

low energy phenomenological dynamics of quantum gravity without choosing any specific background spacetime. One can then particularise the resulting dynamics to any case of interest. Furthermore, the relevant thermodynamic predictions are common for most of the candidate theories of quantum gravity and can even be obtained by model independent considerations.

Thermodynamics of spacetime presents a useful tool for understanding gravitational dynamics. Following the seminal developments of black hole thermodynamics,[12–14] the framework has been extended both to more general spacetimes[15] and beyond general relativity.[16] A key step forward has been the derivation of Einstein equations from thermodynamics of local Rindler horizons.[17]The original approach has since been improved and generalised to work for different constructions of local horizons,[18–22] certain modified theories of gravity[20–26] and even to derive semiclassical gravitational equations of motion.[19,21,22]

Taking a step further, the authors have included quantum gravity effects on the thermodynamics of local causal horizons, obtaining equations governing low energy effective dynamics of quantum gravity.[11] To get sufficiently robust and general results, we concentrated on the leading order quantum correction to Bekenstein entropy, a term logarithmic in the horizon area. This is advantageous, since its presence is predicted by many different approaches to quantum gravity, including loop quantum gravity (LQG),[27,28] string theory[29,30] and AdS/CFT correspondence,[31] non-local effective field theory,[32] entanglement entropy calculations,[33] as well as model independent considerations based on generalised uncertainty principle (GUP) phenomenology[7] and analysis of statistical fluctuations.[34,35] Thus, the effective dynamics we propose is relevant to most of the main approaches to quantum gravity.

While we are chiefly concerned with low energy quantum gravity effects, thermodynamics of spacetime provides interesting insights already on the semiclassical level. Furthermore, a complete understanding of the semiclassical regime is necessary to extend the thermodynamic formalism to the realm of quantum gravity. Therefore, we include a detailed review of the concepts considered in semiclassical thermodynamics of spacetime, especially various notions of entropy. Since derivations of gravitational dynamics rely on equilibrium conditions for local causal horizons which involve Bekenstein, entanglement and Clausius entropy, we further discuss to what extend are these entropies equivalent.

In the present work, we review the main features of our proposal, paying special attention to the various concepts of entropy involved as well as to the unimodular nature of the resulting gravitational dynamics.[36] Section 2 introduces the necessary entropy definitions and discusses their relations both in the semiclassical and low energy quantum gravity settings. In section 3, we first briefly recap derivation of the effective equations. Then we discuss their properties and illustrate their physical implications on a simple cosmological toy model (finding that the Big Bang singularity can be resolved). Lastly, section 4 sums up our results and presents possible directions for future research.

Throughout the paper, we work in four spacetime dimensions and use metric signature $(-,+,+,+)$. Definitions of the curvature-related quantities follow.[37] We use lower case Greek letters to denote abstract spacetime indices and lower case Latin letters for spatial indices with respect to a (local) Cartesian basis. Unless otherwise explicitly stated, we use the SI units.

2. Entropy in thermodynamics of spacetime

Thermodynamic derivations of gravitational dynamics are based on the observation that gravitational dynamic are encoded in the horizon area equilibrium condition for maximal entropy, $\delta S = 0$, if it holds for all local causal horizons. This condition sums together variations of entropy of the horizon, often interpreted in terms of entanglement (von Neumann) entropy due to quantum correlations across the horizon,[17,19,26] and of entropy of the matter. Since the latter is usually described in terms of thermodynamic Clausius entropy,[17,18] it is not obvious that one can combine both entropies to define a meaningful equilibrium condition (it has actually been suggested that this fails in the case of local Rindler wedges[38]). This combination requires that fluxes of Clausius and von Neumann entropy of matter across the horizon are equal with sufficient precission. In the following, we first introduce our implementation of local causal horizons: geodesic local causal diamonds (GLCD). Then we present the definitions of all the relevant entropies associated with GLCD's and review our previous argument for the interchangeability of Clausius and von Neumann entropy.[36]

2.1. *Geodesic local causal diamonds*

We begin by briefly introducing the construction and most important properties of GLCD's. More detailed description of GLCD's can be found, e.g. in.[39–42]

In an arbitrary spacetime point P choose any unit timelike vector $n(P)$. In every direction orthogonal to n send out of P geodesics of parameter length l. These form a spatial geodesic 3-ball, Σ_0, and the region causally determined by Σ_0 constitutes a GLCD (see figure 1). The boundary, $\mathcal{B}$, of Σ_0 is approximately a 2-sphere. Its area reads[19]

$$\mathcal{A} = 4\pi l^2 - \frac{4\pi}{9} l^4 G_{00}(P) + O\left(l^5\right), \tag{1}$$

where $G_{00} = G_{\mu\nu} n^\mu n^\nu$. The GLCD possesses an approximate (up to $O\left(l^3\right)$ curvature dependent terms) conformal Killing vector[19]

$$\zeta = C\left(\left(l^2 - t^2 - r^2\right)\frac{\partial}{\partial t} - 2rt\frac{\partial}{\partial r}\right), \tag{2}$$

where C denotes an arbitrary normalisation constant. It has been argued that one can assign Hawking temperature to the GLCD's conformal horizon, $T_H = \hbar\kappa/2\pi k_B c$, where $\kappa = C/2l$ is the surface gravity corresponding to ζ.[19,42]

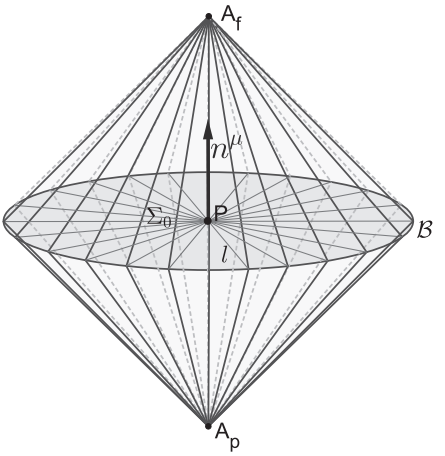

Fig. 1. A sketch of a GLCD with the origin in point P (the angular coordinate θ is suppressed). Σ_0 is a spatial geodesic ball of radius l (several of the geodesics forming it are depicted as grey lines), its boundary an approximate 2-sphere $\mathcal{B}$. Unit timelike vector n^μ is a normal of Σ_0. The tilted lines from the past apex A_p ($t = -l/c$) to the future apex A_f ($t = l/c$) represent the null geodesic generators of the GLCD boundary. The diamond's base Σ_0 is the spatial cross-section of both the future domain of dependence of A_p and the past domain of dependence of A_f at $t = 0$.

2.2. *Bekenstein entropy*

To derive the Einstein equations from thermodynamics of GLCD's (or, conversely, to interpret the first law of GLCD dynamics implied by Einstein equations in thermodynamic terms[42]), one must assume that entropy associated with its horizon obeys the Bekenstein formula[19,22]

$$S_{BH} = \frac{k_B \mathcal{A}}{4 l_P^2}, \tag{3}$$

where $\mathcal{A}$ denotes the horizon area. However, it is far from clear to what types of horizons can one assign Bekenstein entropy. Since its interpretation in terms of quantum entanglement allows a natural extension of the Bekenstein formula to any causal horizon, it is often assumed in the context of thermodynamics of spacetime (although it was originally proposed in a different context[43,44]). To understand the entanglement interpretation of Bekenstein entropy, consider two causally separated spacetime regions. An observer in one region cannot measure vacuum fluctuations in the other one. Since the fluctuations are correlated between regions, some information is inaccessible to the observer and non-zero entanglement entropy appears. Its value is proportional to the area of causal horizon, $S_e = \eta \mathcal{A}$.[33,43,44] The proportionality constant η is infinite unless one introduces a cutoff. Then η becomes finite and depends on the cutoff length, the number and type of quantum fields considered in the theory and even on the position in spacetime.[26,33] To recover the Bekenstein entropy, a universal value $\eta = k_B/4l_P^2$ is necessary (see, e.g.[33,45] for discussions of feasibility and shortcomings of this assumption). Let us stress that

the entanglement interpretation of Bekenstein entropy is in no way necessary to derive gravitational dynamics from thermodynamics. Any microscopic interpretation of black hole entropy which also applies to observer-dependent causal horizons would work just as well. Nevertheless, here we focus on the entanglement entropy as it is currently the most developed proposal with this property.

Beyond this semiclassical picture, many different models indicate that the leading order quantum gravity correction to Bekenstein entropy is a non-local term logarithmic in horizon area[7, 9, 27–35, 46–49]

$$S = \frac{k_B \mathcal{A}}{4 l_P^2} + k_B \mathcal{C} \ln\left(\frac{\mathcal{A}}{\mathcal{A}_0}\right), \tag{4}$$

where $\mathcal{C}$ is a real number and $\mathcal{A}_0$ a constant with dimensions of area. The values of $\mathcal{C}$ and $\mathcal{A}_0$ are model dependent. Considering the entanglement entropy interpretation allows us to calculate modified entropy even for causal horizons in a flat spacetime.[33] Interestingly, a logarithmic term then appears for spherical horizons,[50] but not for planar ones[33] (due to different Euler characteristics). This is the reason we consider GLCD's rather than local Rindler wedges to find effective low energy dynamics of quantum gravity from thermodynamics[11] (for arguments against the Rindler wedges even in the semiclassical setting see, e.g.[20, 38]).

While the presence of a logarithmic term seems to be a very general prediction of quantum gravity, the value and even the sign of $\mathcal{C}$ differ in various approaches. Generally speaking, two types of corrections to Bekenstein entropy have been studied in the literature. On one hand, microcanonical corrections appear due to more precise counting of the microstates at fixed horizon area, which reduces our uncertainty, leading to negative contribution to entropy. On the other hand, canonical corrections stem from thermal fluctuations at fixed temperature, which are an additional source of uncertainty increasing the entropy. As we discuss in section 3, the sign of $\mathcal{C}$ determines the physical implications of the modified dynamics we propose, allowing the avoidance of spacetime singularities only for $\mathcal{C} > 0$. Therefore, the presently unknown overall sign of $\mathcal{C}$ is crucial for the interpretation of our results.

2.3. *Clausius entropy of the matter*

Apart from Bekenstein entropy, derivation of gravitational dynamics from thermodynamics also requires a way to account for the entropy of matter. The simplest approach is to consider the thermodynamic Clausius entropy, $\mathrm{d}S_C = \delta Q/T$. The heat flux δQ across an arbitrary timelike hypersurface Σ reads[18]

$$\delta Q = -\int_\Sigma T_{\mu\nu} V^\nu N^\mu \mathrm{d}^3\Sigma, \tag{5}$$

where V^ν and N^μ are timelike and spacelike unit normals of Σ. If V^ν corresponds to velocity of an eternal, uniformly accelerating observer with acceleration a, we can define the corresponding Unruh temperature, $T_U = \hbar a/2\pi k_B c$. This definition holds with sufficient precission even for observers with slowly varying acceleration

or finite lifetime, as long as the proper length λ of the trajectory with an approximately constant acceleration is large enough, i.e. $\lambda \gg c^2/a$.[51] For the special case of uniformly accelerated observers travelling inside causal diamonds one also finds an equivalent result due to conformal mapping of a Rindler wedge to a causal diamond.[52,53] Therefore, as long as we consider a sufficiently large a, we can use the standard Unruh temperature together with the expression for heat flux to define Clausius entropy flux across a timelike hypersurface

$$S_C \equiv \frac{\delta Q}{T_U} = -\int_\Sigma \frac{2\pi k_B c}{\hbar a} T_{\mu\nu} V^\nu N^\mu \mathrm{d}^3\Sigma. \tag{6}$$

The timelike surface Σ coincides with the causal horizon perceived by the uniformly accelerating observer in the limit $a \to \infty$. Notably, this limit is well defined both for arbitrary causal horizons in flat spacetime and for sufficiently small horizons in curved spacetimes[18] (in that case, one simply considers Riemann normal coordinate expansion to the leading order). Before moving on to the special case of causal diamonds, several further remarks are in order. First, the definition of Clausius entropy flux across null surfaces is completely independent of gravitational dynamics or any requirements on symmetries of the spacetime. Second, the construction of the entropy is semiclassical as it explicitly depends on quantum field theory by invoking the Unruh effect. And, lastly, in contrast with the nature of Clausius entropy in non-relativistic thermodynamics, the entropy flux is manifestly observer dependent.[18]

For a GLCD, the resulting expression for Clausius entropy flux from $t = 0$ (geodesic ball Σ_0) to $t = l/c$ (future apex A_f) takes form[36]

$$\Delta S_C = \int_0^{l/c} \frac{2\pi k_B c}{\hbar} t \left(\int_{\mathcal{S}(t)} T_{\mu\nu} k^\mu k^\nu \mathrm{d}^2\mathcal{A} \right) \mathrm{d}t + O\left(l^5\right), \tag{7}$$

where k^μ denotes the future pointing null normal to the GLCD's boundary. Performing the integration and some straightforward manipulations then yields

$$\Delta S_C = -\frac{8\pi^2 k_B l^4}{9\hbar c} \left(T_{00}(P) + \frac{1}{4} T(P) \right) + O\left(l^5\right), \tag{8}$$

where we explicitly stress that the energy momentum tensor is evaluated at the diamond's origin, P.

When one wishes to take into account low energy quantum gravity effects, defining the Clausius entropy flux becomes more complicated. The subtleties in its definition come from the need to consider the Unruh effect, which requires that the ground state of quantum fields is locally well approximated by Minkowski vacuum. This amounts to invoking Einstein equivalence principle:[26] "Fundamental non-gravitational test physics is not affected, locally and at any point of spacetime, by the presence of a gravitational field".[54] However, the status of the equivalence principle in the low energy quantum gravity regime is far from clear. For instance, possible violations of weak equivalence principle resulting from GUP phenomenology have been explored in a number of works with very different conclusions.[55–58]

A simple way to deal with possible influence of the equivalence principle violations on the Unruh effect is to consider heuristic modifications to Unruh temperature due to GUP, previously suggested in the literature.[59,60] All the proposals for modified Unruh temperature obey

$$T_{mod} = \frac{\hbar a \left(1 + \psi \frac{l_P^2}{c^4} a^2\right)}{2\pi k_B c} + O\left(\frac{l_P^4 a^5}{c^8}\right), \tag{9}$$

where ψ denotes a model dependent real number that is expected to be of the order of unity.[59,60] A similar prescription has also been earlier proposed for modified Hawking temperature.[7,9,33] To our best knowledge, these modifications to temperature have not been confirmed by any rigorous method. However, since GUP phenomenologically implements effects of a minimal resolvable length that arises in a number of approaches to quantum gravity,[1,2] the idea of modified Unruh temperature is worth considering. Hence, to incorporate leading order quantum gravity corrections in thermodynamics of spacetime, we need to show that the previously outlined construction of Clausius entropy flux works with this modified temperature. Note that the previous reasoning does not apply directly, since in the limit $a \to \infty$ correction terms in the modified temperature formula become dominant. Instead, one must consider acceleration much larger than c^2/l but much smaller than $c^2/\sqrt{\psi} l_P$ (this can be satisfied for $l \gg l_P$, i.e., whenever the GLCD is much larger than the Planck scale). The construction of Clausius entropy flux under this assumption has been carried out by the authors,[11] yielding

$$\Delta S_{C,mod} = -\left(1 - \psi \frac{l_P^2 a^2}{c^4}\right) \frac{2\pi k_B c}{\hbar} \int_0^{l/c} t \left(\int_{\mathcal{S}(t)} T_{\mu\nu} k^\mu k^\nu \mathrm{d}^2\mathcal{A} \right) \mathrm{d}t + O\left(l^5, \frac{l_P^4 a^4}{c^8}, \frac{1}{a^2}\right). \tag{10}$$

The only difference with respect to the semiclassical formula are the a-dependent sub-leading terms. We can recover it by setting $\psi = 0$ and then taking the limit $a \to \infty$. Let us note that while we assumed finite acceleration simply for mathematical convenience, the limit $a \lesssim c^2/\sqrt{\psi} l_P$ agrees quite well with the proposal of an upper limit to acceleration a_M set by quantum gravity effects, $a_M = c^2/l_P$.[61]

2.4. *Von Neumann entropy of the matter*

To be consistent with the entanglement interpretation of the entropy of GLCD's horizon, one should consider quantum von Neumann entropy of the matter rather than the thermodynamic Clausius one. For small variations from vacuum, this entropy can be obtained from the vacuum state density operator, $\rho = e^{-K/k_B T_\zeta}/Z$, where Z is the partition function, T_ζ denotes the previously defined temperature associated with conformal Killing vector ζ^μ and K is known as the modular Hamiltonian.[42] While variations of K can in general be non-local, for conformal fields they correspond to variations of the local matter Hamiltonian[42]

$$\delta H = \int_{\Sigma_0} \delta \langle T_{\mu\nu} \rangle \xi^\mu n^\nu \mathrm{d}^2\Omega \mathrm{d}r, \tag{11}$$

where $n = \partial/\partial t$. Then, the variation of entropy reads

$$\delta S_m = \frac{1}{T}\delta K = \frac{2\pi k_B}{\hbar c}\frac{4\pi l^4}{15}\delta\langle T_{00}\rangle + O\left(l^5\right). \tag{12}$$

For non-conformal field theories with a UV fixed point, the von Neumann entropy variation is modified only by the presence of an additional l-dependent spacetime scalar, δX,[19,62,63]

$$\delta S_m = \frac{2\pi k_B}{\hbar c}\frac{4\pi l^4}{15}\left(\delta\langle T_{00}\rangle + \delta X\right). \tag{13}$$

In our study concerning the quantum gravity corrections, we have gone beyond the semiclassical case just by including modifications to the temperature[11] (in a future work we plan to analyse possible corrections to the modular Hamiltonian). Implementing the leading order quantum gravity modification to temperature gives rise to the following modified variation of matter von Neumann entropy

$$\delta S_{m,mod} = \frac{2\pi k_B c}{\hbar}\frac{4\pi}{15}l^4\left(\delta\langle T_{00}\rangle + \delta X\right)\left(1 - \psi l_P^2\kappa^2\right) + O\left(l^5\right). \tag{14}$$

Note that for the particular case $\psi = 0$ we straightforwardly recover the semiclassical expression.

2.5. *Entropy equivalence*

Assuming the entanglement interpretation of Bekenstein entropy, the natural equilibrium condition for the GLCD involves von Neumann entropy of the matter. To consider the Clausius entropy instead, its equivalence with the von Neumann entropy is necessary. This condition requires that fluxes of Clausius and von Neumann entropy of matter across the horizon are equal with sufficient precission. Since the von Neumann entropy is defined for the geodesic ball Σ_0 corresponding to $t = 0$, the meaningful quantities to compare are time derivatives of both entropies evaluated at $t \ll l/c$ (at precisely $t = 0$ the entropy fluxes vanish). We start by considering conformal fields. For the time derivative Clausius entropy we have[36]

$$\frac{\mathrm{d}S_C}{\mathrm{d}t}(t) \approx -\frac{32\pi^2 k_B c}{3\hbar}tl^2 T_{00}, \tag{15}$$

while the time derivative of the von Neumann entropy reads[36]

$$\frac{\mathrm{d}S_m}{\mathrm{d}t} \approx -\frac{32\pi^2 k_B c}{3\hbar}tl^2\delta\langle T_{00}\rangle. \tag{16}$$

Both expressions are indeed equivalent, making the use of Clausius entropy in thermodynamics of spacetime justified for conformal fields. Note that the argument in no way involves gravitational dynamics.

The situation becomes more complicated for non-conformal matter as the previously outlined approach cannot be directly applied to formulas for the von Neumann

entropy.[62,63] Nevertheless, semiclassical gravitational dynamics derived from Clausius and von Neumann entropy are equivalent even in this case,[17,19,36] suggesting that both entropies are at least strongly related.

When low energy quantum gravity effects on the temperature are taken into account, we find for conformal fields

$$\frac{\mathrm{d}S_C}{\mathrm{d}t}(t) \approx -\frac{32\pi^2 k_B c}{3\hbar}\left(1-\psi\frac{l_P^2}{c^4}a^2\right) tl^2 T_{00}, \tag{17}$$

and

$$\frac{\mathrm{d}S_m}{\mathrm{d}t} \approx -\frac{32\pi^2 k_B c}{3\hbar}\left(1-\psi l_P^2\kappa^2\right) tl^2 \delta\langle T_{00}\rangle. \tag{18}$$

Both formulas are equivalent only for a special value of the surface gravity, $\kappa = a/c^2$. Since we are not aware of any way to motivate a specific choice of κ, and a needs to be very large, $a \gg c^2/l$, we cannot say anything conclusive about the equivalence of both entropies. We will return to this question after we introduce the modified gravitational dynamics.

3. Effective low energy quantum gravity dynamics

Upon presenting the various notions of entropy involved, we proceed to discuss our proposal for the effective low energy quantum gravitational dynamics. Details of the derivation can be found in the original paper of the authors;[11] here we just briefly recall the main points. For the sake of comparison, we employed two different thermodynamic derivations. The first one, known as the physical process approach, keeps track of the Clausius entropy flux across the horizon and the corresponding changes in its Bekenstein entropy. Equilibrium condition for this process reads $\Delta S_{e,q} + \Delta S_C = 0$, where the Clausius entropy flux contribution, ΔS_C, was discussed in the previous section. The Bekenstein entropy part, $\Delta S_{e,q}$, can be evaluated from the formula for area of GLCD's boundary cross-section introduced in subsection 2.1. After a series of calculations (see[11] for details), we obtain the modified equations of motion

$$S_{\mu\nu} - \frac{\mathcal{C}l_P^2}{18\pi} S_{\mu\lambda} S^{\lambda}{}_{\nu} + \frac{\mathcal{C}l_P^2}{72\pi}\left(R_{\kappa\lambda}R^{\kappa\lambda} - \frac{1}{4}R^2\right) g_{\mu\nu} = \frac{8\pi G}{c^4}\left(T_{\mu\nu} - \frac{1}{4}T g_{\mu\nu}\right), \tag{19}$$

where $S_{\mu\nu} = R_{\mu\nu} - R g_{\mu\nu}/4$ denotes the traceless part of Ricci tensor. The derivation works for GLCD's length scale l much larger than the Planck length but much smaller than the curvature length scale (square root of the inverse of the largest eigenvalue of the Riemann tensor).

The second method to derive the modified equations of motion starts from the entanglement equilibrium hypothesis: "When the geometry and quantum fields are simultaneously varied from maximal symmetry, the entanglement entropy in a small geodesic ball is maximal at fixed volume".[19] For a small variation from a maximally symmetric spacetime the hypothesis implies $\delta S_{e,q} + \delta S_m = 0$, where δS_m denotes the

variation of matter von Neumann entropy. From here, calculations proceed similarly as for the physical process approach, yielding[11]

$$S_{\mu\nu} - \frac{\mathcal{C} l_{Pl}^2}{30\pi} S_{\mu\lambda} S^{\lambda}{}_{\nu} + \frac{\mathcal{C} l_{Pl}^2}{120\pi} \left(R_{\kappa\lambda} R^{\kappa\lambda} - \frac{1}{4} R^2 \right) g_{\mu\nu} = \frac{8\pi G}{c^4} \left(\delta \langle T_{\mu\nu} \rangle - \frac{1}{4} \delta \langle T \rangle g_{\mu\nu} \right). \tag{20}$$

Notably, in neither derivation does the form of modified temperature affect the resulting equations. This is expected as definitions of both Hawking and Unruh temperature (even modified ones) are purely kinematic with no dependence on gravitational dynamics.[64] The correction terms are thus fully determined by the logarithmic contribution to Bekenstein entropy and they depend only on one presently unknown parameter, $\mathcal{C}$.

Comparing the results of both approaches, we can see that the equations have the same form, although coefficients in front of the terms quadratic in curvature differ. We can write both equations in a common form

$$S_{\mu\nu} - D l_P^2 S_{\mu\lambda} S^{\lambda}{}_{\nu} + \frac{D}{4} l_P^2 \left(R_{\kappa\lambda} R^{\kappa\lambda} - \frac{1}{4} R^2 \right) g_{\mu\nu} = \frac{8\pi G}{c^4} \left(\langle T_{\mu\nu} \rangle - \frac{1}{4} \langle T \rangle g_{\mu\nu} \right), \tag{21}$$

with $D = \mathcal{C}/18\pi$ for the physical process approach and $D = \mathcal{C}/30\pi$ for the entanglement equilibrium hypothesis one. In both cases, the coefficient D has the same sign and differs only by a factor 3/5. The difference might be due to the details of the variation considered in the entanglement equilibrium hypothesis derivation, which is performed at fixed spatial volume.[11,19] Since, for modified theories of gravity, a more complicated quantity known as generalised volume needs to be held fixed instead,[21] finding the appropriate generalised volume in our case could account for the difference in D between both approaches. Alternatively, it might indicate a failure on the equivalence between Clausius and von Neumann entropy of the matter at this level (although, given the similarity of the results, both entropies would have to remain closely related).

Upon reviewing the two derivations of the modified equations of motion, we proceed to discus their properties (for a more detailed treatment, see[11]). First, note that while the value and even the sign of $\mathcal{C}$ is model dependent, any possible value can be viewed as being of the order of unity compared to the squared Planck length, $l_P^2 \approx 2.6 \times 10^{-70}\,\mathrm{m}^2$. Therefore, the correction terms become relevant only when the curvature length scale nears the Planck length (although it needs to remain significantly larger than l_P, otherwise the assumptions of our derivation will break down).

As a second property, it is easy to check that the modified equations are traceless. Hence, they do not imply local energy-momentum conservation. If we want to assume it, we must impose divergence-free energy-momentum tensor, $\langle T_{\mu}{}^{\nu} \rangle_{;\nu} = 0$, as an additional condition. Satisfying it requires

$$\frac{1}{4} R_{;\mu} - D l_P^2 \left(S^{\lambda\nu} S_{\mu\lambda} \right)_{;\nu} + \frac{D l_P^2}{2} \left(R^{\kappa\lambda} R_{\kappa\lambda;\mu} - \frac{1}{4} R R_{;\mu} \right) = -\frac{2\pi G}{c^4} \langle T \rangle_{;\mu}. \tag{22}$$

This condition does not have a general solution for T. Therefore, in general, the equations of motion cannot be recast in a form directly implying a divergence-free energy-momentum tensor. Nevertheless, the condition can be solved for spacetimes with a vanishing Weyl tensor. In that case, the cosmological constant, absent in the traceless equations of motion, appears as an arbitrary integration constant.

Third, while any terms containing higher than fourth derivatives of the metric or more than quadratic in curvature tensors are likely suppressed by higher powers of l_P, the higher derivative terms known from quadratic gravity should appear at the same order as the corrections we propose. They implicitly appear on the right hand side of modified equations in the quantum expectation value of the energy-momentum tensor.[65] In principle, one might also find higher derivative contributions to the left hand side by considering higher orders in the Riemann normal coordinate expansion of the metric. However, these corrections are ambiguous as they depend on shape deformations of the GLCD's horizon.[40] Without a physically motivated way to resolve these ambiguities, it is not possible to determine higher derivative terms contributing to the left hand side of the equations. Since these terms are anyway contained with undetermined coefficients on the right hand side, in the energy-momentum tensor expectation value, their omission on the left hand side does not change the resulting dynamics in any significant way.

Traceless equations of motion and the status of cosmological constant as an arbitrary integration constant both point out to the modified dynamics being a generalisation of unimodular gravity (or, more precisely, Weyl transverse gravity[66]). In fact, even the semiclassical gravitational dynamics derived from thermodynamics has more in common with unimodular gravity than general relativity.[25,36,67] We can partially understand the emergence of unimodular gravity from thermodynamics by noting that only the difference between entropy of two states is relevant for deriving the gravitational dynamics. In other words, vacuum contribution to matter entanglement entropy does not affect the conditions for thermodynamic equilibrium. Consequently, vacuum energy naturally does not couple to gravity, leading to the behaviour of the cosmological constant characteristic for unimodular gravity. Furthermore, thermodynamics of spacetime do not imply local energy-momentum conservation, which always needs to be postulated as an additional condition, again in agreement with unimodular gravity.

3.1. *Application to a cosmological toy model*

To illustrate the physical consequences of the modified dynamics, we examine a simple cosmological toy model, a homogeneous, isotropic, spatially flat universe filled with a perfect fluid with the equation of state $p = (\gamma - 1)\, c^2 \rho$ for some $\gamma \in [1, 2]$ (the limits correspond to dust and stiff matter, respectively). Due to previously noted unimodular character of the equations, we consider a unimodular form of the

Friedmann-Lemaître-Robertson-Walker (FLRW) metric

$$\mathrm{d}s^2 = -\frac{c^2}{a\left(t\right)^6}\mathrm{d}t^2 + a\left(t\right)^2\left(\mathrm{d}r^2 + r^2\mathrm{d}\Omega^2\right), \tag{23}$$

where $a\left(t\right)$ denotes the scale factor. Because of the symmetries of the metric, the modified equations of the motion yield only one non-trivial condition

$$\dot{H} - D\frac{l_P^2\dot{H}^2}{c^2} = -4\pi\gamma G\rho, \tag{24}$$

where $H = \dot{a}/a$ is the Hubble parameter and the dot denotes a time derivative. This condition corresponds to a modified Raychaudhuri equation, with a correction term, $-Dl_P^2\dot{H}^2/c^2$, non-linear in second time derivatives of the scale factor. To simplify it, we assume that the Hubble parameter corresponds to its classical value H_0 up to $O\left(l_P^2\right)$ terms (validity of this assumption is extensively discussed in[11]),

$$H = H_0 + l_P^2 H_1 + O\left(l_P^4\right), \tag{25}$$

and rewrite the modified Raychaudhuri equations in the following way

$$\dot{H} = -4\pi\gamma G\rho\left(1 - 4\pi D\gamma\frac{\rho}{\rho_P}\right), \tag{26}$$

where $\rho_P = \sqrt{c^5/G^2\hbar}$ denotes the Planck density. If we further assume local energy-momentum conservation, we can integrate the modified Raychaudhuri equation to obtain the modified Friedmann equation

$$H^2 = \frac{8\pi G\rho}{3}\left(1 - \frac{2\pi D\gamma\rho}{\rho_P}\right) + \tilde{\Lambda}, \tag{27}$$

where $\tilde{\Lambda}$ is an arbitrary integration constant corresponding to the cosmological term ($\tilde{\Lambda} = \Lambda c^2/3$). We see that the appearance of cosmological constant is indeed consistent with unimodular gravity.

Notably, for $D > 0$, our results correspond to the effective description of loop quantum cosmology (LQC).[68] Since effective dynamics of LQC replaces the Big Bang singularity by a non-singular quantum bounce, the same conclusion holds for our modified equations of motion assuming $D > 0$. The bounce corresponds to a critical density, $\rho_{crit} = \rho_P/2\pi D\gamma$. In other words, if the logarithmic correction to Bekenstein entropy of a GLCD is positive, the resulting modifications of the dynamics are already sufficient to remove the cosmological singularity. On the other hand, the case of $D < 0$ appears to not only preserve the singularity, but actually strengthen the gravitational attraction responsible for it. These preliminary results warrant a more detailed analysis of cosmological models and possible values for parameter D.

4. Discussion

In the present work we have first reviewed the issue of entropy equivalence in thermodynamics of spacetime. For conformal fields in the semiclassical regime, Clausius and von Neumann entropy turn out to be equivalent in the semiclassical regime independently of the gravitational dynamics, although a similar clear result is not available for non-conformal fields.

Then, we proceeded to review our proposal for a new phenomenological perspective on the effects of quantum gravity at low energies. The effective low energy quantum gravitational dynamics we have proposed is based on a single assumption: leading order quantum gravity correction to entropy associated with spherical local causal horizons is logarithmic in the horizon area. Since a number of conceptually different approaches predict such a logarithmic term (at the very least in the case of black hole entropy), our conclusions are fairly robust and relevant to many candidate theories of quantum gravity, e.g. LQG, string theory, AdS/CFT correspondence and GUP phenomenology.

Let us remark that the equations we found are a generalisation of the classical equations of motion of unimodular gravity and cannot even be restated as some generalised Einstein equations. This agrees with our previous results concerning the relation between thermodynamics of spacetime and unimodular gravity in the semiclassical setting. It does appear that the corrections we propose break the equivalence of unimodular gravity and general relativity that holds on the level of classical dynamics.

Our results also extend the semiclassical equivalence between Clausius and entanglement entropies. While they suggest a possible breaking of the exact equivalence on the quantum level, both entropies remain strongly related. Their precise relation should be analysed carefully in a future work. Importantly, a more systematic inclusion of quantum gravity effects on matter entropy will be necessary to completely resolve this issue.

Note that our approach still requires further development. First, issues of diffeomorphism invariance, equivalence principle and locality of the modified dynamics previously discussed by the authors[11] need to be addressed in greater detail. Moreover, the apparent breaking of local energy conservation requires a physically motivated explanation. Relating our proposal to other modified gravity theories might shed some light on all these questions. In particular, our effective equations of motion resemble the 4-dimensional version of Einstein-Gauss-Bonnet gravity[69, 70] and non-local effective field theory of gravity.[71] The latter approach even leads to logarithmic term in Bekenstein entropy consistent with our assumptions.[32]

Another possible further development of our results lies in a careful inclusion of higher order Riemann normal coordinate corrections in the analysis in order to obtain higher derivative terms on the left hand side. Similarly, accounting for low energy quantum gravity effects on the entropy of matter might lead to interesting conclusions.

Furthermore, we have seen that the modified dynamics resolve the Big Bang singularity only if the logarithmic correction to entropy of a GLCD is positive, i.e., $D > 0$. To find which approaches to quantum gravity support this sign and what are the bounds on the magnitude of D they imply would help to constrain the physical implications of our proposal.

Lastly, the emergence of unimodular (Weyl transverse) gravity from thermodynamics needs to be better understood even in the semiclassical case. The first steps in this direction include developing rigorous formalism for thermodynamics of spacetime in the Weyl transverse gravity and connecting Weyl invariance of gravitational dynamics with properties of entropy. All these issues will be addressed in future works.

Gauge theory of gravity based on the correspondence between the 1^{st} and the 2^{nd} order formalisms

David Benisty

DAMTP, Centre for Mathematical Sciences, University of Cambridge, Wilberforce Road, Cambridge CB3 0WA, UK

Institute of Astronomy, University of Cambridge, Madingley Road, Cambridge, CB3 0HA, UK

A covariant canonical gauge theory of gravity free from torsion is studied. Using a metric conjugate momentum and a connection conjugate momentum, which takes the form of the Riemann tensor, a gauge theory of gravity is formulated, with form-invariant Hamiltonian. By the metric conjugate momenta, a correspondence between the Affine-Palatini formalism and the metric formalism is established. For, when the dynamical gravitational Hamiltonian $\tilde{H}_{Dyn}$ does not depend on the metric conjugate momenta, a metric compatibility is obtained from the equation of motions, and the equations of motion correspond to the solution is the metric formalism.

Keywords: Gauge-Theory; Gravity; Hamiltonian formulation.

1. Introduction

General Relativity is one of the well tested theories in physics, with many excellent predictions. A search of a rigorous derivation of General Relativity on the basis of the action principle and the requirement that the description of any system should be form-invariant under general space time transformations has been constructed in the framework of the Covariant Canonical Gauge theory of Gravity.

The Covariant Canonical Gauge theory of Gravity[1,2] is formulated within the framework of the covariant Hamiltonian formalism of classical field theories. The latter ensures by construction that the action principle is maintained in its form requiring all transformations of a given system to be canonical. The imposed requirement of invariance of the original action integral with respect to local transformations in curved space time is achieved by introducing additional degrees of freedom, the gauge fields. In the basis of the formulation there are two independent fields: the metric $g^{\alpha\beta}$, which contains the information about lengths and angles of the space time, and the connection $\gamma^{\lambda}_{\alpha\beta}$, which contains the information how a vector transforms under parallel displacement. In this formulation, these two fields are assumed to be independent dynamical quantities in the action and referred to as the Affine-Palatini formalism (or the 1^{st} order formalism).

Using the structure of metric and the affine connection independently, with their conjugate momenta, yields a new formulation of gauge theories of gravity. In[1] the discussion was with the presence of torsion, and here we discuss about the formulation with no torsion from the beginning, that has a link between the metric affine and the metric formalism.[3]

2. A basic formulation

The Covariant Canonical Gauge theory of Gravity is a well defined formulation derived from the canonical transformation theory in the covariant Hamiltonian picture of classical field theories.[1] It identifies two independent fundamental fields, which form the basis for a description of gravity: the metric $g^{\alpha\beta}$ and the connection $\gamma^{\lambda}_{\alpha\beta}$. In the Hamiltonian description, any fundamental field has a conjugate momentum: the metric conjugate momentum is $\tilde{k}^{\alpha\lambda\beta}$ and the connection conjugate momentum is $\tilde{q}^{\alpha\xi\beta}_{\eta}$:

$$S = \int_R \left(\tilde{k}^{\,\alpha\lambda\beta}\, g_{\alpha\lambda,\beta} - \frac{1}{2}\tilde{q}^{\alpha\xi\beta}_{\eta}\gamma^{\eta}_{\alpha\xi,\beta} - \tilde{\mathcal{H}}_0 \right) d^4x \tag{1}$$

where the "tilde" sign denotes a tensor density, which multiplies the tensor with $\sqrt{-g}$. As the conjugate momentum components of the fields are the duals of the complete set of the derivatives of the field, the formulation is referred to as "covariant canonical". A closed description of the coupled dynamics of fields and space-time geometry has been derived in,[1] where the gauge formalism yields:

$$S = \int_R \left(\tilde{k}^{\,\alpha\lambda\beta}\, g_{\alpha\lambda;\beta} - \frac{1}{2}\tilde{q}^{\alpha\xi\beta}_{\eta}R^{\eta}_{\alpha\xi\beta} - \mathcal{H}(\tilde{q},\tilde{k},g) \right) d^4x \tag{2}$$

As a result of the gauge procedure, all partial derivatives of tensors in Eq. (1) reappear as covariant derivatives. The partial derivative of the (non-tensorial) connection changes into the tensor $R^{\eta}_{\alpha\xi\beta}$, which was shown to be the Riemann-Christoffel curvature tensor:

$$R^{\eta}_{\alpha\xi\beta} = \frac{\gamma^{\eta}_{\alpha\beta}}{x^{\xi}} - \frac{\gamma^{\eta}_{\alpha\xi}}{x^{\beta}} + \gamma^{\tau}_{\alpha\beta}\gamma^{\eta}_{\tau\xi} - \gamma^{\tau}_{\alpha\xi}\gamma^{\eta}_{\tau\beta}. \tag{3}$$

The "dynamics" Hamiltonian $\tilde{H}_{Dyn}$ — which is supposed to describe the dynamics of the free (uncoupled) gravitational field — is to be built from a combination of the metric conjugate momentum, the connection conjugate momentum, and the metric itself.

3. A correspondence between the 1^{st} and the 2^{nd} order formalism

In addition to the foundations of the gauge theory of gravity, it turned out that the part of the action: $\tilde{k}^{\alpha\beta\gamma}g_{\alpha\beta;\gamma}$, which contains the metric conjugate momentum, has a strong impact as a connector between the affine-Palatini formalism (or the 1^{st} order formalism) and the metric formalism (or the 2^{nd} order formalism):

$$\mathcal{L}(g,\gamma)_{\,1^{\mathbf{order}}} + k^{\alpha\beta\gamma}g_{\alpha\beta;\gamma} \Leftrightarrow \mathcal{L}(g)_{\,2^{\mathbf{order}}} \tag{4}$$

In the 1^{st} order formalism, one assumes that there are two independent fields: the metric $g^{\mu\nu}$ and the connection $\gamma^{\mu}_{\alpha\beta}$. In contrast to that, in the 2^{nd} order formalism the connection is assumed to be the Levi Civita or Christoffel symbol:

$$\gamma^{\rho}_{\mu\nu} = \left\{ \begin{matrix} \rho \\ \mu\nu \end{matrix} \right\} = \frac{1}{2}g^{\rho\lambda}(g_{\lambda\mu,\nu} + g_{\lambda\nu,\mu} - g_{\mu\nu,\lambda}) \tag{5}$$

and appears in the action directly in this way. In general, only for Lovelock theories, which includes Einstein Hilbert action, both formulations will yield the same equations of motion and the connection will be in both cases the Christoffel symbol. In Ref,[3] it was proved that for any general action which starts in the 1^{st} order formalism in addition to the term $k^{\alpha\beta\gamma}g_{\alpha\beta;\gamma}$ the energy momentum tensor will be the same as it would be calculated in the 2^{nd} order formalism. The main reason for that correspondence is the metric compatibility constraint. The variation with respect to $k^{\alpha\beta\gamma}$ gives the metricity condition:

$$g_{\alpha\beta;\gamma} = 0 \quad \Rightarrow \quad \gamma^{\rho}_{\mu\nu} = \left\{ \begin{array}{c} \rho \\ \mu\nu \end{array} \right\}, \tag{6}$$

which cause the connection to be the Christoffel symbol. The variation with respect to the connection gives the tensors:

$$\frac{\delta}{\delta\gamma^{\rho}_{\mu\nu}} k^{\alpha\beta\gamma} g_{\alpha\beta;\gamma} = -k^{\alpha\mu\nu} g_{\rho\alpha} - k^{\alpha\nu\mu} g_{\rho\alpha} \tag{7}$$

with a symmetrization between the components μ and ν. The variation with respect to the metric is:

$$\frac{\delta}{\delta g_{\mu\nu}} k^{\alpha\beta\gamma} g_{\alpha\beta;\gamma} = -k^{\mu\nu\lambda}_{;\lambda}. \tag{8}$$

Because of the new contribution to the field equation $k^{\mu\nu\lambda}_{;\lambda}$, the complete field equation will contains additional terms which make the first order field equations to be equivalent to the field equation under the second order formalism. Indeed, isolating the tensor $k^{\mu\nu\lambda}$ and inserting it back into Eq. (8) gives the relation:

$$\frac{\partial \mathcal{L}(\kappa)}{\partial g_{\sigma\nu}} = \frac{1}{2}\nabla_{\mu}\left(g^{\rho\sigma}\frac{\partial \mathcal{L}(\kappa)}{\partial \gamma^{\rho}_{\mu\nu}} + g^{\rho\nu}\frac{\partial \mathcal{L}(\kappa)}{\partial \gamma^{\rho}_{\mu\sigma}} - g^{\rho\mu}\frac{\partial \mathcal{L}(\kappa)}{\partial \gamma^{\rho}_{\nu\sigma}} \right) \tag{9}$$

where $\mathcal{L}(\kappa) = k^{\alpha\beta\gamma}g_{\alpha\beta;\gamma}$. The terms in the right hand side represents the additional terms that appear in the second order formalism. One option for obtain the contributions into the field equation is to solve $k^{\alpha\beta\gamma}$. The direct way is by using this equation, that gives the new contributions for the second order formalism into the field equation, from the variation with respect to the connection $\gamma^{\rho}_{\mu\nu}$. An application for this correspondence is from the Covariant Canonical Gauge theory of gravity action (2).

4. Path to Gauge theories

From the correspondence between the 1^{st} and the 2^{nd} order formalisms theorem, we obtain a basic link between the dependence of the $\mathcal{H}_{\mathbf{Dyn}}$ with the metric conjugate momentum $\tilde{k}^{\alpha\beta\gamma}$ and the structure of the metric energy momentum tensor. In the first case, $\mathcal{H}_{\mathbf{Dyn}}$ does not depend on the metric conjugate momentum $\tilde{k}^{\alpha\beta\gamma}$. A variation with respect to the metric conjugate momentum $\tilde{k}^{\alpha\beta\gamma}$ gives the metric compatibility condition. According to the theorem (4) the gravitational energy momentum tensor is the same as the gravitational energy momentum tensor in the

second order formalism. In the second case $\mathcal{H}_{\mathbf{Dyn}}$ does depend on the metric conjugate momentum $\tilde{k}^{\alpha\beta\gamma}$. A variation with respect to the metric conjugate momentum $\tilde{k}^{\alpha\beta\gamma}$ breaks the metric compatibility condition. This basic framework is not a special feature only for the Covariant Canonical Gauge Theory of Gravity, but leads to a fundamental correlation for many options of $\mathcal{H}_{Dyn}$.

In analogy to the definition of the metric energy-momentum tensor density of the given system Hamiltonian, the metric energy-momentum tensor density is being define as the variation of the $\tilde{\mathcal{L}}_m$ with respect to the metric:

$$T^{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\partial\tilde{\mathcal{L}}_m}{\partial g_{\mu\nu}} \tag{10}$$

Therefore the complete action takes the form:

$$\tilde{\mathcal{L}} = \tilde{k}^{\alpha\beta\gamma}g_{\alpha\beta;\gamma} - \frac{1}{2}\tilde{q}^{\alpha\beta\gamma}_{\lambda}R^{\lambda}_{\alpha\beta\gamma} - \tilde{\mathcal{H}}_{\mathbf{dyn}}(\tilde{q},\tilde{k},g) + \tilde{\mathcal{L}}_m \tag{11}$$

The variation with respect to the metric conjugate momenta:

$$g_{\alpha\beta;\gamma} = \frac{\partial\tilde{H}_{\mathbf{Dyn}}}{\partial\tilde{k}^{\alpha\beta\gamma}} \tag{12}$$

which presents the existence of non-metricity if $\mathcal{H}_{Dyn}$ depends on $k^{\alpha\beta\gamma}$. The second variation is the variation with respect to the connection:

$$-\left(\tilde{k}^{\alpha\mu\nu} + \tilde{k}^{\alpha\nu\mu}\right)g_{\alpha\rho} = \frac{1}{2}\nabla_{\beta}\left(\tilde{q}^{\mu\beta\nu}_{\rho} + \tilde{q}^{\nu\beta\mu}_{\rho}\right), \tag{13}$$

which contracts the relation between the momenta of the metric and the connection. The third variation is with respect to the connection conjugate momentum $\tilde{q}^{\mu\nu\rho}_{\sigma}$, which gives:

$$\frac{\partial\tilde{H}_{\mathbf{Dyn}}}{\partial\tilde{q}^{\mu\nu\rho}_{\sigma}} = -\frac{1}{2}R^{\sigma}_{\mu\nu\rho} \tag{14}$$

If $\tilde{H}_{\mathbf{Dyn}}$ is not depend on $\tilde{q}$, the Riemann tensor will be zero. Therefore the contribution for the stress energy tensor comes from the Dynamical Hamiltonian and from the metric conjugate momenta:

$$T^{\mu\nu} = g^{\mu\nu}(k^{\alpha\beta\gamma}g_{\alpha\beta;\gamma} - \frac{1}{2}q^{\alpha\beta\gamma}_{\lambda}R^{\lambda}_{\alpha\beta\gamma}) - 2k^{\mu\nu\gamma}_{;\gamma} + \frac{2}{\sqrt{-g}}\frac{\partial\tilde{\mathcal{H}}_{\mathbf{Dyn}}}{\partial g_{\mu\nu}} \tag{15}$$

From the variation with respect the connection (13), the value of the momentum $\tilde{k}^{\alpha\beta\gamma}$. As an example, we consider a Dynamical Hamiltonian which has no dependence with the metric conjugate momentum.

5. Sample $\tilde{\mathcal{H}}_{\mathbf{dyn}}$ without breaking metricity

Our starting point is a dynamical Hamiltonian with the connection conjugate momentum up to the second order, without a dependence on the metric conjugate momentum:

$$\tilde{\mathcal{H}}_{\mathbf{dyn}} = \frac{1}{4g_1}\tilde{q}^{\alpha\epsilon\beta}_{\eta}q^{\eta\tau\lambda}_{\alpha}g_{\epsilon\tau}g_{\beta\lambda} - g_2\,\tilde{q}^{\alpha\tau\beta}_{\eta}g_{\alpha\beta}\delta^{\eta}_{\tau} + g_3\sqrt{-g} \tag{16}$$

This Hamiltonian was investigated in[4] under the original formalism for non-zero torsion (which is finally set to zero), and led to resolving the cosmological constant problem. In our case, assuming that there is no torsion, the formalism demands that the energy momentum tensor is covariantly conserved, as is supposed to be in the second order formalism.

The variation with respect to the metric conjugate momenta $\tilde{k}^{\alpha\beta\gamma}$ give the the metricity condition. The variation with respect to the connection conjugate momenta $\tilde{q}^{\mu\nu\rho}_{\sigma}$ gives

$$q_{\eta\alpha\epsilon\beta} = g_1 \left(R_{\eta\alpha\epsilon\beta} - \hat{R}_{\eta\alpha\epsilon\beta} \right) \tag{17}$$

where:

$$\hat{R}_{\eta\alpha\epsilon\beta} = g_2 \left(g_{\eta\epsilon} g_{\alpha\beta} - g_{\eta\beta} g_{\epsilon\alpha} \right) \tag{18}$$

refers to the ground state geometry of space-time which is the de Sitter (dS) or the anti-de Sitter (AdS) space-time for the positive or the negative sign of g_2, respectively. The last variation is with respect to the metric. In order to isolate the tensor $k^{\mu\nu\gamma}$ one can use the following process: First, we multiply by the metric $g^{\rho\sigma}$ and sum over the index σ:

$$-\tilde{k}^{\sigma\mu\nu} - \tilde{k}^{\sigma\nu\mu} = \frac{1}{2} \nabla_\alpha \left(\tilde{q}^{\ \sigma\mu\alpha\nu} + \tilde{q}^{\ \sigma\nu\alpha\mu} \right) \tag{19}$$

Switching the indices $\sigma \leftrightarrow \nu$ and the indices $\mu \leftrightarrow \nu$ gives a new combination of the $k^{\alpha\beta\gamma}$ tensor. By summing the Eqs. the isolated value gives:

$$-\tilde{k}^{\sigma\nu\mu} = \frac{1}{2} \nabla_\alpha \left(\tilde{q}^{\sigma\mu\alpha\nu} + \tilde{q}^{\nu\mu\alpha\sigma} \right) \tag{20}$$

Therefore, the contribution for the stress energy momentum comes from the covariant derivative of (20):

$$T^{\mu\nu} = -\frac{1}{2} g^{\mu\nu} q^{\alpha\beta\gamma}_{\lambda} R^{\lambda}_{\alpha\beta\gamma} + \nabla_\gamma \nabla_\alpha \left(q^{\mu\gamma\nu\alpha} + q^{\nu\gamma\mu\alpha} \right) + \frac{2}{\sqrt{-g}} \frac{\partial \tilde{\mathcal{H}}_{\mathbf{Dyn}}}{\partial g_{\mu\nu}} \tag{21}$$

Plugging in the value of the tensor $q_{\alpha\beta\gamma\delta}$ from Eq. (17) gives the result:

$$\begin{aligned} T^{\mu\nu} &= \frac{1}{8\pi G} G^{\mu\nu} + g^{\mu\nu} \Lambda \\ &+ g_1 \left(R^{\mu\alpha\beta\gamma} R^{\nu}_{\alpha\beta\gamma} - \frac{1}{4} g^{\mu\nu} R^{\alpha\beta\gamma\delta} R_{\alpha\beta\gamma\delta} + (\nabla_\alpha \nabla_\beta + \nabla_\beta \nabla_\alpha) R^{\mu\alpha\nu\beta} \right) \end{aligned} \tag{22}$$

where $G^{\mu\nu}$ is the Einstein tensor. The coupling constants relate to the physical quantities with the relations:

$$g_1 g_2 = \frac{1}{16\pi G}, \quad 6 g_1 g_2^2 + g_3 = \frac{\Lambda}{8\pi G} \tag{23}$$

This stress energy momentum tensor is exactly the same metric energy momentum tensor if our starting point was the effective Lagrangian:

$$\mathcal{L} = g_1 R^{\alpha\beta\gamma\delta} R_{\alpha\beta\gamma\delta} - \frac{1}{16\pi G} (R - 2\Lambda) \tag{24}$$

and the stress energy momentum tensor is the same stress energy momentum tensor for this Lagrangian in the second order formalism. One from the big benefits of this formulation is common in many gauge theories of gravity,[5] where the starting point is with additional variables with no higher derivatives in the action, and the equations of motion are equivalent to actions with higher derivatives of metric. In this specific case, the starting point is with the quartic momentum q and at the end is equivalent to an action with quadratic Riemann term.

6. Discussion

In this paper we investigated the formulation of the covariant canonical gauge theory of gravity free from torsion. Diffeomorphisms appear as canonical transformations. A tensor field which plays the role of the canonical conjugate of the metric is introduced. It enforces the metricity condition provided that the "Dynamics" Hamiltonian does not depend on this field. The resulting theory has a direct correspondence with our recent work concerning the correspondence between the first order formalism and the second order formalism through the introduction of a Lagrange multiplier field which in this case corresponds with the field that is used to provide the metric with a canonically conjugate momentum. The procedure is exemplified by using a "Dynamics" Hamiltonian which consists of a quadratic term of the connection conjugate momentum. The effective stress energy momentum tensor that emerged from the canonical equations of motion were equivalent to Einstein Hilbert tensor in addition to quadratic term.[6] derives the complete combination for the quadratic theories of gravity with R^2 and $R_{\mu\nu}R^{\mu\nu}$.[7] derives inflation from fermios based on the Covariant Canonical Gauge theories of Gravity approach to spinors.[8]

In this work we made use of a general static cillindrically symmetric metric to find $U(1)$ local cosmic string solutions in the context of the hybrid metric-Palatini theory of gravity in it's scalar-tensor representation. After finding the dynamical equations for this particular case, we imposed boost invariance along t and z directions, which simplified the equations of motions, leaving only one single metric tensor component, $W^2(r)$. For an arbitrary potential $V(\phi)$, the solutions obtained can be put in a closed parametric form, with ϕ taken as a parameter. Several particular cases of the potential were studied, some yielding simple mathematical forms, others with only numerical solutions. In this way, we obtain a large class of novel stable stringlike solutions in the context of hybrid metric-Palatini gravity, in which the basic parameters, such as the scalar field, metric tensor components, and string tension, depend essentially on the initial values of the scalar field, and of its derivative, on the $r(0)$ circular axis.

Keywords: Cosmic Strings, Modified Gravity, hybrid metric-Palatini theory

1. Introduction

The recent observation of the accelerated expansion of the Universe[1] brought an identity crisis upon the standard theory of gravity, General Relativity. Albeit being a well established theory, with several important experimental confirmations, there is now a wide agreement that General Relativity may be, at the very least, an incomplete theory.[2] Not only due to the observations that demand the introduction of a Dark Sector to the energy budget of the Universe, but also due to theoretical difficulties, namely the existence of mathematical singularities and the non-quantization of the theory.[3] All of these issues paved the way to more general theories for gravitation, focusing on solving some of these problems, or at least to be used to falsify the theory. Lovelock's theorem[4] is a crucial roadmap to this quest,

as it establishes the GR equations as the only possible solution (minus constant factors), if one assumes the same conditions Einstein followed when he proposed the theory. In order to produce a viable modified gravity theory, at least one of the assumptions must be broken.

The hybrid metric-Palatini theory was proposed by Capozzielo, Harko, Koivisto, Lobo and Olmo in 2011[5] in order to overcome the difficulties faced by $f(R)$ theories of gravity and successfully unifies the late-time cosmic acceleration period with the weak-field solar system dynamics without the need for chameleon mechanisms.[5] For a more in-depth review of the theory, we refer the reader to the review article.[6] In this theory, the connection is considered an independent dynamical variable, adding to the metric.

Cosmic strings are one of the possible topological defects formed after spontaneous symmetry breaking (SSB) during phase transitions in the history of the Universe. In fact, many grand unification theories (GUTs) postulate that the universe, as it cooled, underwent a series of phase transitions associated with SSB, meaning that at sufficiently high temperatures there was invariance under a more general group of symmetries. Each of these phase transitions may have left behind a network of topological defects, through the Kibble-Zurek mechanism. For a more in depth review of topological defects, we refer the reader to Ref. 7.

The type of strings to be considered in this work are local $U(1)$ cosmic strings, which are an extension of the global $U(1)$ strings to include gauge fields. Local strings differ from the global cosmic strings in what concerns the symmetry that is effective above the spontaneous breaking scale; in the case of local strings, the lagrangian remains invariant under local transformations of the type $\phi(x) \longrightarrow e^{i\alpha(x)}\phi(x)$.

The study of the properties and dynamics of cosmic strings in the context of modified theories of gravity is crucial in the advent of powerful observatories, such as LISA, as it may allow us to constrain both Modified Gravity theories and Grand Unified theories.

2. Hybrid metric-Palatini gravity

In this hybrid regime, the metric and Palatini approaches are combined, by adding a new term, $f(\mathcal{R})$ to the Einstein-Hilbert action:

$$S = \frac{1}{2\kappa^2}\int \sqrt{-g}\; d^4x\;\left[R + f(\mathcal{R}) + \mathcal{L}_m\right]. \tag{1}$$

where $\mathcal{R}$ is the Ricci-Palatini scalar, the geometrical analogous to the Ricci scalar, constructed in terms of an independent connection, $\hat{\Gamma}$:

$$\mathcal{R}_{\mu\nu} = \partial_\alpha \hat{\Gamma}^\alpha_{\mu\nu} - \partial_\nu \hat{\Gamma}^\alpha_{\mu\alpha} + \hat{\Gamma}^\alpha_{\alpha\beta}\hat{\Gamma}^\beta_{\mu\nu} - \hat{\Gamma}^\alpha_{\mu\beta}\hat{\Gamma}^\beta_{\alpha\nu}. \tag{2}$$

$$\mathcal{R} = g^{\mu\nu}\mathcal{R}_{\mu\nu} \tag{3}$$

In this theory we have two dynamical variables, the metric and the (independent) connection. And so, we apply variation calculations of the action with respect to both.

Varying (1) with respect to the metric, $g_{\mu\nu}$ we obtain

$$G_{\mu\nu} + \frac{df}{d\mathcal{R}}\mathcal{R}_{\mu\nu} - \frac{1}{2}f(\mathcal{R})g_{\mu\nu} = \kappa^2 T_{\mu\nu} \tag{4}$$

where $T_{\mu\nu}$ is the energy-momentum tensor defined, as usual, as:

$$T_{\mu\nu} \equiv -\frac{2}{\sqrt{-g}}\frac{\delta(\sqrt{-g}\mathcal{L}_m)}{\delta(g^{\mu\nu})} \tag{5}$$

When we perform the variation of the action (1) with respect to the independent connection, $\hat{\Gamma}$, the resulting equation is:

$$\hat{\nabla}_\alpha = \left(\sqrt{-g}\frac{df}{d\mathcal{R}}g^{\mu\nu}\right) \tag{6}$$

which has an interesting feature: if we consider a metric conformally related to $g_{\mu\nu}$ by a $\frac{df}{d\mathcal{R}}$ factor, $h_{\mu\nu} = \frac{df}{d\mathcal{R}}g_{\mu\nu}$, equation (6) implies that the independent connection $\hat{\Gamma}$ is the Levi-Civita connection of such metric.

One of the useful features of the hybrid metric-Palatini theory is that it admits a scalar-tensor representation, which simplifies the analysis of the dynamics of the theory.

Let's introduce an auxiliary field, A, so that the action (1) becomes

$$S = \frac{1}{2\kappa^2}\int \sqrt{-g}\; d^4x \left[\Omega_A R + f(A) + \frac{df}{dA}(\mathcal{R} - A) + \mathcal{L}_m\right]. \tag{7}$$

where the coupling constant Ω_A is introduced for generality. If we further define $\phi \equiv \frac{df}{dA}$ and $V(\phi) \equiv A\frac{df}{dA} - f(A)$, the action becomes:

$$S = \frac{1}{2\kappa^2}\int \sqrt{-g}\; d^4x \left[\Omega_A R + \phi\mathcal{R} - V(\phi) + \mathcal{L}_m\right]\ . \tag{8}$$

Since we now have three dynamical variables, the metric $g_{\mu\nu}$, the independent connection, $\hat{\Gamma}$ and the scalar field ϕ, we perform the variation of the action (8) with respect to each of the dynamical variables, resulting in the following equations of motion:

$$\Omega_A R_{\mu\nu} + \phi\mathcal{R}_{\mu\nu} - \frac{1}{2}(\Omega_A R + \phi\mathcal{R} - V(\phi))g_{\mu\nu} = \kappa^2 T_{\mu\nu} \tag{9}$$

$$\mathcal{R} - V_\phi = 0 \tag{10}$$

$$\hat{\nabla}_\alpha = \left(\sqrt{-g}\phi g_{\mu\nu}\right) \tag{11}$$

As we've seen before, the last equation implies that the independent connection is the Levi-Civita connection to a conformal related metric to $g_{\mu\nu}$: $h_{\mu\nu} = \phi g_{\mu\nu}$,

allowing us to write the Ricci-Palatini tensor from the Ricci tensor and the conformal factor ϕ:

$$\mathcal{R}_{\mu\nu} = R_{\mu\nu} - \frac{1}{\phi}\left(\nabla_\mu\nabla_\nu\phi + \frac{1}{2}g_{\mu\nu}\Box\phi\right) + \frac{3}{2\phi^2}\partial_\mu\phi\partial_\nu\phi \tag{12}$$

$$R = \mathcal{R} + \frac{3}{\phi}\Box\phi - \frac{3}{2\phi^2}\partial_\mu\phi\partial^\mu\phi \tag{13}$$

where $\Box \equiv \nabla_\mu\nabla^\mu$ in the D'Alembert operator. Eq.(13) can be used to recast the action (8) into the following form:

$$S = \frac{1}{2\kappa^2}\int \sqrt{-g}\; d^4x \left[(\Omega_A + \phi)R + \frac{3}{2\phi}\partial_\mu\phi\partial^\mu\phi - V(\phi) + \mathcal{L}_m\right] . \tag{14}$$

We can note now three different cases for the value of the coupling constant Ω_A, for $\Omega_A = 1$ we have the original hybrid threory, for $\Omega_A = 0$ we have the Palatini-$f(\mathcal{R})$ gravity and for $\Omega_A \to \infty$ we recover the metric-$f(R)$ theory.

Using eqs.(2) and (10), we can rewrite eq.(9) in the scalar-tensor representation for the original hybrid theory as:

$$(1+\phi)R_{\mu\nu} = \kappa^2\left(T_{\mu\nu} - \frac{1}{2}g_{\mu\nu}T\right) + \frac{1}{2}g_{\mu\nu}(V + \Box\phi) + \nabla_\mu\nabla_\nu\phi - \frac{3}{2\phi}\partial_\mu\phi\partial_\nu\phi \tag{15}$$

In this equation we can conclude that the curvature of spacetime is due not only to the matter distribution, but also to the presence of the scalar field.

Taking the trace of equation (9) with $g^{\mu\nu}$, and using equation (10), we get

$$2V - \phi V_\phi = \kappa^2 T + \Omega_A R \tag{16}$$

If we now rewrite eq. (16) using eqs. (13) and (10), we get an effective Klein-Gordon equation for the scalar field:

$$-\Box\phi + \frac{1}{2\phi}\partial_\mu\phi\partial^\mu\phi + \frac{\phi\left[2V - (1+\phi)V_\phi\right]}{3} = \frac{\phi\kappa^2}{3}T \tag{17}$$

Which demonstrates that, unlike the purely Palatini case, the scalar field is dynamic and the theory is therefore not affected by the instabilities found in the Palatini gravity.[8]

3. Dynamical equations of local strings in Hybrid metric-palatini using Vilenkin's approximation

For the study of local $U(1)$ string in the context of the hybrid metric-Palatini gravity, we will start by defining the energy-momentum tensor of a straight, infinite cosmic string along the z-direction. Following Vilenkin's prescription,[9] one possible energy-momentum tensor is

$$T^r_r = T^t_t = -\sigma(r) \tag{18}$$

where $\sigma(r)$ is the linear energy density of the string.

We consider a general cylindrically symmetric static metric

$$ds^2 = -e^{2(K-U)}dt^2 + e^{2(K-U)}dr^2 + e^{-2U}W^2 d\theta^2 + e^{2U}dz^2 \tag{19}$$

Where t, r, θ and z denote the time, radial, angular and axial cylindrical coordinates respectively, and K, U and W are functions of r alone.

Inserting the metric (19) into the gravitational field equation (15) provides the following components

$$(1+\phi)\left(-U'^2 + K'\frac{W'}{W} - \frac{W''}{W}\right) = \phi'' - \frac{3}{4\phi}\phi'^2 - \left(K' - U' - \frac{W'}{W}\right)\phi' + \left(\kappa^2\sigma + \frac{1}{2}V\right)e^{2(K-U)}\,, \tag{20}$$

$$(1+\phi)\left(-U'^2 + K'\frac{W'}{W}\right) = -\frac{3}{4\phi}\phi'^2 - \left(K' - U' + \frac{W'}{W}\right)\phi' - \frac{1}{2}Ve^{2(K-U)}\,, \tag{21}$$

$$(1+\phi)\left(U'^2 + K''\right) = -\phi'' + \frac{3}{4\phi}\phi'^2 - U'\phi' - \frac{1}{2}Ve^{2(K-U)}\,, \tag{22}$$

$$(1+\phi)\left(U'^2 + K'' - 2U'' - 2U'\frac{W'}{W} + \frac{W''}{W}\right) = -\phi'' + \frac{3}{4\phi}\phi'^2 + \left(U' - \frac{W'}{W}\right)\phi' - \left(\kappa^2\sigma + \frac{1}{2}V\right)e^{2(K-U)}. \tag{23}$$

Additionally, we can use Eq. (17) to determine the effective Klein-Gordon equation for the scalar field ϕ:

$$e^{-2(K-U)}\left(-\phi'' - \frac{W'}{W}\phi' + \frac{\phi'^2}{2\phi}\right) + \frac{\phi}{3}\left[2V - (\phi+1)V_{,\phi}\right]\frac{2\phi\kappa^2\sigma}{3} = 0\,. \tag{24}$$

Since in this model the matter field couples minimally with curvature, it's possible to show that the energy conservation equation still holds, i.e.,

$$\nabla_\mu T^\mu{}_\nu = 0 \tag{25}$$

which yields $K'\sigma = 0$, and apart from the trivial vacuum solution, $\sigma = 0$, this implies that $K' = 0$. Thus, we consider from now on that $e^K = 1$, so that Eqs. (20)–(23) simplify to the following relations

$$(1+\phi)\left(-U'^2 - \frac{W''}{W}\right) = \phi'' - \frac{3}{4\phi}\phi'^2 + \left(U' + \frac{W'}{W}\right)\phi' + \left(\kappa^2\sigma + \frac{1}{2}V\right)e^{-2U}\,, \tag{26}$$

$$(1+\phi)U'^2 = \frac{3}{4\phi}\phi'^2 + \left(-U' + \frac{W'}{W}\right)\phi' + \frac{1}{2}Ve^{-2U}\,, \tag{27}$$

$$(1+\phi)U'^2 = -\phi'' + \frac{3}{4\phi}\phi'^2 - U'\phi' - \frac{1}{2}Ve^{-2U}\,, \tag{28}$$

$$(1+\phi)\left(U'^2-2U''-2U'\frac{W'}{W}+\frac{W''}{W}\right)=-\phi''+\frac{3}{4\phi}\phi'^2 + \left(U'-\frac{W'}{W}\right)\phi'-\left(\kappa^2\sigma+\frac{1}{2}V\right)e^{-2U}\,, \tag{29}$$

With the effective Klein-Gordon equation for the scalar field ϕ reducing to

$$e^{2U}\left(-\phi''-\frac{W'}{W}\phi'+\frac{\phi'^2}{2\phi}\right)+\frac{\phi}{3}\left[2V-(\phi+1)V_{,\phi}\right]+\frac{2\phi\kappa^2\sigma}{3}=0\,. \tag{30}$$

If we further consider that local gauge strings preserve boost invariance along the t and z directions,[9] meaning, in this case, that $U=0$, the gravitational field equations simplify considerably:

$$(1+\phi)\left(-\frac{W''}{W}\right)=\phi''-\frac{3}{4\phi}\phi'^2+\frac{W'}{W}\phi'+\kappa^2\sigma+\frac{1}{2}V\,, \tag{31}$$

$$0=\frac{3}{4\phi}\phi'^2+\frac{W'}{W}\phi'+\frac{1}{2}V\,, \tag{32}$$

$$0=-\phi''+\frac{3}{4\phi}\phi'^2-\frac{1}{2}V\,, \tag{33}$$

$$(1+\phi)\frac{W''}{W}=-\phi''+\frac{3}{4\phi}\phi'^2-\frac{W'}{W}\phi'-\kappa^2\sigma-\frac{1}{2}V\,. \tag{34}$$

where we can see now that Eqs. (31) and (34) become redundant. Combining Eqs. (32) and (33) yields the following relation for the potential V:

$$V=-\phi''-\frac{W'}{W}\phi'\,, \tag{35}$$

substituting into the Klein-Gordon equation (30), the latter reduces to:

$$V\,(3+2\phi)-V_\phi\phi\,(\phi+1)+2\kappa^2\sigma\phi+\frac{3\phi'^2}{2\phi}=0\,. \tag{36}$$

Additionally, we can further deduce:

$$\kappa^2\sigma=\frac{1}{W}\left[(1+\phi)W'\right]'\,, \tag{37}$$

and

$$\frac{\left[(1+\phi)W\right]''}{W}=-(V+\kappa^2\sigma)\,. \tag{38}$$

An important physical parameter characterizing the cosmic string properties is the mass per unit length of the string, which is defined as

$$\begin{aligned} m(r)&=\int_0^{2\pi}d\theta\int_0^{R_s}\sigma(r)W(r)dr \\ &=2\pi\int_0^{R_s}\sigma(r)W(r)dr, \end{aligned} \tag{39}$$

where R_s is the string radius.

The set of the previous equations allows us to write the gravitational equations of a cosmic string in hybrid metric-Palatini gravity in an exact(closed) form, with all the geometric and physical quantities expressed in a parametric form, in ϕ taken as the parameter.

By taking into account Eq. (33), the field equations (31) and (34) reduce to the form

$$(1+\phi)\frac{W''}{W} = -\frac{W'}{W}\phi' - \kappa^2\sigma. \tag{40}$$

3.1. *Parametric form of the dynamical equations*

From a mathematical point of view Equation (33) is independent of the metric tensor coefficient W and it represents a second order nonlinear differential equation. In order to solve it we first rescale the radial coordinate r according to the transformation $r = \beta\xi$. Hence Eq. (33) takes the form

$$\frac{d^2\phi}{d\xi^2} - \frac{3}{4\phi}\left(\frac{d\phi}{d\xi}\right)^2 + \frac{1}{2}\beta^2 V(\phi) = 0. \tag{41}$$

In order to solve Eq. (41) we introduce the transformations

$$\frac{d\phi}{d\xi} = u, \quad \frac{d^2\phi}{d\xi^2} = \frac{du}{d\xi} = \frac{du}{d\phi}\frac{d\phi}{d\xi} = u\frac{du}{d\phi} = \frac{1}{2}\frac{d}{d\phi}u^2, \tag{42}$$

and

$$u^2 = v, \tag{43}$$

respectively. Then Eq. (41) becomes a first order linear differential equation of the form

$$\frac{dv}{d\phi} - \frac{3}{2\phi}v + \beta^2 V(\phi) = 0, \tag{44}$$

with the general solution given by

$$v(\phi) = \phi^{3/2}\left[C - \beta^2\int \phi^{-3/2}V(\phi)d\phi\right], \tag{45}$$

where C is an arbitrary constant of integration. We immediately obtain

$$u(\phi) = \phi^{3/4}\sqrt{\left[C - \beta^2\int \phi^{-3/2}V(\phi)d\phi\right]}, \tag{46}$$

and

$$\xi + C_0 = \int \frac{\phi^{-3/4}d\phi}{\sqrt{\left[C - \beta^2\int \phi^{-3/2}V(\phi)d\phi\right]}}, \tag{47}$$

respectively, where C_0 is an arbitrary constant of integration.

Equation (32) can be successively transformed as

$$\frac{1}{W}\frac{dW}{d\xi}\frac{d\phi}{d\xi}=-\frac{3}{4\phi}\left(\frac{d\phi}{d\xi}\right)^2-\frac{\beta^2}{2}V(\phi), \tag{48}$$

and

$$\begin{aligned}\frac{1}{W}\frac{dW}{d\phi}=&-\frac{3}{4\phi}-\frac{\beta^2}{2}\frac{\phi^{-3/2}V(\phi)}{\left[C-\beta^2\int\phi^{-3/2}V(\phi)d\phi\right]}\\ =&-\frac{3}{4\phi}+\frac{1}{2}\frac{d}{d\phi}\ln\left[C-\beta^2\int\phi^{-3/2}V(\phi)d\phi\right],\end{aligned} \tag{49}$$

yielding

$$W(\phi)=W_0\phi^{-3/4}\sqrt{C-\beta^2\int\phi^{-3/2}V(\phi)d\phi}, \tag{50}$$

where W_0 is an arbitrary constant of integration.

As a last step we need to obtain the expression of σ. With the use of Eq. (32), then Eq. (40) can be rewritten as

$$(1+\phi)\frac{1}{W}\frac{d^2W}{d\xi^2}=\frac{3}{4\phi}\left(\frac{d\phi}{d\xi}\right)^2+\frac{1}{2}\beta^2V(\phi)-\beta^2\kappa^2\sigma. \tag{51}$$

With the use of the mathematical identities

$$\frac{dW}{d\xi}=\frac{dW}{d\phi}\frac{d\phi}{d\xi}=\frac{dW}{d\phi}u, \tag{52}$$

$$\frac{d^2W}{d\xi^2}=\frac{d^2W}{d\phi^2}v+\frac{1}{2}\frac{dW}{d\phi}\frac{dv}{d\phi}, \tag{53}$$

Eq. (51) takes the form

$$(1+\phi)\left(\frac{1}{W}\frac{d^2W}{d\phi^2}v+\frac{1}{2}\frac{1}{W}\frac{dW}{d\phi}\frac{dv}{d\phi}\right)=\frac{3}{4\phi}v+\frac{1}{2}\beta^2V(\phi)-\beta^2\kappa^2\sigma. \tag{54}$$

Finally, after some simple calculations we obtain

$$\begin{aligned}\kappa^2\sigma(\phi)=&\frac{1}{4\phi}\left\{\left[2\phi(\phi+1)V'(\phi)+3\sqrt{\phi}\int\frac{V(\phi)}{\phi^{3/2}}\,d\phi\right.\right.\\ &\left.\left.-2(2\phi+3)V(\phi)\right]-3\left(C/\beta^2\right)\sqrt{\phi}\right\}.\end{aligned} \tag{55}$$

Equation (47), (50) and (55) give the complete solution of the field equations describing the geometry of a cosmic string in hybrid metric-Palatini gravity. The solution is obtained in a parametric form, with ϕ taken as a parameter. It also contains three arbitrary integration constants ξ_0, C, and W_0 which must be obtained from the initial or boundary conditions imposed on the cosmic string configuration.

As for the mass of the string, in the dimensionless variable ξ it can be obtained as

$$m(\xi) = 2\pi\beta \int_0^{\xi_s} \sigma(\xi) W(\xi) d\xi, \tag{56}$$

where $\xi_s = R_s/\beta$.

In order to study specific cosmic string solutions in the hybrid metric-Palatini framework, we need now to specify the form of the potential $V(\phi)$.

4. Solutions to the dynamical equations with specific potentials

In this section we will investigate the application of the set of parametric equations deduced on the previous section to different potential configurations, for a more complete set of possible potential configurations, we refer the reader to the original article Ref. 10.

4.1. *Power law potential*

The gravitational field equations describing a cosmic string in hybrid metric-Palatini gravity admit an exact solution, corresponding to the power law type scalar field potential $V(\phi) = V_0\phi^{3/4}$. We rescale the radial coordinate r by imposing the condition $\beta^2 V_0 = 1$, which gives $r = \xi/\sqrt{V_0}$. With these choices from Eq. (47) we obtain explicitly the scalar field as a function of ξ, given by

$$\phi(\xi) = \frac{\left(\xi^2 {\phi_0}^{3/4} \pm 2\xi\phi_0' \pm 8\phi_0\right)^4}{4096{\phi_0}^3}, \tag{57}$$

where we have used the usual initial conditions $\phi(0) = \phi_0$ and $\phi'(0) = \phi_0'$, respectively. For the metric tensor component W we obtain

$$W(\xi) = \frac{W_0}{\left(\xi^2 {\phi_0}^{3/4} \pm 2\xi\phi_0' \pm 8\phi_0\right)^3 \sqrt{2\xi \pm 2\phi_0'/{\phi_0}^{3/4}}}. \tag{58}$$

where W_0 is an arbitrary constant of integration. On the string axis, i.e., $\xi = 0$, we obtain $W^2(0) = \pm {W_0}^2/524288\,{\phi_0}^{21/4}\phi_0'$. Since the metric tensor component W^2 must be positive for all $\xi \geq 0$, it follows that the physical solution for the string configuration is the one with the positive sign. Hence in the case of the $V(\phi) = V_0\phi^{3/4}$ potential, the solutions of the field equations describing a cosmic string in hybrid metric-Palatini gravity are

$$\begin{aligned} \phi(\xi) &= \frac{\left(\xi^2 {\phi_0}^{3/4} + 2\xi\phi_0' + 8\phi_0\right)^4}{4096{\phi_0}^3}, \\ W^2(\xi) &= \frac{{W_0}^2}{\left(\xi^2 {\phi_0}^{3/4} + 2\xi\phi_0' + 8\phi_0\right)^6 \left(2\xi + 2\phi_0'/{\phi_0}^{3/4}\right)}, \end{aligned} \tag{59}$$

respectively, with ${W_0}^2 = 524288\, W^2(0){\phi_0}^{21/4}\phi_0'$, a condition that implies $\phi_0 > 0$ and $\phi_0' > 0$. For the string tension as a function of ϕ and ξ we obtain the expressions

$$\kappa^2\sigma(\phi) = V_0\frac{-6C - 5(\phi-3)\sqrt[4]{\phi}}{8\sqrt{\phi}}, \tag{60}$$

and

$$\kappa^2\sigma(\xi) = \frac{V_0\phi_0^{3/4}}{\left(\xi^2\phi_0^{3/4}+2\xi\phi_0'+8\phi_0\right)^2}\left\{-48C\phi_0^{3/4} - 5\left(\xi^2\phi_0^{3/4}+2\xi\phi_0'+8\phi_0\right)\times \left[\frac{\left(\xi^2\phi_0^{3/4}+2\xi\phi_0'+8\phi_0\right)^4}{4096\phi_0^3} - 3\right]\right\}, \tag{61}$$

respectively.

In this case, the scalar field is a monotonically increasing function of the radial distance from the string axis and tends to infinity for $\xi \to \infty$. On the other hand, the metric tensor component decreases monotonically from a finite value on the string axis to zero at infinity. For $\xi = 0$, the string tension takes the finite value

$$\sigma(0) = V_0\left[-48C\phi_0^{3/4} - 40\left(\phi_0 - 3\right)\phi_0\right]/64\phi_0^{5/4} \tag{62}$$

while $\lim_{\xi\to\infty}\sigma(\xi) = -\infty$, indicating that σ is a monotonically decreasing function of the radial coordinate. In the first order of approximation we obtain for the mass of the string of radius ξ_s the expression

$$m = \frac{\pi\beta W_0\xi_s}{8192\phi_0^{33/8}{\phi_0'}^{3/2}}\left\{6C\xi_s\phi_0^{7/4} + 15\xi_s{\phi_0'}^2\left(C - 2\sqrt[4]{\phi_0}\right) - 4\phi_0\phi_0'\left[6C + 5\left(\phi_0 - 3\right)\sqrt[4]{\phi_0}\right] + 5\xi_s\left(\phi_0 - 3\right)\phi_0^2\right\}. \tag{63}$$

In this approximation the mass monotonically increases with the string radius.

4.2. *The Higgs-type potential*

Next we consider the case where the scalar field potential is of the Higgs type, given by

$$V(\phi) = \pm\frac{\bar{\mu}^2}{2}\phi^2 + \frac{\nu}{4}\phi^4, \tag{64}$$

where $\bar{\mu}^2$ and ν are constants. In the following we will investigate only the case with $\bar{\mu}^2 < 0$, meaning we will adopt the minus sign in the definition of the potential. By following the standard approach in elementary particle physics, we assume that the constant $\bar{\mu}^2$ is related to the mass of the scalar field particle as $m_\phi^2 = 2\xi v^2 = 2\bar{\mu}^2$, where $v^2 = \bar{\mu}^2/\xi$ gives the minimum value of the potential. The Higgs self-coupling constant ν can be obtained, in the case of strong interactions, from the determination of the mass of the Higgs boson in laboratory experiments, and its

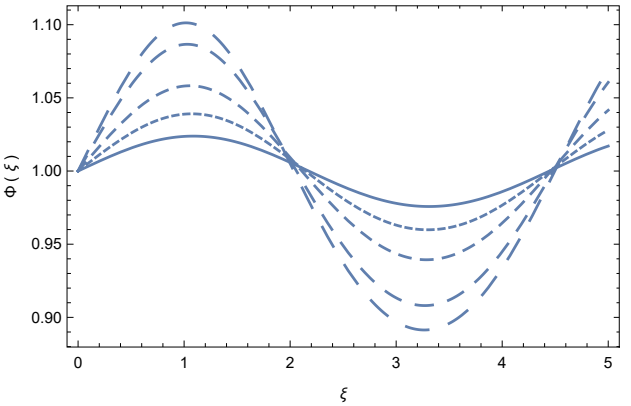

Fig. 1. Variation of the scalar field for the cosmic string configuration in the presence of a Higgs-type potential $V(\Phi) = -\Phi^2 + \Phi^4$ for $\Phi(0) = \Phi_0 = 1$, and for different values of Φ_0': $\Phi_0' = 0.034$ (solid curve), $\Phi_0' = 0.056$ (dotted curve), $\Phi_0' = 0.084$ (short dashed curve), $\Phi_0' = 0.126$ (dashed curve), and $\Phi_0' = 0.148$ (long dashed curve), respectively.

numerical value is of the order of $\nu \approx 1/8$.[11] By rescaling the radial coordinate and the scalar field according to

$$r = \sqrt{2}\bar{\mu}\xi, \qquad \phi = \frac{\Phi}{(\nu\bar{\mu})^{1/3}}, \tag{65}$$

then Eq. (47) provides the profile of the scalar field in the following form

$$\frac{d^2\Phi}{d\xi^2} - \frac{3}{4\phi}\left(\frac{d\Phi}{d\xi}\right)^2 - \Phi^2 + \Phi^4 = 0. \tag{66}$$

The general solution for this equation is given in a closed form by

$$\xi + C_0 = \int \frac{1}{\Phi^{3/4}\sqrt{C + \frac{2}{21}\left(7 - 3\Phi^2\right)\Phi^{3/2}}}\, d\Phi. \tag{67}$$

However, this solution cannot be expressed in an analytical form in terms of known functions. In the first order approximation, we obtain

$$\xi + C_0 \approx \frac{4\sqrt[4]{\Phi}}{\sqrt{C}} - \frac{4\Phi^{7/4}}{21C^{3/2}} + O\left(\Phi^{9/4}\right), \tag{68}$$

but this representation is not particularly useful from the point of view of concrete calculations.

The variation of the scalar field with Higgs potential supporting a string configuration in hybrid metric-Palatini gravity is represented in Fig. 1. There is a significant qualitative difference between this string model and the constant, simple power law or exponential potentials. Note that the scalar field for the Higgs-type potential shows a basically periodic structure, changing between successive maxima and minima. There are singularities in the field. Its behavior is strongly affected by the initial conditions on the string axis, and the field extends to infinity.

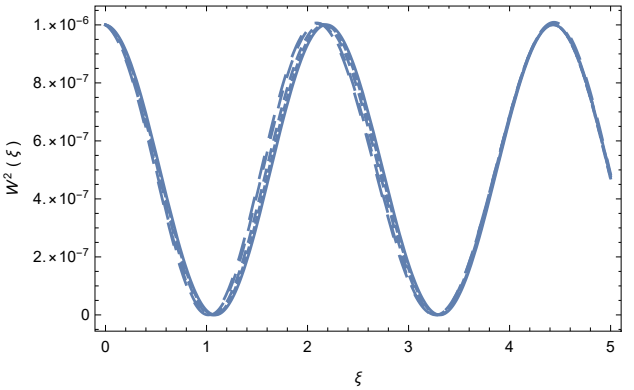

Fig. 2. Variation of the metric tensor component $W^2(\xi)$ of the cosmic string configuration in the presence of a Higgs type potential $V(\Phi) = -\Phi^2 + \Phi^4$ for $\Phi(0) = 1$, $W(0) = 10^{-3}$, and for different values of Φ_0': $\Phi_0' = 0.034$ (solid curve), $\Phi_0' = 0.056$ (dotted curve), $\Phi_0' = 0.084$ (short dashed curve), $\Phi_0' = 0.126$ (dashed curve), and $\Phi_0' = 0.148$ (long dashed curve), respectively.

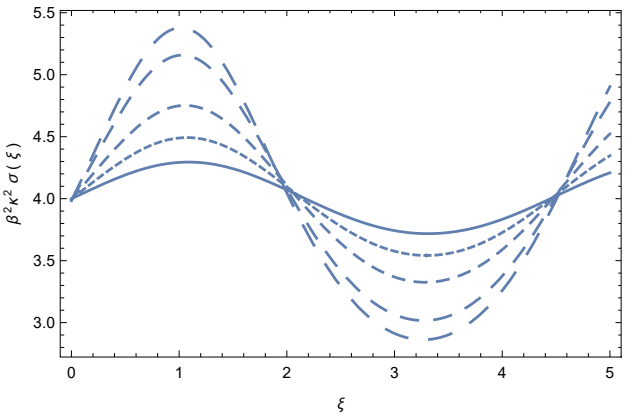

Fig. 3. Variation of the string tension $\kappa^2\sigma(\xi)$ of the cosmic string configuration in the presence of a Higgs type potential $V(\Phi) = -\Phi^2 + \Phi^4$ for $\Phi(0) = 1$, $W(0) = 10^{-3}$, and for different values of Φ_0': $\Phi_0' = 0.034$ (solid curve), $\Phi_0' = 0.056$ (dotted curve), $\Phi_0' = 0.084$ (short dashed curve), $\Phi_0' = 0.126$ (dashed curve), and $\Phi_0' = 0.148$ (long dashed curve), respectively.

The variation of the metric tensor component $W^2(\xi)$ in the presence of a Higgs potential is represented in Fig. 2. The same oscillatory pattern can also be observed in the case of the metric tensor component W^2. However, there is a difference in the phase of these to quantities. When the field reaches its maximum at $\xi \approx 1$, the metric tends to zero, $W^2(1) \approx 0$. Then, while the scalar field decreases, the metric tensor increases, reaching its maximum at the minimum of the field, corresponding to $\xi \approx 2$. This pattern is repeated up to infinity.

The variation of the string tension with respect to the radial coordinate in the presence of the Higgs potential is depicted in Fig. 3. The variation of σ is in

phase with that of the scalar field, and both quantities reach their maxima and minima at the same position. The string tension also has an oscillatory behaviour, which is a general property of all physical and geometrical parameters of the string configurations supported by scalar fields with a Higgs-type potential.

5. Conclusions

In this work we studied the existence and physical properties of cosmic strings in the context of the hybrid metric-Palatini gravity. The theory is an extension to General Relativity, combining both metric and Palatini formalism. A main success of the theory is the possibility to generate long-range forces that pass the classical local tests of gravity at the Solar System level, thus avoiding some problematic features of the standard $f(R)$ theories. Another interesting advantage of the theory is that it admits an equivalent scalar-tensor representation, simplifying greatly the dynamical equations. The type of strings studied in this work are local gauge strings, using an approximation to the Vilenkin-prescribed energy-momentum tensor and different potential configurations. For the case of the potential of the form $V = V_0\phi^{3/4}$. The requirement of the positivity of the metric tensor for $r = 0$ imposes the condition that the metric tensor and the string tension are decreasing functions of r, since both ϕ_0 and ϕ_0' are required to be positive. In this case, the scalar field becomes singular at infinity. However, it is possible to construct finite string configurations: defining a string radius by introducing an effective cuttoff length, ξ_{co} for both the metric and the scalar field. This radius would allow us to get finite values for the scalar field, the metric tensor components and the string tension. For this type of potential the choice of ξ_{co} should be made based on empirical considerations, such as consistency with observational data. The case of the Higgs-type potential is quite different, since the string tension does not vanish for any value of the radial coordinate but it does reaches its minimum value at $\xi \approx 3.5$, where the scalar field is also at its minimum and $W^2(\xi)$ is singular and tends to zero. Another possible choice for the string radius could be $\xi \approx 1$, the first zero of the metric tensor component; in this case both the string tension and the scalar field are at their maxima. Or we could, as in the exponential potential, introduce a cutoff radius to be determined by confrontation with observations, matching the solution with the cosmological background or another GR string solution, thus achieving a well behaved structure throughout the radius of the string.

We consider inflationary scenarios of the supersymmetric quantum cosmology of FRLW models with a scalar field. We use the superfield formalism with a superpotential for the scalar superfield. The probability amplitude solution of the supersymmetric Wheeler-DeWitt equation, gives a probability density from which we can compute mean trajectories that can be parametrized by the scalar. By suitable choices of the superpotential, the resulting evolutions of the scale factor correspond to consistent inflationary scenarios. We show the acceleration, the resulting e-folds and the horizon for several superpotentials.

Keywords: FRW metric; supersymmetry; quantum cosmology; inflation.

1. Introduction

We can think of the universe as originating from a homogeneous early phase, that lies presumably in the Planck scale, based on the numerous observations available nowadays from worldwide experiments and satellite missions which tell us about of the past convergnece of matter, the homogeneity and isotropy of the CMB, light elements abundance, the distribution and content of large scale structures, etc. To attack directly this early phase one would desire to be armed with a theory of the quantum spacetime, which we lack today. Nonetheless at classical level we have descriptions of the early universe with a FRLW metric, see e.g.,[1] which can be allowed to incorporate inhomogeneity perturbations of the metric and scalar fields, which upon quantization are believed to seed the structure we observe today.[2] However, this picture does not account for the very known problems we are confronted by the observations, such as the horizon problem, the homogeneity of the CMB and the flatness problem. The most accepted solution to these problems is inflation, see e.g.,[3] a mechanism that produces enough fluctuation growth as well as the suitable causal relations on the universe, from which, by means of a semiclassical quantum gravity treatment, one can obtain the seeds of structure at the ending of the homogeneous phase, making natural to think that the early homogenous phase should be treated by quantum mechanics. In this line of thought, quantum cosmology[4] gives

a canonical quantization of cosmology, resulting in a time independent Schrödinger equation for the wave function of the universe, the Wheeler-deWitt equation. Given that the hamiltonian operator acting on the wave function vanishes, this is a timeless theory, but time can be reinstated in some way for the subsequent classical universe.[5–7]

In,[8] we are given a way to obtain a time, where a scalar field is chosen to be time, and a time dependent effective wave function is defined by the conditional probability of measuring a value of the scale factor for a given value of the scalar field, this allows to compute mean values (dependent on time) from the wave function. On the other hand, the knowledge of the fermionic and bosonic constituents of matter, as well as the required symmetry breaking, has led to the search and construction of unified theories, including fermions and bosons related and interacting in a non trivial way. Supersymmetry,[9] lies well in the category of such theories and it has given the way to supergravity and string theory. In this view, supersymmetric quantum cosmology[10–12] is a good option to study the early universe and attains its goals by the extension of spacetime diffeomorphisms to diffeomorphisms in a Grassmann, extended spacetime, called superspace. This supersymmetry-superspace has additional fermionic coordinates, and the fields become superfields, power expansions on the grassmann variables. Thus, supergravity is formulated as general relativity theory on a supermanifold.[9,18] There are several formulations for supersymmetric extensions of homogeneous models.[11,12] The type of formulation we consider here, is obtained by the extension of time general reparametrizations, to general reparametrizations on a "time superspace".[13,14] Another option is dimensional reduction which involves fields depending only on time, and the spatial coordinates are integrated out.[10] In the simple cases this system has exact solutions,[13–15] and the wave functions have several independent components. In[16] a semiclassical WKB analysis has been made, from which follow a classical hamiltonian, and the corresponding classical equations of motion, for the two relevant spinorial components of the wave function.

In this work we consider the supersymmetric quantum cosmology model of,[8] to explore inflationary scenarios. In sections 2 and 3, we review the supersymmetric model and its component formulation. In section 4 we review the quantization of the model from.[8] In section 5 we make a discussion of the problem of time. Following,[8] a time dependent, effective wave function, can be given. We obtain inflationary behavior from suitable exponential superpotentials, as shown in section 6. We illustrate the inflationary behavior for two types of decaying superpotentials. Finally, in section 7, we make a short discussion with some remarks and future work perspectives.

2. Supersymmetric FRLW model with a scalar field

We begin with a model consisting of a FRLW metric with a scalar field, a setting that can account for inflation, primordial matter generation and structure formation, and

possibly dark energy, thus our model is

$$I=\frac{1}{\kappa^2}\int\left\{-\frac{3}{c^2}N^{-1}a\dot{a}^2+3Nka-Na^3\Lambda+\kappa^2a^3\left[\frac{1}{2c^2}N^{-1}\dot{\phi}^2-NV\left(\phi\right)\right]\right\}dt, \quad (1)$$

where $\kappa^2=\frac{8\pi G}{c^4}$.

2.1. *Supersymmetric cosmology*

Supersymmetric cosmology can be obtained from one dimensional supergravity.[13] Here we review the derivation of the supersymmetric Wheeler-DeWitt equation following,[8,14] with several minor modifications. In particular we introduce SI dimensional constants into the action and the ensuing equations, and correct typos. In these works, we have formulated it as general relativity on supersymmetry-superspace, $t\rightarrow z^M=(t,\Theta,\bar{\Theta})$, where Θ and $\bar{\Theta}$ are anticommuting coordinates. Hence, under $z^M\rightarrow z'^M=z^M+\zeta^M(z)$, the superfields, see e.g.,[9,18] transform as $\delta_\zeta\Phi(z)=-\zeta^M(z)\partial_M\Phi(z)$, and their covariant derivatives are $\nabla_A\Phi=\nabla_A^{\ M}(z)\partial_M\Phi$. $\nabla_A^{\ M}(z)$ is the superspace vielbein, whose superdeterminant gives the invariant superdensity $\mathcal{E}=\mathrm{Sdet}\nabla_M^{\ A}$, $\delta_\zeta\mathcal{E}=(-1)^m\partial_M(\zeta^M\mathcal{E})$. For the supersymmetric extension of the FRLW metric, in the covariant Wess-Zumino gauge,[18] we have $\mathcal{E}=-e-\frac{i}{2}(\Theta\bar{\Psi}+\bar{\Theta}\Psi)$.[14] In this formulation, to the scale factor and the scalar field correspond real scalar superfields[9,13]:

$$\mathcal{A}\left(t,\Theta,\bar{\Theta}\right)=a\left(t\right)+\Theta\lambda\left(t\right)-\bar{\Theta}\bar{\lambda}\left(t\right)+\Theta\bar{\Theta}B\left(t\right), \quad (2)$$

$$\Phi\left(t,\Theta,\bar{\Theta}\right)=\phi\left(t\right)+\Theta\eta\left(t\right)-\bar{\Theta}\bar{\eta}(t)+\Theta\bar{\Theta}G\left(t\right). \quad (3)$$

Thus the superfield extension of the model (1), for $k=0,1$, is $I=I_G+I_M$, where I_G is the supergravity action and I_M is the matter term[8,13,21]

$$I_G=\frac{3}{\kappa^2}\int\mathcal{E}\left(\mathcal{A}\nabla_{\bar{\Theta}}\mathcal{A}\nabla_\Theta\mathcal{A}-\sqrt{k}\mathcal{A}^2\right)d\Theta d\bar{\Theta}dt, \quad (4)$$

$$I_M=\int\mathcal{E}\mathcal{A}^3\left[-\frac{1}{2}\nabla_{\bar{\Theta}}\Phi\nabla_\Theta\Phi+W\left(\Phi\right)\right]d\Theta d\bar{\Theta}dt. \quad (5)$$

W is the superpotential.

3. Component formulation

Upon component expansion of the superfields in (4) and (5), once we have performed the integration of the ferminic coordinates, we have[8]

$$L_G=\frac{1}{\kappa^2}\left[-\frac{3a}{c^2e}\dot{a}^2+\frac{3a}{ce}\dot{a}\left(\psi\lambda-\bar{\psi}\bar{\lambda}\right)+\frac{3i}{c}a\left(\lambda\dot{\bar{\lambda}}+\bar{\lambda}\dot{\lambda}\right)+eaB\left(6\sqrt{k}-3B\right)\right.$$
$$\left.+e\left(6\sqrt{k}-3B\right)\lambda\bar{\lambda}+ia\left(3\sqrt{k}-\sqrt{3\Lambda}a\right)\left(\bar{\psi}\bar{\lambda}+\psi\lambda\right)-\frac{3a}{2e}\lambda\bar{\lambda}\psi\bar{\psi}\right], \quad (6)$$

$$
\begin{aligned}
L_M = & \frac{a^3}{2c^2e}\dot{\phi}^2 + \frac{a^3}{2ce}\dot{\phi}\left(\bar{\psi}\bar{\eta} - \psi\eta\right) + \frac{3ia^2}{2c}\dot{\phi}\left(\lambda\bar{\eta} + \bar{\lambda}\eta\right) \\
& - \frac{ia^3}{2c}\left(\eta\dot{\bar{\eta}} + \bar{\eta}\dot{\eta}\right) - 3ea^2BW - ea^3GW' + \frac{ea^3}{2}G^2 \\
& - 6eaW\lambda\bar{\lambda} - ea^2\left(\frac{3B}{2} + aW''\right)\eta\bar{\eta} - \frac{3ia^2}{2}W\left(\psi\lambda + \bar{\psi}\bar{\lambda}\right) \\
& + 3ea^2\left(\frac{1}{2}G - W'\right)\left(\lambda\bar{\eta} - \bar{\lambda}\eta\right) - \frac{ia^3}{2}W'\left(\psi\eta + \bar{\psi}\bar{\eta}\right) \\
& + \frac{a^3}{4e}\eta\bar{\eta}\psi\bar{\psi} - 3ea\eta\bar{\eta}\lambda\bar{\lambda},
\end{aligned}
\tag{7}
$$

where $W \equiv W(\phi)$, $W' \equiv \partial_\phi W(\phi)$, and $W'' \equiv \partial^2_\phi W(\phi)$. We note the presence of auxiliary fields B and G, whose equations of motion are purely algebraic and can be solved straigthforward, $B = \sqrt{k} - \frac{\lambda\bar{\lambda}}{2a} - \frac{a\kappa^2}{2}(W - \frac{1}{2}\eta\bar{\eta})$ and $G = W' + \frac{3}{2a}(\bar{\lambda}\eta - \lambda\bar{\eta})$.

Then, substituting the previous equations in (6) and (7), and making the redefinitions $\lambda \to a^{1/2}\lambda$, $\bar{\lambda} \to a^{1/2}\bar{\lambda}$, $\eta \to a^{3/2}\eta$, $\bar{\eta} \to a^{3/2}\bar{\eta}$, we end up with the following lagrangian

$$
\begin{aligned}
L_{Tot} = & -\frac{3a\dot{a}^2}{c^2e\kappa^2} + \frac{a^3\dot{\phi}^2}{2c^2e} + \frac{3kea}{\kappa^2} + 3\sqrt{k}ea^2W + \frac{3e\kappa^2}{4}a^3W^2 \\
& - \frac{1}{2}a^3eW'^2 + \frac{3i}{c\kappa^2}\left(\lambda\dot{\bar{\lambda}} + \bar{\lambda}\dot{\lambda}\right) - \frac{i}{2c}\left(\eta\dot{\bar{\eta}} + \dot{\eta}\bar{\eta}\right) + \frac{3\sqrt{a}\dot{a}}{c\kappa^2e}\left(\psi\lambda - \bar{\psi}\bar{\lambda}\right) \\
& - \frac{a^{3/2}\dot{\phi}}{2ce}\left(\psi\eta - \bar{\psi}\bar{\eta}\right) + \frac{3i\dot{\phi}}{2c}\left(\lambda\bar{\eta} + \bar{\lambda}\eta\right) + 3e\left(\frac{\sqrt{k}}{\kappa^2 a} - \frac{3}{2}W\right)\lambda\bar{\lambda} \\
& + e\left(-\frac{3\sqrt{k}}{2a} + \frac{3\kappa^2}{4}W - W''\right)\eta\bar{\eta} + 3ia^{3/2}\left(\frac{\sqrt{k}}{\kappa^2 a} - \frac{1}{2}W\right)\left(\psi\lambda + \bar{\psi}\bar{\lambda}\right) \\
& - \frac{ia^{3/2}}{2}W'\left(\psi\eta + \bar{\psi}\bar{\eta}\right) - \frac{3eW'}{2}\left(\lambda\bar{\eta} - \bar{\lambda}\eta\right) - \frac{3}{2e\kappa^2}\psi\bar{\psi}\lambda\bar{\lambda} + \frac{1}{4e}\psi\bar{\psi}\eta\bar{\eta}.
\end{aligned}
$$

The conjugated momenta are $\pi_a = -\frac{6a\dot{a}}{c^2\kappa^2e} + \frac{3\sqrt{a}}{c\kappa^2e}\left(\psi\lambda - \bar{\psi}\bar{\lambda}\right)$, $\pi_\phi = \frac{a^3\dot{\phi}}{c^2e} - \frac{a^{3/2}}{2ce}\left(\psi\eta - \bar{\psi}\bar{\eta}\right) + \frac{3i}{2c}\left(\lambda\bar{\eta} + \bar{\lambda}\eta\right)$, $\pi_\lambda = -\frac{3i}{c\kappa^2}\bar{\lambda}$, $\pi_{\bar{\lambda}} = -\frac{3i}{c\kappa^2}\lambda$, $\pi_\eta = \frac{i}{2c}\bar{\eta}$, $\pi_{\bar{\eta}} = \frac{i}{2c}\eta$. The Dirac Brackets are $\{a, \pi_a\} = \{\phi, \pi_\phi\} = 1$, $\{\lambda, \bar{\lambda}\}_+ = \frac{c\kappa^2}{6}$, $\{\eta, \bar{\eta}\}_+ = -c$, where $\{,\}_+$ are fermionic Dirac brackets. Therefore, the Hamiltonian is $H = NH_0 + \frac{1}{2}\psi S - \frac{1}{2}\bar{\psi}\bar{S}$, where the hamiltonian and supersymmetric constraints are

$$
\begin{aligned}
H_0 = & -\frac{c^2\kappa^2\pi_a^2}{12a} + \frac{c^2\pi_\phi^2}{2a^3} - \frac{3ic\pi_\phi}{2a^3}\left(\lambda\bar{\eta} + \bar{\lambda}\eta\right) - \frac{3ak}{\kappa^2} + 3\sqrt{k}a^2W \\
& - \frac{3\kappa^2}{4}a^3W^2 + \frac{1}{2}a^3W'^2 + \frac{9}{2}W\lambda\bar{\lambda} - \frac{3\kappa^2}{4}W\eta\bar{\eta} + \frac{3}{2}W'\left(\lambda\bar{\eta} - \bar{\lambda}\eta\right) \qquad (8) \\
& + W''\eta\bar{\eta} - \frac{3\sqrt{k}}{\kappa^2 a}\lambda\bar{\lambda} + \frac{3\sqrt{k}}{2a}\eta\bar{\eta} - \frac{9\lambda\bar{\lambda}\eta\bar{\eta}}{4a^3}, \qquad (9)
\end{aligned}
$$

$$S = \frac{c\pi_a \lambda}{\sqrt{a}} + \frac{c\pi_\phi \eta}{a^{3/2}} - \frac{6i\sqrt{k}}{\kappa^2}\sqrt{a}\lambda + 3ia^{\frac{3}{2}}W\lambda + ia^{\frac{3}{2}}W'\eta + \frac{3i}{2}a^{-3/2}\lambda\eta\bar{\eta}, \tag{10}$$

$$\bar{S} = \frac{c\pi_a \bar{\lambda}}{\sqrt{a}} + \frac{c\pi_\phi \bar{\eta}}{a^{3/2}} + \frac{6i\sqrt{k}}{\kappa^2}\sqrt{a}\bar{\lambda} - 3ia^{3/2}W\bar{\lambda} - ia^{3/2}W'\bar{\eta} - \frac{3i}{2a^{3/2}}\bar{\lambda}\eta\bar{\eta}, \tag{11}$$

they satisfy the Dirac fermionic brackets

$$\{S, \bar{S}\}_+ = -2H_0, \tag{12}$$

$$\{H_0, S\} = \{H_0, \bar{S}\} = 0. \tag{13}$$

Further, the scalar potential in the hamiltonian H_0 is

$$V_S = \frac{3\sqrt{k}}{a}W - \frac{3\kappa^2}{4}W^2 + \frac{1}{2}W'^2. \tag{14}$$

4. Quantization

There are several well known problems of the quantization of this system, which are address in.[19] In particular the time problem, a consequence of the invariance under time reparametrizations. It has been argued that time is an internal property that can be determined by a the choice of a clock.[5] On the other side, the observed universe is classical,[19] hence its description is given by mean values of the quantum operators. We further discuss the time problem in section 5.

We follow,[8,20] for the derivation of the Wheeler-DeWitt equation, which follows from the Hamiltonian constraint. In the supersymmetric case, the supercharges (10) and (11) give first order differential equations, from which the Hamiltonian constraint follows (12). For consistency it is required that the Hamiltonian is hermitian, hence the supercharges must satisfy $\bar{S} = S^\dagger$ and $S = \bar{S}^\dagger$. In fact, the constraints (9), (10), (11), and the algebra (12), (13) are symmetric under complex conjugation, with $\lambda^* = \bar{\lambda}$ and $\eta^* = \bar{\eta}$. As the momenta of the fermionic variables satisfy second class constraints, Dirac brackets must be implemented. It follows that the non-zero brackets are

$$[a, \pi_a] = [\phi, \pi_\phi] = i\hbar, \qquad \{\lambda, \bar{\lambda}\}_+ = \frac{4\pi}{3}l_p^2, \qquad \{\eta, \bar{\eta}\}_+ = -\hbar c. \tag{15}$$

$l_p^2 = \frac{\hbar G}{c^3}$ is the Planck length. For the quantization, we redefine the fermionic degrees of freedom as $\lambda = \sqrt{\frac{\hbar c\kappa^2}{6}}\alpha$, $\bar{\lambda} = \sqrt{\frac{\hbar c\kappa^2}{6}}\bar{\alpha}$, $\eta = \sqrt{\hbar c}\beta$ and $\bar{\eta} = \sqrt{\hbar c}\bar{\beta}$. Hence the anticommutators are

$$\{\alpha, \bar{\alpha}\}_+ = 1, \qquad \{\beta, \bar{\beta}\}_+ = -1. \tag{16}$$

as well as $\alpha^2 = \beta^2 = \bar{\alpha}^2 = \bar{\beta}^2 = 0$. The bosonic momenta are represented by derivatives, α and β are annihilation operators, and $\bar{\alpha}$ and $\bar{\beta}$ are creation operators. We fix the ordering ambiguities in the first and last terms of (10) and (11) by Weyl

ordering, which for fermions is antisymmetric. Hence

$$\begin{aligned}\frac{1}{\sqrt{\hbar c}}S &= \frac{c\kappa}{2\sqrt{6}}\left(a^{-\frac{1}{2}}\pi_a + \pi_a a^{-\frac{1}{2}}\right)\alpha + ca^{-\frac{3}{2}}\pi_\phi\beta + \frac{3i\kappa}{\sqrt{6}}a^{\frac{3}{2}}W\alpha \\ &\quad + ia^{\frac{3}{2}}W'\beta - i\frac{\sqrt{6k}}{\kappa}a^{\frac{1}{2}}\alpha - \frac{i\sqrt{3}}{4\sqrt{2}}\hbar c\kappa a^{-\frac{3}{2}}\alpha[\bar\beta,\beta], \qquad (17)\\ \frac{1}{\sqrt{\hbar c}}\bar S &= \frac{c\kappa}{2\sqrt{6}}\left(a^{-\frac{1}{2}}\pi_a + \pi_a a^{-\frac{1}{2}}\right)\bar\alpha + ca^{-\frac{3}{2}}\pi_\phi\bar\beta - \frac{3i\kappa}{\sqrt{6}}a^{\frac{3}{2}}W\bar\alpha \\ &\quad - ia^{\frac{3}{2}}W'\bar\beta + i\frac{\sqrt{6k}}{\kappa}a^{\frac{1}{2}}\bar\alpha + \frac{i\sqrt{3}}{4\sqrt{2}}\hbar c\kappa a^{-\frac{3}{2}}\bar\alpha[\bar\beta,\beta]. \qquad (18)\end{aligned}$$

The anticommutator of these operators is $\{S,\bar S\}_+ = -2\hbar c H_0$, hence the quantum hamiltonian is[a]

$$\begin{aligned}H_0 &= -\frac{c^2\kappa^2}{24}\left(a^{-1}\pi_a^2 + \pi_a^2 a^{-1}\right) + \frac{c^2}{2}a^{-3}\pi_\phi^2 - \frac{\sqrt{k}}{4}\hbar c a^{-1}[\alpha,\bar\alpha] \\ &\quad - \frac{\sqrt{3}i}{2\sqrt{2}}\hbar c^2\kappa a^{-3}\pi_\phi(\alpha\bar\beta + \bar\alpha\beta) + \frac{3\sqrt{k}}{4}\hbar c a^{-1}[\beta,\bar\eta] \\ &\quad - \frac{3k}{\kappa^2}a - \frac{3\kappa^2}{4}a^3W^2 + 3\sqrt{k}a^2W + \frac{1}{2}a^3W'^2 \qquad (19)\\ &\quad + \frac{3}{8}\hbar c\kappa^2 W[\alpha,\bar\alpha] - \frac{3}{8}\hbar c\kappa^2 W[\beta,\bar\beta] + \frac{1}{2}\hbar c W''[\beta,\bar\beta] \\ &\quad + \frac{\sqrt{3}}{2\sqrt{2}}\hbar c\kappa W'(\alpha\bar\beta - \bar\alpha\beta) + \frac{3}{16}(\hbar c\kappa)^2 a^{-3}\left(\bar\alpha\alpha\beta\bar\beta + \alpha\bar\alpha\bar\beta\beta\right).\end{aligned}$$

Thus, $\bar S = S^\dagger$, and H_0 is self-adjoint. The Hilbert space is generated from the vacuum state $|1\rangle$, which satisfies $\alpha|1\rangle = \beta|1\rangle = 0$. Hence, there are four orthogonal states

$$|1\rangle, \quad |2\rangle = \bar\alpha|1\rangle, \quad |3\rangle = \bar\beta|1\rangle \quad \text{and} \quad |4\rangle = \bar\alpha\bar\beta|1\rangle, \qquad (20)$$

which have norms $\langle 2|2\rangle = \langle 1|1\rangle$, $\langle 3|3\rangle = -\langle 1|1\rangle$ and $\langle 4|4\rangle = -\langle 1|1\rangle$. Further, from the constraint equation $S|\Psi\rangle = 0$, we get, up to nonvanishing factors[8]

$$a\left(\partial_a - \frac{3}{\hbar c}a^2W + \frac{6\sqrt{k}}{\hbar c\kappa^2}a + \frac{1}{2}a^{-1}\right)\psi_2 - \frac{\sqrt{6}}{\kappa}\left(\partial_\phi - a^3W'\right)\psi_3 = 0, \qquad (21)$$

$$\left(\partial_a - \frac{3}{\hbar c}a^2W + \frac{6\sqrt{k}}{\hbar c\kappa^2}a - a^{-1}\right)\psi_4 = 0 \quad \text{and} \quad \left(\partial_\phi - \frac{1}{\hbar c}a^3W'\right)\psi_4 = 0, \qquad (22)$$

[a]Note that the ordering differs from the one in[8]

while from $\bar{S}\Psi = 0$, we get

$$a\left(\partial_a + \frac{3}{\hbar c}a^2 W - \frac{6\sqrt{k}}{\hbar c\kappa^2}a + \frac{1}{2}a^{-1}\right)\psi_3 - \frac{\sqrt{6}}{\kappa}\left(\partial_\phi + a^3 W'\right)\psi_2 = 0, \quad (23)$$

$$\left(\partial_a + \frac{3}{\hbar c}a^2 W - \frac{6\sqrt{k}}{\hbar c\kappa^2}a - a^{-1}\right)\psi_1 = 0, \quad \text{and} \quad \left(\partial_\phi + \frac{1}{\hbar c}a^3 W'\right)\psi_1 = 0, \quad (24)$$

4.1. *Solutions*

Since the Wheeler-DeWitt equation is second order, its solutions require boundary conditions. However, in the supersymmetric theory the equations are first order (21)-(24), and have unique solutions, which can be fixed by the requirement of normalization.[8,17,20] The equations for ψ_1 and ψ_4 can be straightforwardly solved, yielding the, up to constant factors, unique solutions

$$\psi_1(a,\phi) = a\exp\left[-\frac{1}{\hbar c}\left(a^3 W(\phi) - \frac{3\sqrt{k}a^2}{\kappa^2}\right)\right], \quad (25)$$

$$\psi_4(a,\phi) = a\exp\left[\frac{1}{\hbar c}\left(a^3 W(\phi) - \frac{3\sqrt{k}a^2}{\kappa^2}\right)\right]. \quad (26)$$

Following[8,20] and the arguments stated there, we choose as the only physical solutions $|\Psi\rangle = C_1\,\psi_1(a,\phi)\,|1\rangle + C_4\,\psi_4(a,\phi)\,|4\rangle$, where the factors are arbitrary constants.

In the following, unless otherwise stated, we will consider $k = 0$, in this case we can write (25) and (26), together as

$$\Psi(a,\phi) = Ca\exp\left[-\frac{1}{\hbar c}a^3|W(\phi)|\right], \quad (27)$$

where the normalization constant is

$$|C|^2 = \frac{6}{c\hbar}\left\{\int_{-\infty}^{\infty}\frac{d\phi}{|W(\phi)|}\right\}^{-1}. \quad (28)$$

In[20] the corresponding expressions for $k = 1$ are given.

5. Time

A brief but comprehensive discussion of the problem of time in quantum cosmology is given in,[20] for the moment let us give some plausibility coments in the same line of thought. The wave function of a quantum system should give high probabilities on paths around classical trajectories in superspace.[19] Hence, it is possible to identify mean trajectories along regions around maxima of the wave function, and it should be possible to parameterize these trajectories, to give a time. Strictly speaking, measurements should give random values around these mean values. Therefore,

this time would correspond itself to a sort of mean value. We consider the standard interpretation of quantum mechanics for the solutions of the Wheeler-DeWitt equation, i.e. the square module of the wave function is the probability density of measuring a certain three-geometry. Thus, the wave function must give probabilities for all possible three geometries of the universe.

In our case, the configuration space is given by the scale factor and the scalar field. If the probability density has crests, we could speak of "trajectories" in the (a, ϕ) plane. From (27) we see, that for ϕ constant, we have a bell curve for (27), with a maximum at $a_{\max}(\phi) = \left[\frac{c\hbar}{3W(\phi)}\right]^{1/3}$, and $\psi_{\max}(\phi) = \psi(a_{\max}, \phi) = e^{-1/3} a_{\max}(\phi)$. As an example, we set $W(\phi) = \phi^{-1}(e^{-\phi^2} + 1)$, with the probability density given in figure 2, and taking the scalar field to lie in $\phi \in [0, \infty)$, then the most probable value for the universe would be somewhere at $\phi \to \infty$; hence, the system is not localized. But, if the universe is at some value ϕ_0, it will be less probable to find it for $\phi < \phi_0$, and more probable to find it for $\phi > \phi_0$, around $a_{\max}(\phi)$, this behaviour suggest that the field ϕ can take the role of time,[6,8,20] as far as it is causal. This corresponds to the comoving gauge, where the scalar field is constant on the spacial slices.

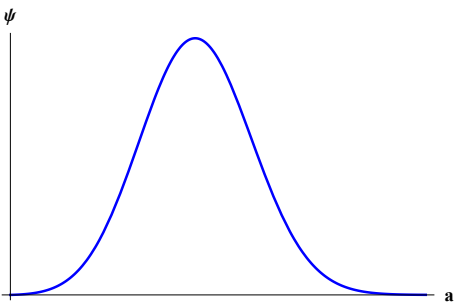

Fig. 1. Profile of $\psi(a, \phi)$, for ϕ constant.

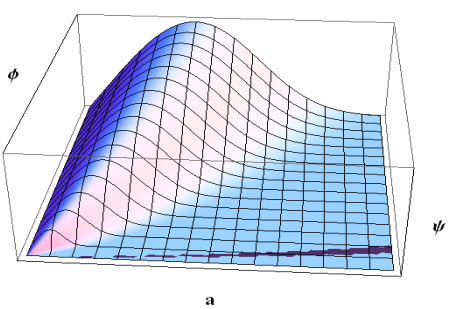

Fig. 2. Probability density for $W(\phi) = 1/\phi$.

Hence we set $\phi \to t$, with a probability amplitude[8]

$$\Psi(a,t) = \frac{1}{\sqrt{\int_0^\infty da\,|\psi(a,t)|^2}}\,\psi(a,t) = \sqrt{\frac{6|W(t)|}{\hbar c}}\,a\exp\left[-\frac{a^3|W(t)|}{\hbar c}\right], \tag{29}$$

normalized as $\int_0^\infty da\,|\Psi(a,t)|^2 = 1$, where the resulting probability density[8]

$$|\Psi(a,t)|^2 = \frac{|\psi(a,t)|^2}{\int_0^\infty da\,|\psi(a,t)|^2}, \tag{30}$$

is the conditional probability of the universe being at a and $t \sim \phi$, if the universe is at ϕ regardless of a. It satisfies a conservation equation as stated in.[8,20]

Since we do not have the possibility of recreating the universe in order to give a meaning to probabilities, what we can give a meaning is to mean values. Therefore, under the preceding ansatz, the classical setup arises from mean values with the probability amplitude (29), upon this line we get a time dependent scale factor

$$a(t) = \int_0^\infty a|\Psi(a,t)|^2 da = \Gamma\left(4/3\right)\left[\frac{\hbar c}{2|W(t)|}\right]^{1/3}. \tag{31}$$

with the standard deviations

$$(\Delta a)^2 = \left[\Gamma\left(5/3\right) - \Gamma\left(4/3\right)^2\right]\left[\frac{\hbar c}{2|W|}\right]^{2/3}, \tag{32}$$

and

$$(\Delta\pi_a)^2 = \hbar^2\,\Gamma\left(1/3\right)\left[\frac{2|W|}{\hbar c}\right]^{2/3}, \tag{33}$$

from which follows the uncertainty relation holds

$$\Delta a\Delta\pi_a = \sqrt{\Gamma\left(1/3\right)\left[\Gamma\left(5/3\right) - \Gamma\left(4/3\right)^2\right]}\,\hbar \approx 0.53\,\hbar. \tag{34}$$

6. Inflationary scenarios

In this section we will consider several superpotentials that lead to cosmological scenarios. The scalar field has real values, from $-\infty$ to ∞, and as mentioned in 4.1 and,[20] we require that the superpotential is a symmetric function and always positive. It is convenient to choose time beginning at $t = 0$. Hence, these superpotentials correspond to bouncing universes. With these settings, we are considering universes with a defined origin at t=0, described by homogeneous quantum cosmology from its very beginning. We will consider two types of superpotentials, depending on the initial conditions. The first type is suitable for $a(0) = 0$, hence $\lim_{t\to 0} W(t) = \infty$ (31), and the wave function (29) will vanish at $t = 0$, $\Psi(a,0) = 0$, similar to figure 1. Hence, the universe will arise for $t > 0$ from nothing. Otherwise, if $W(0)$ takes some

finite value, then $a(0) = \Gamma(4/3)\left[\frac{\hbar c}{2|W(0)|}\right]^{1/3}$. We can obtain superpotentials of the first type by $W(\phi) \to \phi^{-2\alpha} W(\phi)$, with α a positive number.

From (31) we get

$$\ddot{a}(t) = \frac{a(t)}{9}\left[4\frac{\dot{W}^2(t)}{W^2(t)} - 3\frac{\ddot{W}(t)}{W(t)}\right]. \tag{35}$$

Hence the acceleration is positive if $\dot{W}^2(t) > \frac{3}{4}W(t)\ddot{W}(t)$. We consider inflation starting when the scale factor acceleration becomes positive, at $t = t_i$, until the exit when it becomes zero again $\ddot{a}(t_e) = 0$, with $N = \ln\frac{a(t_e)}{a(t_i)} = \frac{1}{3}\ln\frac{W(t_i)}{W(t_e)}$ e-folds. Note that in this way N is independent of the time parametrization.

The feasibility of inflation has an indicative in the Hubble horizon

$$(aH)^{-1} = -\frac{3 \times 2^{1/3}}{\Gamma(4/3)(c\hbar)^{1/3}}\frac{W(t)^{4/3}}{W'(t)}. \tag{36}$$

For simplicity, in the following we will consider an adimensional time $t \to \tau = t/t_p$, where $t_p = \sqrt{\hbar G/c^5}$ is the Planck time.

6.1. *Superpotentials*

We consider two types of superpotentials[20]

Gaussian superpotentials

$$W(\tau) = \frac{c^4 M_p^3}{\hbar^2}\tau^{-2\alpha}\left(e^{-\tau^2} + \lambda\right), \tag{37}$$

and Step superpotentials

$$W(\tau) = \frac{c^4 M_p^3}{\hbar^2}\tau^{-2\alpha}\left(\frac{1}{\tau^2 + \lambda} + 1\right), \tag{38}$$

where $M_p = \sqrt{\frac{\hbar c}{8\pi G}}$ is the reduced Planck mass, $\alpha \geq 0$, and λ is a positive constant. We consider representative cases which reproduce an inflationary period with $N \sim 60$ e-folds, evaluated considering the beginning and exit of inflation from the time interval where acceleration is positive, and a consistent Hubble horizon. As we will see, a very small λ is required for enough e-folds, and we set $\lambda = e^{-\nu}$. Regarding other parameters, as the tensor-scalar ratio, an estimate considering an effective one scalar FRLW cosmology leads to inconsistent results, a more precise evaluation is needed.

The general behaviour of the system under these superpotentials, (37) and (38), is as follows: the scale factor has an initial value $a(0) > 0$ with a very small positive acceleration for $\alpha = 0$, and $a(0) = 0$, with a vanishing acceleration for $\alpha \geq 1$. In order to see if there is a consistent inflation, we evaluate the values of the scale factor at $\tau = 0$, and the corresponding acceleration. If $a(0) > 0$, then inflation

begins at the time $\tau = \tau_i$, when the acceleration becomes positive, until it becomes negative, at $\tau = \tau_f$. If the acceleration is positive already at $\tau = 0$, inflation begins right away. Further, if $a(0) = 0$ and $\ddot{a}(0) \geq 0$, and afterwards $\ddot{a} > 0$, then there will be exit, but there are infinite e-folds, unless we discard some initial period, for any reason. Otherwise, if $a(0) = 0$ and $\ddot{a}(0) < 0$, then inflation will begin as soon as the acceleration becomes positive, at $\tau = \tau_i$, and finish when acceleration becomes negative again, at $\tau = \tau_f$.

6.2. *Gaussian superpotentials*

The scale factor for (37) is

$$a(\tau) = \frac{\Gamma(4/3)\hbar\tau^{\alpha/3}}{2^{1/3}cM_p\left(e^{-\tau^2}+\lambda\right)^{1/3}}. \tag{39}$$

In the following, we will consider unities $c = 1$, $\hbar = 1$, and $\kappa = 1$. The acceleration vanishes around the value at which the superpotential (37) becomes nearly constant, at $e^{-\tau^2} \approx \lambda$, i.e. $\tau \approx \sqrt{\nu}$. Thus, for $\tau > \sqrt{\nu}$, the scale factor behaves as $a \gtrsim (\sqrt{\nu})^{\alpha/3}\lambda^{-1/3}$. Hence to have $a \lesssim 1$ for late times, it is convenient to rescale (39) by $\lambda^{1/3}$, such that

$$a(\tau) = \frac{\Gamma(4/3)\hbar\tau^{\alpha/3}}{2^{1/3}cM_p\left(\lambda^{-1}e^{-\tau^2}+1\right)^{1/3}} \tag{40}$$

Therefore, for $\alpha = 0$, we have

$$a_0 = a(0) = \frac{\Gamma(4/3)\hbar}{2^{1/3}cM_p}\left(\frac{\lambda}{1+\lambda}\right)^{1/3} \approx \frac{\Gamma(4/3)\hbar\lambda^{1/3}}{2^{1/3}cM_p}, \tag{41}$$

with a positive acceleration

$$\ddot{a}(0) \approx \frac{2^{2/3}\Gamma(4/3)\hbar\lambda^{1/3}}{3cM_p}. \tag{42}$$

On the other side, for large times, $\tau > \sqrt{\nu}$, the gaussian in (37) can be neglected, and the scale factor is almost constant

$$a(\tau) \approx a_e = \frac{\Gamma(4/3)\hbar}{2^{1/3}cM_p}, \tag{43}$$

see figure 4. Thus, for $\alpha = 0$, the e-fold number satisfies

$$N \lesssim \ln\frac{a_e}{a_0} = -\frac{1}{3}\ln\lambda = \frac{\nu}{3}. \tag{44}$$

It turns out that a value $\lambda \sim 10^{-79}$ is necessary for ~ 60 e-folds. From (41), we see that there is a very small initial value $a(0) \sim 3 \times 10^{-27}$, with an initial velocity

$\dot{a}(0) = 0$. The initial acceleration is also very small $\ddot{a}(0) \sim 10^{-27}$, but inflation begins right away, until the acceleration slows and becomes negative at $\tau_f \approx 13.4$, see figure 3. We get $N = \ln \frac{a(\tau_f)}{a_0} \approx 60.1$, consistently with (44). A plot for the horizon is given in figure 5.

For $\alpha > 0$, $a(0) = 0$, and at early times, $\tau \ll 1$, the scale factor can be approximated by $a(\tau) \approx \frac{\Gamma(4/3)\hbar\lambda^{1/3}}{2^{1/3}cM_p}\tau^{\alpha/3}e^{\frac{\tau^2}{3}}$, and $\ddot{a}(\tau) \approx \frac{\Gamma(4/3)\kappa(c\hbar)^{1/2}\lambda^{1/3}}{9\times 2^{1/3}}[\alpha(\alpha-3)+2(2\alpha+3)\tau^2]\tau^{\alpha/3-2}$. The acceleration at late times is shown in figure 3 for $\alpha = 1, 2, 3$, for higher values it is similar. Further, for early times, we have: For $\alpha = 1, 2$, $\ddot{a}(0) = -\infty$, grows and becomes positive. For $\alpha = 3$, $\ddot{a}(0) = 0$, and then grows. For $\alpha = 4, 5$, $\ddot{a}(0) = \infty$, decreases almost to zero for $0 < \tau \lesssim 0.5$, and then grows again. For $\alpha = 6$, $\ddot{a}(0) = \frac{2^{2/3}\Gamma(4/3)\hbar}{cM_p} \sim 3 \times 10^{-27}$, and grows. Finally, the cases $\alpha > 6$ are similar to $\alpha = 3$.

For $\alpha = 1$ a meaningful e-fold number can be obtained. Namely, for $\lambda \sim 10^{-77}$, the acceleration becomes positive at $\tau_i \sim 0.4$, with $N = \ln a(\tau_f)/a(\tau_i) \sim 60.2$. For $\alpha = 2$, the initial acceleration is infinite; hence as $a(0) = 0$, N is unbounded. However, the initial acceleration is very quickly decreasing, see figure 11, and we could discard the initial, decelerating period, which presumably would require full quantum gravity. In this case, if we consider inflation starting at $\tau \sim 0.3$, where acceleration becomes practically zero and begins to grow, we get similar values as for $\alpha = 1$.

Thus, the previous three cases $\alpha = 0, 1, 2$, are consistent with inflation, see figures 3 and 4. Even if the previous results are alike, the event horizons, plotted in figure 5, are quite different. With the previous results, we can compute the effective matter density and pressure for a perfect fluid. It turns out that the resulting potential differs from the scalar potential following from the hamiltonian (14). Moreover, for the gaussian potential and $k = 0$, in the analysed cases, the fluid has phantom energy. The effective potentials for $k = 0$ and $k = 1$ are given in figures 6 and 7. Note that the second case seems to correspond to a tunneling.

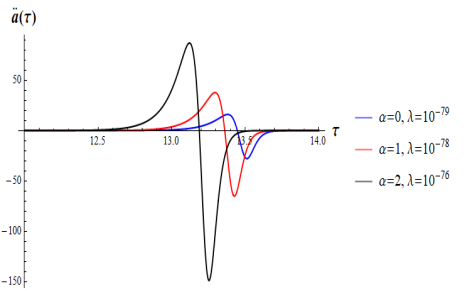

Fig. 3. Acceleration $\ddot{a}(\tau)$ for gaussian superpotentials.

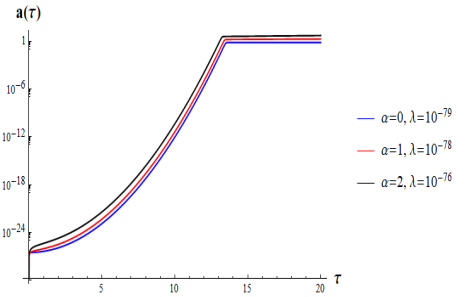

Fig. 4. Scale factor $a(\tau)$ for gaussian superpotentials, the graphics are logarithmic for clarity.

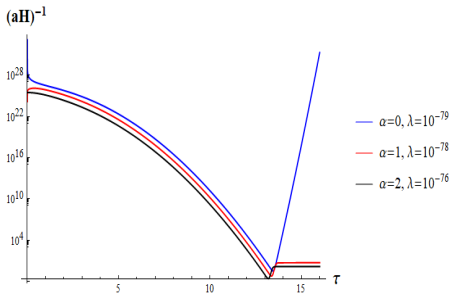

Fig. 5. Comoving Hubble radius $(aH)^{-1}$ for gaussian superpotentials, the graphics are logarithmic for clarity.

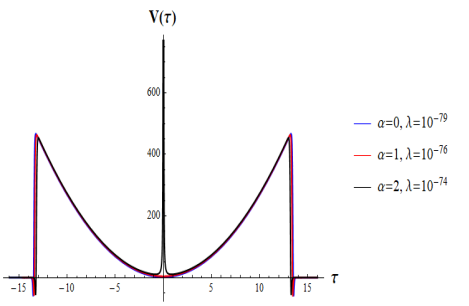

Fig. 6. Effective potentials from Friedmann equations, for $k = 0$, for $k = 1$, for $\alpha = 1, 2$ the potential becomes ∞ at $\tau = 0$.

6.3. *Step superpotentials*

For the step superpotentials (38), we have

$$a(\tau) = \frac{\Gamma(4/3)\hbar\tau^{\alpha/3}}{2^{1/3}cM_p\left[(\tau^2+\lambda)^{-1}+1\right]^{1/3}} \tag{45}$$

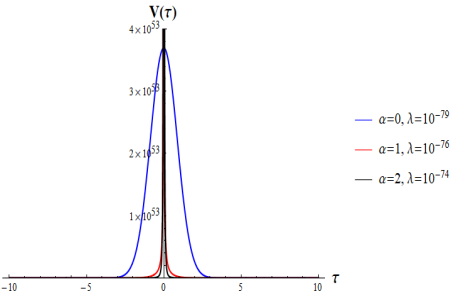

Fig. 7. Effective potentials from Friedmann equations, for $k = 1$, for $\alpha = 2$ the potential becomes ∞ at $\tau = 0$.

And the behaviour of the system is the same as for gaussian superpotentials, if $\alpha = 0$ the scale factor initial value is (41), and for large time values, $\tau \gg 1$, the scale factor tends to (43). Hence, the e-folds satisfy as well (44). The initial velocity and acceleration are zero, $\dot{a}(0) = 0$, $\ddot{a}(0) = 0$, and inflation begins from this moment, and ends at $\tau \approx 0.51$, when the acceleration becomes negative. For $N \sim 60$ a value $\lambda \sim 10^{-80}$ is required.

In the case $\alpha \geq 1$ the situation is also similar to the one of the preceding section, the initial values are practically the same. The acceleration initial behavior is similar, but after a short time the differences become notable, as can be seen from figures 11 and 12. We give also the corresponding profiles for the event horizons, shown in figures 5 and 10. For $\alpha = 1$, the 60 e-folds are reached for $\lambda \sim 10^{-53}$.

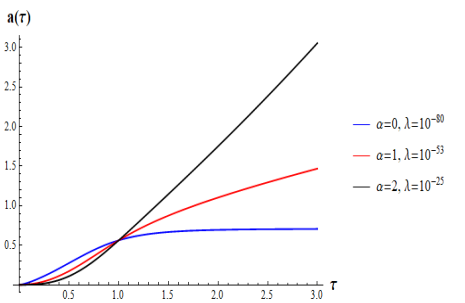

Fig. 8. Scale factor $a(\tau)$ for step superpotentials.

In this case the effective potentials, from the Friedmann equations, look qualitatively similar to the previous ones.

7. Discussion

Quantum cosmology gives a canonical quantization of general relativity in the Schrödinger picture. The invariance under time reparametrizations leads to the

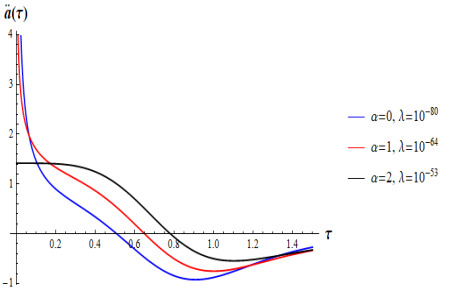

Fig. 9. Acceleration $\ddot{a}(\tau)$ for step superpotentials.

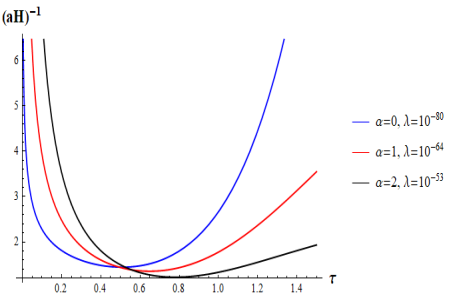

Fig. 10. Comoving Hubble radius $(aH)^{-1}$ for step superpotentials.

hamiltonian constraint that corresponds to a zero energy time independent Schrödinger equation, i.e. the Wheeler-DeWitt equation. There is no time dependent Schrödinger equation that generates a time dependence for the wave function. Thus, the wave function encodes the probability amplitudes for all possible configurations at any time. The observed universe is classical and has time, and classical physics should follow from quantum physics, hence a time evolution should follow from the

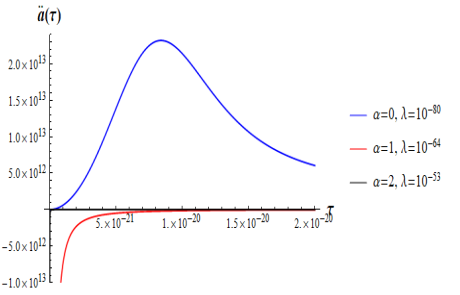

Fig. 12. Initial acceleration for step superpotentials.

quantum description. The Wheeler-DeWitt equation in the supersymmetric case is a system of first order equations, whose solutions are spinorial wave functions, see e.g.,[11,12] whose meaning has not been established. In general, there are only two nonvanishing components, see e.g.,[15] given by real exponentials with opposite exponent sign. Here we have considered a homogeneous theory with a minimally coupled scalar field. In this case, the solution of the supersymmetric Wheeler-DeWitt equation (21)-(24) has four components, two of them have analytic expressions (25),(26), and only one is physically consistent. As the equations are homogeneous and two components decouple, the other ones can be taken as trivial. The form of the solution, (27), suggests that in a certain gauge, time can be given by the scalar field and trajectories for the observables can be given by their mean values. We compute an evolution for the scale factor $a(t)$, and time reparametrizations can be performed. It remains the general question of how far can we get classical trajectories from a quantum state in this way.

We have considered several inflationary scenarios with this approach, with superpotentials (37) and (38). These superpotentials have a factor $\tau^{-2\alpha}$ that, for suitable values, gives a wave function that vanishes for $\tau = 0$ and produces a path of increasing probabilities, we can interpret this as giving the direction of time. The exit of inflation is implemented at the level of the superpotential through a constant $\lambda \sim e^{-3N}$, where N are the observationally required e-folds. Three cases were given in plots for each type of superpotential, figures 3-12. These results indicate that this kind of models could be realistic. The inclusion of inhomogeneous perturbations and the evolution of the fluctuations are part of future work. Further, more complex models, e.g. with several scalars could be considered, as in.[14]

Although General Relativity (GR) is an extremely successful theory, at least for weak gravitational fields, it breaks down at very high energies. For example, extrapolating the expansion of the Universe backwards in time yields an infinite energy density, which is referred to as the initial singularity problem. Quantum Gravity is expected to provide a solution to this open question. In fact, one alternative scenario to the Big Bang, that avoids the singularity, is offered by Loop Quantum Cosmology (LQC), which predicts that the Universe undergoes a collapse to an expansion through a bounce. In this work we use metric f(R) gravity to reproduce the modified Friedmann equations, which have been obtained in the context of modified loop quantum cosmologies (mLQC). Using a order reduction method, we obtain covariant effective actions that lead to a bounce, for specific models of mLQC, considering a massless scalar field.

Keywords: Initial singularity, cyclic cosmology, loop quantum cosmology, $f(R)$ gravity, covariant order reduction.

1. Introduction

1.1. *Motivations: Loop quantum cosmology and its modifications*

A quantum theory of gravity is expected to provide insight on the behaviour of gravity at quantum scales,[1] and consequently in addressing fundamental open questions,[2] such as the initial singularity problem. Loop Quantum Gravity (LQG)[3–5] is one of the main candidates we have today. Indeed, through an effective Hamiltonian description, LQC, which is described as a symmetry-reduced model of LQG,[6] yields a modified Friedmann equation that dictates that the big bang singularity is

replaced by a quantum bounce:[7–13]

$$H^2 = \frac{1}{3}\kappa\rho\left(1 - \frac{\rho}{\rho_c}\right), \tag{1}$$

where $H \equiv \dot{a}/a$ is the Hubble function, given in terms of the scale factor $a(t)$, and $\rho_c = \sqrt{3}/(32\pi^2\gamma^3)$ is the critical energy density, where $\gamma \approx 0.2375$ is the Barbero–Immirzi parameter.[14] Throughout this work, we will be using the geometrized system of natural units in which $c = \hbar = G = 1$ and, accordingly, $\kappa \equiv 8\pi$. It is clear from Eq. (1) that the Universe behaves in a cyclic way and that the quantum bounce occurs at the critical density, when $H = 0$ and $\ddot{a} > 0$.

Nevertheless, the procedure used in LQC, to obtain the Hamiltonian constraint which then leads to Eq. (1), differs from the one used in the full theory of LQG. In LQC the Lorentzian and Euclidean terms are treated as proportional to each other, contrary to LQG, leading to different Hamiltonian constraints in the process of quantization.[9] One of the first attempts to construct a Hamiltonian constraint that is similar to the construction in LQG was undertaken in Ref. 15, in which Thiemann's regularization was used. Even so, there is still no systematic way of deriving LQC as a cosmological sector of LQG and different paths to obtain LQG-like Hamiltonians from LQC followed.[16–19] Given these quantization ambiguities in constructing the effective Hamiltonian constraint operator, in isotropic LQC, there is a need to understand how different quantization methods affect the physical predictions. More specifically, there are still great possibilities for the expanding universe to recollapse due to quantum gravity effects.

In this work, we focus on two specific modified loop quantum cosmology (mLQC) models,[15,20] which differ from standard LQC in the way the Lorentzian term in the Hamiltonian constraint is treated.[21]

1.2. *Modified loop quantum cosmology – I: mLQC-I*

This model was derived in Ref. 20, by treating the Lorentzian term in the Hamiltonian constraint separately and using Thiemann's regularization,[15] yielding a fundamental difference between LQC and mLQC-I, in that in the latter the evolution of the universe is described by two different branches, b_+ and b_-, which coincide at the bounce.

The modified Friedmann equation for the b_- branch takes the form[20,21]

$$H_-^2 = \frac{\kappa\rho}{3}\left(1 - \frac{\rho}{\rho_c^I}\right)\left[1 + \frac{\gamma^2\rho/\rho_c^I}{(\gamma^2+1)\left(1+\sqrt{1-\rho/\rho_c^I}\right)^2}\right], \tag{2}$$

where $\rho_c^I \equiv \rho_c/[4(1+\gamma^2)]$ is the critical density at which the quantum bounce occurs. Notice how, for $\rho/\rho_c^I \ll 1$, the standard Friedmann equation $H^2 \approx \kappa\rho/3$ is recovered.

Concerning the b_+ branch, on the other hand, the modified Friedmann equation takes the form[20,21]

$$H_+^2 = \frac{\kappa\alpha\rho_\Lambda}{3}\left(1-\frac{\rho}{\rho_c^I}\right)\left[1+\frac{\rho\left(1-2\gamma^2+\sqrt{1-\rho/\rho_c^I}\right)}{4\gamma^2\rho_c^I\left(1+\sqrt{1-\rho/\rho_c^I}\right)}\right], \tag{3}$$

where $\alpha \equiv (1-5\gamma^2)/(\gamma^2+1)$, $\rho_\Lambda \equiv 3/[\kappa\alpha\lambda^2(1+\gamma^2)^2]$, and $\lambda^2 \equiv 4\sqrt{3}\pi\gamma$. The limit of Eq. (3) when $\rho/\rho_c \ll 1$, is given by $H^2 \approx 8\pi G_\alpha(\rho+\rho_\Lambda)/3$, where $G_\alpha := \alpha G$. Comparing with the standard Friedmann equation, this limit shows that quantum geometric effects are still present for low energy densities in the form of a modified Newtonian constant, G_α, and an emergent positive cosmological constant, ρ_Λ. If this branch lies in the post-bounce universe, in which we live, these pose phenomenological problems. It can be shown that the classical energy conservation law still holds in this modified model of LQC, concerning both branches.[20]

1.3. *Modified loop quantum cosmology – II: mLQC-II*

The second model that we consider in this work was derived by using Thiemann's regularization, similarly to the previous model, while also using the proportionality of between the Ashtekar's connection and the extrinsic curvature.[15,22] In doing so, yields [15]

$$H^2 = \frac{2\kappa\rho}{3}\left(1-\frac{\rho}{\rho_c^{II}}\right)\left[\frac{1+4\gamma^2\left(\gamma^2+1\right)\rho/\rho_c^{II}}{1+2\gamma^2\rho/\rho_c^{II}+\sqrt{1+4\gamma^2\left(1+\gamma^2\right)\rho/\rho_c^{II}}}\right], \tag{4}$$

where the quantum bounce occurs at the critical density $\rho_c^{II} \equiv 4(\gamma^2+1)\rho_c$. Unlike in mLQC-I, the bounce in this model is perfectly symmetric, as in LQC. Similarly to the mLQC-I model, the dynamics in the Planck regime are less trivial and the classical limit is given by the usual Friedmann equation.[22] Moreover, the energy-momentum conservation law still holds without any change in the properties of the barotropic equation of state (EoS).

1.4. *Covariant order reduction*

The only covariant action that leads to second-order equations, under metric variation, is the Einstein–Hilbert (EH) action which leads to the usual Friedmann equation. In this work, we are interested in asking if the modified Friedmann Eqs. (2)–(4) can be obtained from different actions. An interesting analysis was considered in the Palatini approach of $f(R)$ gravity in Ref. 23, where R is the Ricci scalar and f some function of it. In this case, the modified Friedmann equation does not involve higher than second-order derivatives of the geometrical quantities and is just a function of the matter sources.[24]

In this work, however, we have used metric $f(R)$ gravity,[25–31] where the full field equations are of fourth-order. Given that our current theory of gravity is a

second-order one, we have considered our chosen theory as an effective one, by applying the method of covariant order reduction, in which only the solutions that are perturbatively close to GR are considered as physical ones and the rest considered spurious.[32–34]

This technique has been applied within the context of bouncing cosmologies, for different modifications of GR. In Ref. 35, bouncing solutions in a modified Gauss–Bonnet gravity theory were explored, of the type $R + f(G)$, where G is the Gauss–Bonnet term.[35] This analysis was then extended in the context of $f(R, G)$ gravity.[36] The same approach has also been implemented in the context of $f(Q)$ symmetric teleparallel gravity theories, where Q is the non-metricity scalar.[37] Indeed, in all of these works, a covariant gravitational action, that leads to the quantum bounce observed in LQC, was found by demanding that the Friedmann equation derived within such gravity theories coincides with the one emerging from LQC.

2. Reduced equations in $f(R)$ gravity

In metric $f(R)$ gravity, the corresponding action is given by

$$S = \frac{1}{2\kappa}\int_{\mathcal{V}} d^4x\sqrt{-g}f(R) + S_M(g_{\mu\nu}, \Psi)\,, \tag{5}$$

where g is the determinant of the metric tensor $g_{\mu\nu}$, S_M is the matter action defined as $S_M = \int_{\mathcal{V}} d^4x\sqrt{-g}\,\mathcal{L}_M(g_{\mu\nu}, \Psi)$, being $\mathcal{L}_M$ the matter Lagrangian density, in which matter is minimally coupled to the metric $g_{\mu\nu}$, and Ψ collectively denotes the matter fields. Without loss of generality, we parametrize the Lagrangian density $f(R)$ as the sum of the gravitational Lagrangian of GR and a deviation term, as follows

$$f(R) = R + 2\Lambda + \epsilon\varphi(R)\,, \tag{6}$$

where Λ is the cosmological constant, ϵ is a dimensionless parameter, and $\epsilon\varphi(R)$ represents the deviation from GR. Substituting Eq. (6) in Eq. (5), and varying the action with respect to the metric, yields the following field equations

$$G_{\mu\nu} - g_{\mu\nu}\Lambda + \epsilon\left[-\frac{1}{2}g_{\mu\nu}\varphi(R) + \varphi'(R)R_{\mu\nu} - (\nabla_\mu\nabla_\nu - g_{\mu\nu}\Box)\,\varphi'(R)\right] = \kappa T_{\mu\nu}\,, \tag{7}$$

where the energy-momentum tensor $T_{\mu\nu}$ is defined as

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}}\,\frac{\delta(\sqrt{-g}\mathcal{L}_M)}{\delta g^{\mu\nu}}\,. \tag{8}$$

In simple terms, applying the order reduction technique to Eq. (7) amounts to replacing the Ricci scalar and the Ricci tensor, in the terms of order ϵ, by the expression we get for them, from the $\epsilon = 0$ version of the same equations. Thus, setting $\epsilon = 0$ in Eq. (7), yields the following

$$R^T_{\mu\nu} = \frac{1}{2}g_{\mu\nu}(R_T + 2\Lambda) + \kappa T_{\mu\nu}\,, \tag{9}$$

as the reduced expression of the Ricci tensor, where R_T is the order reduced Ricci scalar. Taking into account the trace of Eq. (9), the latter provides $R_T = -\kappa T - 4\Lambda$, and after substituting it into Eq. (9), we arrive at

$$R^T_{\mu\nu} = \kappa T_{\mu\nu} - \frac{1}{2} g_{\mu\nu}\kappa T - \Lambda g_{\mu\nu} \,. \tag{10}$$

Replacing R and $R_{\mu\nu}$, in the ϵ-order terms in Eq. (7), with the expressions for R_T and $R^T_{\mu\nu}$ respectively, yields the reduced field equations

$$\begin{aligned} G_{\mu\nu} - g_{\mu\nu}\Lambda + \epsilon \Bigg[&- \frac{1}{2} g_{\mu\nu}\varphi(R_T) + \varphi'(R_T)\left(\kappa T_{\mu\nu} - \frac{1}{2} g_{\mu\nu}\kappa T - \Lambda g_{\mu\nu}\right) \\ &- \left(\nabla_\mu \nabla_\nu - g_{\mu\nu}\Box\right)\varphi'(R_T)\Bigg] = \kappa T_{\mu\nu} \,, \end{aligned} \tag{11}$$

which are valid for

$$|\epsilon\varphi(R)| \ll |R| \,. \tag{12}$$

Throughout this work, we consider the FLRW metric with a $(-,+,+,+)$ signature, which in spherical coordinates is given by

$$ds^2 = -dt^2 + a(t)^2\left[\frac{dr^2}{1-kr^2} + r^2 d\theta^2 + r^2 \sin^2\theta d\phi^2\right], \tag{13}$$

where $a(t)$ is the scale factor and k is the curvature of the universe. We assume a perfect fluid description for the content of the universe, given by the energy-momentum tensor, $T_{\mu\nu} = (\rho + p)U_\mu U_\nu + p g_{\mu\nu}$, where U^μ is the four-velocity field of an observer comoving with the fluid, defined in such a way that $U_\mu U^\mu = -1$, and $\rho = \rho(t)$ and $p = p(t)$ are the fluid's energy density and isotropic pressure, respectively.

Now, by taking into account a EoS $p = w\rho$, with $-1 \leq w \leq 1$, and taking into account Eq. (13), then Eq. (11) provides the following modified Friedmann equation in $f(R)$ gravity[38]

$$\begin{aligned} H^2 = \frac{1}{3}\kappa\rho - \frac{k}{a^2} - \frac{\Lambda}{3} - \frac{\epsilon}{3}\Bigg[&\frac{1}{2}(3w+1)\varphi'(R_T)\kappa\rho + \varphi'(R_T)\Lambda + \frac{1}{2}\varphi(R_T) \\ &- \left(3\kappa\rho - \frac{9k}{a^2} - 3\Lambda\right)\varphi''(R_T)(1+w)(1-3w)\kappa\rho\Bigg], \end{aligned} \tag{14}$$

where $\varphi_T = \varphi(R_T)$. It is clear that this equation is effectively a second-order one and that we recover the standard Friedmann equation for $\epsilon = 0$. With this result, we aim to find a function $\varphi(R_T)$, such that Eq. (14) is the same as some Friedmann equation with a modified source.

3. Strategy to obtain effective actions

Here, we describe the procedure for finding effective actions, which was used in Ref. 38, in order to determine an effective action for LQC. In this context, we consider a spatially flat universe ($k = 0$) with a zero cosmological constant ($\Lambda = 0$).

In order to be in agreement with the approach leading to Eq. (1), we consider a massless scalar field ($w = 1$) so that

$$R_T = -2\kappa\rho\,. \tag{15}$$

Taking these aspects into account, then Eq. (14) becomes

$$H^2 = \frac{1}{3}\kappa\rho - \frac{\epsilon}{3}\left[2\varphi'(R_T)\kappa\rho + \frac{1}{2}\varphi(R_T) + 12\kappa^2\rho^2\varphi''(R_T)\right], \tag{16}$$

In the following sections, our goal is to determine $\varphi(R_T)$ such that Eq. (16) is the same as the modified Friedmann Eqs. (2)–(4), considered in the modified loop quantum cosmologies. We conveniently write Eqs. (2)–(4) in a general way as

$$H^2 = \frac{1}{3}\kappa\rho + \Psi(\rho)\,, \tag{17}$$

where $\Psi(\rho)$ depends on the model. Using Eq. (15) and comparing Eq. (17) with Eq. (16), the requirement is that $\varphi(R_T)$ satisfies

$$-\frac{\epsilon}{3}\left[\frac{1}{2}\varphi(R_T) - R_T\varphi'(R_T) + 3R_T^2\varphi''(R_T)\right] = \Psi(R_T)\,. \tag{18}$$

In finding the deviation term $\varphi(R_T)$, a metric $f(R)$ action of the form

$$f(R) = R + \epsilon\varphi(R) \tag{19}$$

is found, that leads to the quantum bounce which characterizes the models we are considering.

4. Effective actions for modified loop quantum cosmology models

Independently of the model of LQC, the solution to the non-homogeneous Eq. (18) consists of the sum of the solution to the corresponding homogeneous equation and its particular solution, $\varphi(R_T) = \varphi_h(R_T) + \varphi_p(R_T)$. The homogeneous equation is a second order Cauchy–Euler equation, with a characteristic equation given by $m^2 - 4m/3 + 1/6 = 0$. Solving for m, we get two real roots, $m = \frac{1}{6}(4 \pm \sqrt{10})$, meaning that the solution to the homogeneous equation is given by

$$\varphi_h(R) = c_1 R^{\frac{1}{6}(4-\sqrt{10})} + c_2 R^{\frac{1}{6}(4+\sqrt{10})}\,. \tag{20}$$

This solution is not locally given by a convergent power series. For this reason, and also for the fact that $\varphi_h(R)$ does not contribute to the full Eq. (18), we set $c_1 = c_2 = 0$, without loss of generality.[38] As such, the solutions to Eq. (18) are simply given by the particular solution in question, i.e. $\varphi(R_T) = \varphi_p(R_T)$, depending on $\Psi(R_T)$.

4.1. *Effective actions for mLQC-I*

As described in the Introduction, mLQC-I is divided in two branches. As such, we consider each of them separately and find an effective action for both.

4.1.1. *Effective action for the b_- branch*

Considering Eq. (2) for the b_- branch, the definition for $\Psi(\rho)$ given by Eq. (17) and Eq. (15), $\Psi(R_T)$ is given by

$$\Psi(R_T) = -\frac{R_T^2}{12\rho_c^I\kappa} + \frac{R_T}{6}\left(1+\frac{R_T}{2\kappa\rho_c^I}\right)\frac{\gamma^2 R_T/(2\kappa\rho_c^I)}{(\gamma^2+1)\left(1+\sqrt{1+R_T/(2\kappa\rho_c^I)}\right)^2}\,. \tag{21}$$

Therefore, in this case, Eq. (18) is given by

$$-\frac{\epsilon}{3}\left[\frac{1}{2}\varphi_T - R_T\varphi_T' + 3R_T^2\varphi_T''\right] = -\frac{R_T^2}{12\rho_c^I\kappa} + \frac{R_T}{6}\frac{\left(1+\frac{R_T}{2\kappa\rho_c^I}\right)\gamma^2 R_T/(2\kappa\rho_c^I)}{(\gamma^2+1)\left(1+\sqrt{1+R_T/(2\kappa\rho_c^I)}\right)^2}\,, \tag{22}$$

This equation was solved for $\varphi(R_T)$ using *Wolfram Mathematica*. Thus a metric $f(R)$ action, Eq. (19), was found which, when treated as an effective action, leads to the modified Friedmann Eq. (3). This effective action is given by

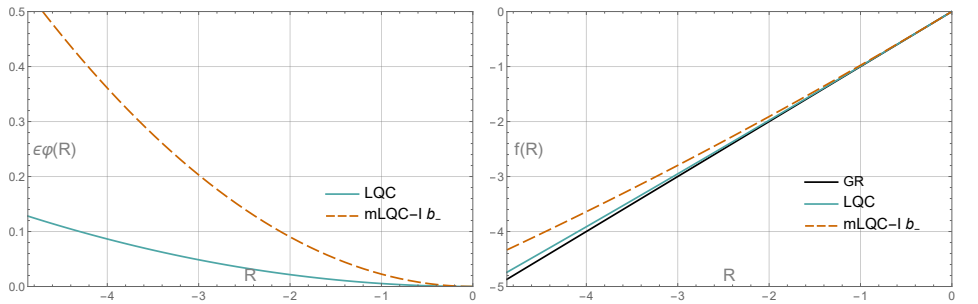
$$\begin{aligned}
f(R) = R + \frac{1}{90(\gamma^2+1)}\Bigg\{ & 5\left(-72\gamma^2\kappa\rho_c^I + \frac{R^2}{\kappa\rho_c^I} + 54\gamma^2 R\right) \\
& + \frac{18\gamma^2}{\sqrt{10}+10}\Bigg[3\left(4\left(5-4\sqrt{10}\right)\kappa\rho_c^I + \left(\sqrt{10}+10\right)R\right) \\
& \quad {}_2F_1\left[-\frac{1}{2},\frac{1}{6}\left(-\sqrt{10}-4\right);\frac{1}{6}\left(2-\sqrt{10}\right);-\frac{R}{2\kappa\rho_c^I}\right] \\
& + 3\left(12\left(2\sqrt{10}+5\right)\kappa\rho_c^I + \left(\sqrt{10}+10\right)R\right) \\
& \quad {}_2F_1\left[-\frac{1}{2},\frac{1}{6}\left(\sqrt{10}-4\right);\frac{1}{6}\left(\sqrt{10}+2\right);-\frac{R}{2\kappa\rho_c^I}\right] \\
& + (2\kappa\rho_c^I + R)\Bigg(9\sqrt{10}\,{}_2F_1\left[\frac{1}{2},\frac{1}{6}\left(-\sqrt{10}-4\right);\frac{1}{6}\left(2-\sqrt{10}\right);-\frac{R}{2\kappa\rho_c^I}\right] \\
& - \left(11\sqrt{10}+20\right)\,{}_2F_1\left[\frac{1}{2},\frac{1}{6}\left(\sqrt{10}-4\right);\frac{1}{6}\left(\sqrt{10}+2\right);-\frac{R}{2\kappa\rho_c^I}\right]\Bigg)\Bigg]\Bigg\}\,.
\end{aligned} \tag{23}$$

where we have dropped the subscript T since, to ϵ order, $f(R)$ and $f(R_T)$ are the same. This action contains hypergeometric functions, denoted by ${}_2F_1$, and its domain is given by $-2\kappa\rho_c^I \leq R$. Since it is only physically meaninful to consider $R \leq 0$, given Eq. (15), we have that our physical solution is defined for the range $-2\kappa\rho_c^I \leq R \leq 0$.

Using *Wolfram Mathematica*, a Taylor expansion of Eq. (23), about $R = 0$ and up to third order, was also determined and is given by

$$f(R) = R + \epsilon\varphi(R) = R + \frac{(4+3\gamma^2)R^2}{72(1+\gamma^2)\kappa\rho_c^I} + \frac{\gamma^2 R^3}{992(1+\gamma^2)(\kappa\rho_c^I)^2} + \cdots\,. \tag{24}$$

In order to visualize our solution, we provide two different plots in Fig. 1 regarding Eq. (23). In Fig. 1a we present the deviation terms of Eq. (23) and the deviation term of the effective action for LQC, given by $\epsilon\varphi(R) = R^2/(18\kappa\rho_c)$ according to Ref. 38. In Fig. 1b, we compare Eq. (23) with the effective $f(R)$ function for the case of LQC and the Lagrangian density of GR, with $\Lambda = 0$.



(a) (b)

Fig. 1. Figure 1a presents the comparison between the deviation, from GR, of the effective Lagrangian for the case of LQC (solid blue line), given by $\epsilon\varphi(R) = R^2/(18\kappa\rho_c)$, and the deviation terms of Eq. (23), for the b_- branch of mLQC-I (dashed dark orange line), for $-2\kappa\rho_c^I \leq R \leq 0$. Although the deviation is higher for the case of the b_- branch of this modified model, both of them are dominated by the quadratic term. Figure 1b illustrates the differences between the Lagrangian density of GR (solid black line), with $\Lambda = 0$, and the effective $f(R)$ functions for the case of LQC (solid blue line) and Eq. (23), for the b_- branch of mLQC-I (dashed dark orange line), for the interval $-2\kappa\rho_c^I \leq R \leq 0$.

4.1.2. *Effective action for the b_+ branch*

Considering Eq. (2) for the b_+ branch, the definition for $\Psi(\rho)$ given by Eq. (17) and Eq. (15), $\Psi(R_T)$ is given by

$$\Psi(R_T) = \frac{R_T}{6} + \frac{1}{3}\alpha\kappa\rho_\Lambda\left(1 + \frac{R_T}{2\kappa\rho_c^I}\right)\left[1 - \frac{R_T\left(1 - 2\gamma^2 + \sqrt{1 + R_T/(2\kappa\rho_c^I)}\right)}{8\gamma^2\kappa\rho_c^I\left(1 + \sqrt{1 + R_T/(2\kappa\rho_c^I)}\right)}\right]. \tag{25}$$

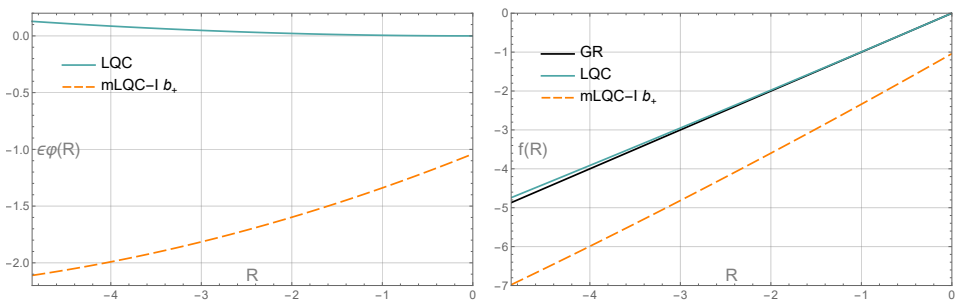
Therefore, in this case, Eq. (18) becomes

$$-\frac{\epsilon}{3}\left[\frac{\varphi_T}{2} - R_T\varphi_T' + 3R_T^2\varphi_T''\right] = \frac{R_T}{6} + \frac{\alpha\kappa\rho_\Lambda}{3}\left[1 + \frac{R_T}{2\kappa\rho_c^I}\right]\left[1 - \frac{R_T\left(1 - 2\gamma^2 + \sqrt{1 + \frac{R_T}{2\kappa\rho_c^I}}\right)}{8\gamma^2\kappa\rho_c^I\left(1 + \sqrt{1 + \frac{R_T}{2\kappa\rho_c^I}}\right)}\right], \tag{26}$$

As before, this equation was solved for $\varphi(R)$ using *Wolfram Mathematica*, and the corresponding effective action, that leads to the modified Friedmann Eq. (3), is

given by

$$
\begin{aligned}
f(R) = R - \alpha\kappa\rho_\Lambda + R + \frac{\alpha\rho_\Lambda R\left(18\left(2\gamma^2-1\right)\kappa\rho_c^I + R\right)}{72\gamma^2\kappa(\rho_c^I)^2} \\
+ \frac{\alpha\rho_\Lambda}{20\rho_c^I}\Bigg\{ -3\left[R - 2\left(\sqrt{10}-2\right)\kappa\rho_c^I\right] \\
{}_2F_1\left[-\frac{1}{2}, \frac{1}{6}\left(-\sqrt{10}-4\right); \frac{1}{6}\left(2-\sqrt{10}\right); -\frac{R}{2\kappa\rho_c^I}\right] \\
-3\left(2\left(\sqrt{10}+2\right)\kappa\rho_c^I + R\right) {}_2F_1\left[-\frac{1}{2}, \frac{1}{6}\left(\sqrt{10}-4\right); \frac{1}{6}\left(\sqrt{10}+2\right); -\frac{R}{2\kappa\rho_c^I}\right] \\
+ (2\kappa\rho_c^I + R)\Bigg(-\left(\sqrt{10}-1\right) {}_2F_1\left[\frac{1}{2}, \frac{1}{6}\left(-\sqrt{10}-4\right); \frac{1}{6}\left(2-\sqrt{10}\right); -\frac{R}{2\kappa\rho_c^I}\right] \\
+ \left(\sqrt{10}+1\right) {}_2F_1\left[\frac{1}{2}, \frac{1}{6}\left(\sqrt{10}-4\right); \frac{1}{6}\left(\sqrt{10}+2\right); -\frac{R}{2\kappa\rho_c^I}\right]\Bigg)\Bigg\}. \qquad (27)
\end{aligned}
$$



(a) (b)

Fig. 2. Figure 2a. presents the comparison between the deviation, from GR, for the case of LQC (solid blue line), given by $\epsilon\varphi(R) = R^2/(18\kappa\rho_c)$, and the deviation terms of Eq. (27), for the b_+ branch of mLQC-I (dashed light orange line), for $-2\kappa\rho_c^I \leq R \leq 0$. Contrary to the previous case, for this branch the deviation is predominantly negative since it is dominated by the linear term. Figure 2b. illustrates the differences between the Lagrangian density of GR (solid black line), with $\Lambda = 0$, and the effective $f(R)$ functions for the case of LQC (solid blue line) and Eq. (27), for the b_+ branch of mLQC-I (dashed light orange line), for the interval $-2\kappa\rho_c^I \leq R \leq 0$.

For the same reasons as in the previous branch, the physical domain of this solution is also given by $-2\kappa\rho_c^I \leq R \leq 0$. The Taylor expansion of Eq. (27) up to third order, about $R = 0$, was computed using *Wolfram Mathematica*, resulting in

$$
f(R) = -2\alpha\kappa\rho_\Lambda + \left(\frac{\alpha\left(5\gamma^2-1\right)\rho_\Lambda}{4\gamma^2\rho_c^I} + 2\right)R + \frac{\alpha\left(4-3\gamma^2\right)\rho_\Lambda R^2}{288\gamma^2\kappa(\rho_c^I)^2} + \frac{\alpha\rho_\Lambda R^3}{3968\kappa^2(\rho_c^I)^3} + \ldots . \qquad (28)
$$

We observe that, for this particular branch, $f(0) \neq 0$. We recall that ρ_Λ was interpreted as the energy density of an emergent positive cosmological constant in Ref. 20. Finally we provide similar plots for this branch, in Fig. 2.

4.2. *Effective action for mLQC-II*

We now consider the mLQC-II model, in which the modified Friedmann equation is given by Eq. (4). Considering the definition for $\Psi(\rho)$ given by Eq. (17) and Eq. (15), $\Psi(R_T)$ is given by

$$\Psi(R_T) = \frac{R_T}{6} - \frac{R_T\left(1 + R_T/(2\kappa\rho_c^{II})\right)\left(1 - 2\gamma^2\left(\gamma^2+1\right)R_T/(\kappa\rho_c^{II})\right)}{3\left(1 - \gamma^2 R_T/(\kappa\rho_c^{II}) + \sqrt{1 - 2\gamma^2\left(\gamma^2+1\right)R_T/(\kappa\rho_c^{II})}\right)}. \tag{29}$$

Therefore, in this case, Eq. (18) is given by

$$-\frac{\epsilon}{3}\left[\frac{1}{2}\varphi_T - R_T\varphi_T' + 3R_T^2\varphi_T''\right] = \frac{R_T}{6} - \frac{R_T\left(1 + \frac{R_T}{2\kappa\rho_c^{II}}\right)\left(1 - \frac{2\gamma^2\left(\gamma^2+1\right)R_T}{\kappa\rho_c^{II}}\right)}{3\left(1 - \frac{\gamma^2 R_T}{\kappa\rho_c^{II}} + \sqrt{1 - \frac{2\gamma^2(\gamma^2+1)R_T}{\kappa\rho_c^{II}}}\right)}. \tag{30}$$

This equation was solved for $\varphi(R)$ using *Wolfram Mathematica*. The corresponding metric $f(R)$ action which, when treated as an effective one, leads to the modified Friedmann Eq. (4) is given by

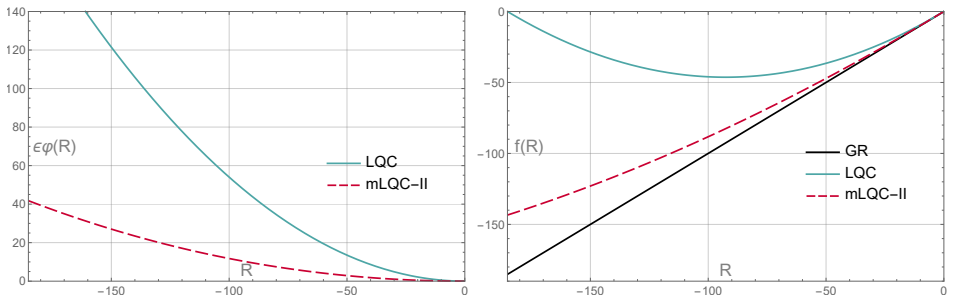
$$\begin{aligned}
f(R) = R + \frac{1}{90\gamma^4}\Bigg\{ & 270\left(\gamma^4+\gamma^2\right)R + 90\kappa\rho_c^{II} + \frac{20\left(\gamma^6+\gamma^4\right)R^2}{\kappa\rho_c^{II}} \\
& + 9\Bigg[3\left(\left(\sqrt{10}-2\right)\kappa\rho_c^{II} + 2\left(\gamma^4+\gamma^2\right)R\right) \\
& \quad {}_2F_1\left[-\frac{1}{2}, \frac{1}{6}\left(-\sqrt{10}-4\right); \frac{1}{6}\left(2-\sqrt{10}\right); \frac{2R\gamma^2\left(\gamma^2+1\right)}{\kappa\rho_c^{II}}\right] \\
& + \left(6\left(\gamma^4+\gamma^2\right)R - 3\left(\sqrt{10}+2\right)\kappa\rho_c^{II}\right) \\
& \quad {}_2F_1\left[-\frac{1}{2}, \frac{1}{6}\left(\sqrt{10}-4\right); \frac{1}{6}\left(\sqrt{10}+2\right); \frac{2R\gamma^2\left(\gamma^2+1\right)}{\kappa\rho_c^{II}}\right] \\
& + \left(2\left(\gamma^4+\gamma^2\right)R - \kappa\rho_c^{II}\right)\Bigg(\left(\sqrt{10}-1\right) \\
& \quad {}_2F_1\left[\frac{1}{2}, \frac{1}{6}\left(-\sqrt{10}-4\right); \frac{1}{6}\left(2-\sqrt{10}\right); \frac{2R\gamma^2\left(\gamma^2+1\right)}{\kappa\rho_c^{II}}\right] \\
& - \left(\sqrt{10}+1\right) {}_2F_1\left[\frac{1}{2}, \frac{1}{6}\left(\sqrt{10}-4\right); \frac{1}{6}\left(\sqrt{10}+2\right); \frac{2R\gamma^2\left(\gamma^2+1\right)}{\kappa\rho_c^{II}}\right]\Bigg)\Bigg]\Bigg\}.
\end{aligned} \tag{31}$$

This solution also contains hypergeometric functions but, for this model, they present a different argument. According to this argument the domain of Eq. (31) is given by $R \leq \kappa\rho_c^{II}/\left(2\gamma^2(\gamma^2+1)\right)$. As such, since the Ricci scalar must be less or equal to zero for a massless sclar field scenario, in this case the solution only has physical meaning for the interval $R \leq 0$.

Using *Wolfram Mathematica*, a Taylor expansion of Eq. (31), about $R = 0$ and up to third order, was computed and is given by

$$f(R) = R + \frac{\left(-3\gamma^4 - 2\gamma^2 + 1\right) R^2}{18\kappa\rho_c^{II}} - \frac{\gamma^2\left(\gamma^2+1\right)^3 R^3}{62(\kappa\rho_c^{II})^2} + \dots\,, \tag{32}$$

The solution for the mLQC-II model is depicted in Fig. 3. In Fig. 3a, we present the deviation terms of Eq. (31) and the deviation term of the effective action for LQC, given by $\epsilon\varphi(R) = R^2/(18\kappa\rho_c)$ according to Ref. 38. In Fig. 3b, we compare Eq. (31) with the effective $f(R)$ function for the case of LQC and the Lagrangian density of GR, with $\Lambda = 0$. As a summary, a combination of our results is presented in Fig. 4.



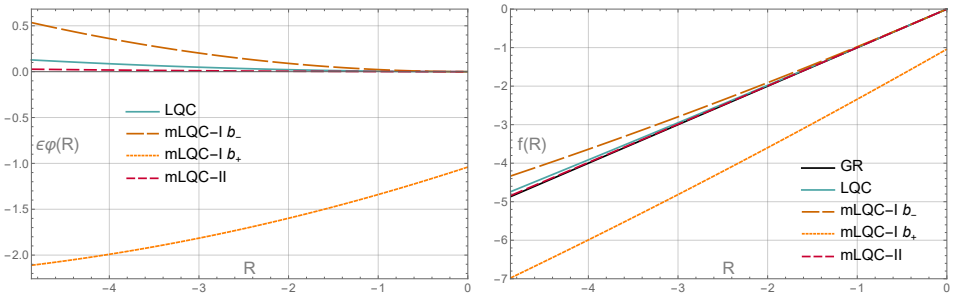
(a) (b)

Fig. 3. Figure 3a. presents the comparison between the deviation, from GR, of the effective Lagrangian for the case of LQC (solid blue line), given by $\epsilon\varphi(R) = R^2/(18\kappa\rho_c)$, and the deviation terms of Eq. (31), for the case of mLQC-II (dashed pink line), for $-18\kappa\rho_c \leq R \leq 0$. Both of the deviations are dominated by the quadratic term. Figure 3b. illustrates the differences between the Lagrangian density of GR (solid black line), with $\Lambda = 0$, and the effective $f(R)$ functions, for the case of LQC (solid blue line), and Eq. (31), for mLQC-II (dashed pink line), for the interval $-18\kappa\rho_c \leq R \leq 0$.

5. Conclusions

In this work, we have addressed the initial singularity problem that is present in the ΛCDM model and considered a possible resolution to this question, as proposed by LQC, in which the Big Bang is replaced by a quantum bounce. Since this result comes from a different field in physics, it is relevant to ask if it is possible to replicate it in the framework of GR and its modifications. In this context we considered the class of metric $f(R)$ gravity. Motivated by Ref. 38, we have used the same procedure with two modifications of standard LQC, that also yield a quantum bounce, which are two attempts to bridge the gap between LQG and LQC, by means of similar treatments of the Hamiltonian constraint.

We have applied the covariant order reduction method to obtain a reduced version of the full field equations in $f(R)$ gravity. The corresponding modifed



(a) (b)

Fig. 4. Figure 4a. presents the comparison between the deviation, from GR, of the effective Lagrangian for the case of LQC (solid blue line), given by $\epsilon\varphi(R) = R^2/(18\kappa\rho_c)$, and the deviation terms of Eq. (23), for the b_- branch of mLQC-I (dashed dark orange line), Eq. (27), for the b_+ branch of mLQC-I (dashed light orange line) and Eq. (31), for mLQC-II (dashed pink line), for $-2\kappa\rho_c^I \leq R \leq 0$. Figure 4b. presents the differences between the Lagrangian density of GR (solid black line), with $\Lambda = 0$, and the effective $f(R)$ functions for the case of LQC (solid blue line), Eq. (23), for the b_- branch of mLQC-I (dashed dark orange line), Eq. (27), for the b_+ branch of mLQC-I (dashed light orange line) and Eq. (31), for mLQC-II (dashed pink line), for $-2\kappa\rho_c^I \leq R \leq 0$.

Friedmann equation depends on the $f(R)$ function, which we chose to parametrize as $f(R) = R + \epsilon\varphi(R)$. In this framework, we have determined functions $\varphi(R)$, such that Eqs. (2)–(4) are the same as Eq. (18). In other words, we have determined effective covariant $f(R)$ actions which lead to Eqs. (2)–(4). Moreover, these effective actions allow for a positive effective gravitational coupling constant and avoid the Dolgov–Kawasaki instability.[25] According to Eq. (12), the approximation that we use is valid for $|R| \ll \rho_c \sim l_p^{-2}$, therefore, breaking down at the bounce, since there $|R| \sim \rho_c \sim l_p^{-2}$. Thus, the argument that the effective Lagrangians deduced in this work yield Eqs. (2)–(4) is not quite a rigorous statement. However, our claim is that, at stages close enough to the bounce, the solutions found in this work may effectively, and correctly, describe the collapsing universe.

If a quantum theory of gravity is found, a proper description of the beginning of the Universe could eventually be reached. In this regard, the ΛCDM model is incomplete and, for this reason, there is motivation for attempting modifications of GR, in order to accommodate scenarios in which the Big Bang singularity is non-existent, such as the covariant effective actions determined in this work. In a forthcoming paper we will extend our analysis for mLQC-II to arbitrary values of w.

Probing multiverse using gravitational wave observations

Moe Kukihara* and Kazuhiro Hayama†

**E-mail: sd211003@cis.fukuoka-u.ac.jp*

†*E-mail: hayama@fukuoka-u.ac.jp*

From the theory of the multiverse cosmology, it is possible that our universe collides with other universes locally in its history, which may result in local changes of the curvature of the spacetime. In this paper, we propose a method to probe the multiverse using gravitational wave observations for the first time. Our method firstly makes triangles using two detected gravitational wave sources and the Sun, and then measures the curvature of the triangles. We use 11 gravitational wave sources detected by LIGO and Virgo during O1 and O2, and make 55 triangles by combining them to measure their curvature. The curvature is measured by comparing the distance between two gravitational wave sources estimated by the gravitational wave observations with the one obtained with assumption of a simple model of the cosmological evolution.

As a result, we found that, for 43 of 55 triangles, the distances estimated by the model are greater than the ones obtained by the gravitational wave observations. This indicates a negative curvature, which may be due to the simplification of the cosmological evolution. For the rest 12, the distances are not determined because of uncertainty of the parameters of the gravitational wave observations. Further gravitational wave observations and more sophisticated model of the cosmological evolution is essential to test the multiverse cosmology observationally.

Keywords: Gravitational wave observations, multiverse, spacetime geometry, cosmological evolution

1. Introduction

Since E. Hubble discovered the expansion of the universe in 1929,[1] it has been considered of the possibility that the beginning of the universe was a small point. G. Gamow proposed the Big Bang theory, from which the beginning of the universe was a fireball. The Big Bang theory was supported by observations such as the first observation of the cosmic microwave background radiation in 1965[2] and the discovery of temperature fluctuations originating in the early universe by the cosmic background radiation explorer COBE in 1989.[3] However, the Big Bang theory has problems such as the homogeneity and the flatness problem. Inflation theory proposed to solve these problems,[4–6] but inflation theory also has following problems: The average value of the vacuum energy density predicted by the field theory is $\rho_\Lambda \sim 10^{113}$ J/m^3, whereas the currently observed vacuum energy density is, $\rho_\Lambda \sim 10^{-9}$ J/m^3. There is a difference of about 120 digits in size between the theoretical value and the observed value.[7]

Multiverse cosmology may solve these problems. In the multiverse cosmology, each universe is allowed to have different vacuum energy density, and our universe happened to have current vacuum energy densities. Thus, in the multiverse cosmology, the formation of multiple universes is naturally predicted. It is possible that our universe collides with other universes locally and there is a local change of curvature at the collision surface.[8] The measurement of the curvature performed by the cosmic microwave background radiation observation satellite WMAP[9,10] showed that the curvature of the entire universe was flat. But there were uncertainties that the vortex-shaped polarization component were not discovered by CMB polarization observations, and therefore the determination of the curvature needs to be further refined in future observations.

In order to find whether there has been collisions between our universe and other universes in the past, There are studies that explore the temperature fluctuations that occur at the collisions surface. This temperature fluctuation appears as a ring pattern on the cosmic microwave background radiation. Several radio observations were conducted to see the properties,[11,12] and as a result, four sky areas were reported from the WMAP observations that were consistent with the ring patterns that appeared due to collision between the universes.[13,14] It should be noted that as the universe is expanded with time, the effects of collisions tend to be diluted as much as the structure of the initial universe.

In this paper, we proposed for the first time a method for probing the multiverse using gravitational wave observations, which is independent of radio wave observations performed so far.[15] Chapter 2 describes how to measure the local curvature of the universe, and Chapter 3 describes the results and discussion.

2. Measurement of the local curvatures of the universe

We will explain how we estimate local curvatures of the universe.The gravitational waves GW150914, GW151012, GW151226, GW170104, GW170608, GW170729, GW170809, GW170814, GW170817, GW170818, GW170823 were detected by the LIGO and Virgo observations.[16] Two of the 11 gravitational wave sources and the sun are used to form a triangle, and the distance between the two gravitational wave sources is estimated by gravitational wave observations.The distances are also estimated by simple assumption that the gravitational wave sources were born in the early universe and the distance between the two sources is the size of the flat universe. The local curvature of the universe was measured by comparing these values.

2.1. *Distance between gravitational waves by gravitational wave observations*

The sky locations of the almost all detected gravitational waves are highly uncertain. The summary plots in the paper B. P. Abbott, *et al.*[16] which show 50% and 90% credible area for the sky locations of detected gravitational wave events and most

of the events have error regions with several hundred square degrees. But the error regions are estimated to be reduced in future observations. In this paper we regard the sky locations of the gravitational waves as the positions with the highest probabilities in the contours.

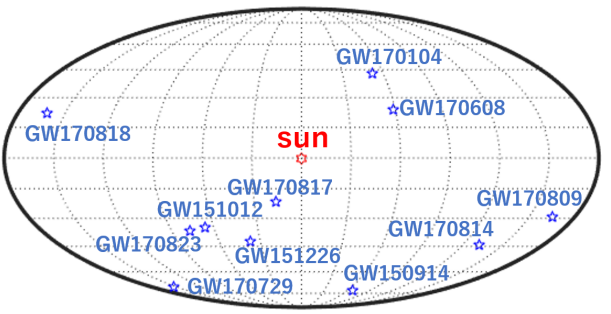

Fig. 1. Most probable sky locations of the detected gravitational waves in 2015-2017 in the Mollweide coordinates.[16]

Figure 1 shows the sky positions of the gravitational wave sources used here and the sun. we constructed triangles using the sun and two of the gravitational wave sources. The distances between the two gravitational wave sources were estimated using the estimated distances and sky locations of the gravitational wave sources in the triangle. Figure 2 shows 55 combinations of two gravitational sources for making triangles including the Sun.

2.2. *Distance between gravitational waves by a flat universe model*

We consider of the following four-dimensional metric that describes a uniform and isotropic expansion universe.

$$ds^2 = -c^2dt^2 + a^2(t)\left[\frac{dr^2}{1-Kr^2} + r^2(d\theta^2 sin^2\theta d\phi^2)\right] \tag{1}$$

c: speed of light, a(t): Scale factor at time t, r: Radius in 3D spherical coordinates, θ, ϕ: Declination in 3D spherical coordinates, K: constant

Using the natural unit system, the metric of the flat universe model is,

$$ds^2 = -dt^2 + a^2(t)[dr^2 + r^2(d\theta^2 + sin^2\theta d\phi^2)] \tag{2}$$

When a gravitational wave with a redshift z is observed, the relation of the scale factor and z is as follows:

$$\frac{a(t)}{a(t_0)} = \frac{1}{1+z} \tag{3}$$

Here, when we estimate the distance between two gravitational wave sources in the flat universe model, we put simple assumption that the gravitational wave sources occurred in the early universe and the evolution of the universe are not affected by gravity from other objects such as dark matter and galaxies.[17,18] z is the average of the redshifts of the two gravitational wave sources, and the distances between the two points are estimated to be the size of the universe at z. Hereafter we refer this as the simple universe model.

2.3. *Comparison of the estimated distances for 55 triangular areas*

Figure 3 shows the distances between the sources by gravitational wave observations and the distances between the sources by the simple universe model for each triangular area. The blue cross marks show the value distances estimated from the gravitational wave observations. The error bars reflect the uncertainties of the distances of the gravitational wave sources and the uncertainties of the sky locations of the gravitational wave sources. The red asterisks are the distances between the two gravitational wave sources in the simple universe model.

Figure 4 shows the curvature of each area. The curvature of each area was estimated by comparing the distances estimated by the two ways. If the two estimated

distances are equal each other, then the local curvature of the universe is zero. If the distance estimated by gravitational wave observations is larger than the distance estimated by the simple universe model, the positive curvature is suggested, and if smaller, the negative curvature is suggested.

In the 43 areas among 55 areas, the distances estimated by the simple universe model were larger than the distances estimated by gravitational wave observations, so negative curvatures were suggested. On the other hands area 5, area 14, area 22, area 29, area 34, area 35, area 41, area 42, area 43, area 44, area 45, area 55 in this 12 areas, the estimated distances estimated by the simple universe model were in the error bars of the distances estimated by gravitational wave observations, so the curvatures were not estimated from all at the gravitational wave observations.

3. Summary

In this study, we proposed for the first time a method to probe the multiverse cosmology using gravitational wave observations. We estimated the local curvatures of various areas in the universe by measuring the sums of the internal angles of the 55 triangles formed by the sun and the all combinations of 11 gravitational wave sources.

In the 43 areas among 55 areas, the distances estimated by the simple universe model were larger than the distances estimated by gravitational wave observations, so negative curvatures were suggested. This is due to the simplification of the universe model, and it is necessary to sophisticate the model of the universe by including the effects of other astronomical objects, dark matter, dark energy, and so on. On the other hands in the area 5, area 14, area 22, area 29, area 34, area 35, area 41, area 42, area 43, area 44, area 45, area 55 in this 12 areas, the distances estimated by the simple universe model were in the error bar of the distances estimated by gravitational wave observations, so the curvatures could not be estimated at the current gravitational wave observations. In the future, it will be important to reduce the error in order to limit the sign of the curvature.

We discuss the status of observables and operator ordering ambiguity in the quantum cosmology model with Brown-Kuchař dust as the matter field. In order to study the dynamics of the FLRW universe, Hubble parameter and Ricci scalar are expressed as a function of phase space variables. As these functions exhibit operator ordering ambiguity, we write several Hermitian extensions corresponding to these observables. For the unitarily evolving semiclassical wave packet constructed in,[1] we have computed the expectation value of these observables, which shows that very early in the collapsing branch and very late in the expanding branch, the expectation values of the Hubble parameter and the Ricci scalar matches the classically obtained results irrespective of the operator ordering chosen. The expectation value of the Hubble parameter vanishes, and Ricci scalar attains an extremum at the point of classical singularity for all orderings, showing a robust singularity resolution. The signature of the operator ordering ambiguity is most pronounced at the classical singularity. For Weyl ordering, the expectation value of the Ricci scalar becomes negative for certain parameter values. We have computed the expectation value of other curvature invariants as well, which follows the trend.

Keywords: FLRW Model, Wheeler-DeWitt equation, Operator ordering ambiguity, Quantum Cosmology, Brown-Kuchař dust

1. Introduction

Any consistent quantization scheme for gravity must address the longstanding issues that plague the theory, like observables in quantum gravity or operator ordering ambiguity. In this work we will address the issue of operator ordering ambiguity in the observables of quantum gravity, in the context of flat FLRW model with Brown-Kuchař dust.[2]

General relativity is an example of singular systems, which has diffeomorphisms and time reparametrizations as gauge freedom.[3] A consistent (Dirac) observable in the general relativity must be invariant under diffeomorphisms and time reparametrizations. Now the systems with time reparametrization symmetry are tricky to handle, as the Hamiltonian of such systems itself is a constraint. Which would means that physical observables in the theory would be frozen in time or are constant of motion. To circumvent this issue, a possible resolution is proposed by Kuchař,[4] a phase space function does not need to have weakly vanishing Poisson bracket with Hamiltonian constraint to be an observable of general relativity.

The special objects which have vanishing Poisson bracket with Hamiltonian constraint are called a perennials.

Upon quantization, one would ideally like to obtain a self-adjoint extension of all the relevant observables appearing in the theory and study their spectral properties. But if one is interested in the expectation value of the operators in a wave packet, Hermiticity of the operator is sufficient to ensure the reality of the expectation value. For that reason we will concern ourselves with the Hermitian extensions of the observables and their expectation value for the wave packets constructed in the quantum model.

In this analysis, we will follow Kuchař's prescription[4] of observables in the quantum gravity models. For the FLRW model we will write the Hermitian extension of the operators that correspond to the Hubble parameter and the curvature invariants. We will find the expectation value of these operators and show the robustness of the singularity resolution claimed in the aforementioned quantum cosmology model. Apart from that, we will also address the operator ordering ambiguity in these observables and discuss at what stage this ambiguity will play a role.

2. FLRW Model with Brown-Kuchař Dust

We will start with the canonical formulation of the flat FLRW model coupled to Brown-Kuchař dust. We will first write the Hamiltonian constraint for this system and then write the phase space expression for the observables we are interested in.

The line element and the Ricci scalar for a homogeneous and isotropic flat FLRW spacetime is

$$ds^2 = -\mathcal{N}^2(t)dt^2 + a^2(t)d\mathbf{x}^2, \tag{1}$$

$$\mathcal{R} = \frac{6}{\mathcal{N}^2}\left[-\frac{\dot{\mathcal{N}}\dot{a}}{\mathcal{N}a} + \frac{\ddot{a}}{a} + \left(\frac{\dot{a}}{a}\right)^2\right], \tag{2}$$

where $a(\tau)$ is the scale factor and $\mathcal{N}$ is the lapse function. The action for this model with Brown-Kuchař dust[2,5] written in ADM form is,

$$S = S_G + S_m = \int \left(p\dot{a} + p_\tau\dot{\tau} - \mathcal{N}(H^G + H^D)\right) dt. \tag{3}$$

The Hamiltonian constraint for this model is given by,

$$\mathsf{H} = H^G + H^D = -\frac{\kappa^2}{6V_0}\frac{p_a^2}{2a} + p_\tau \approx 0. \tag{4}$$

In the further analysis, we will choose $\kappa^2 = 6V_0$. The solution of the Friedmann's equations with dust as matter is $a(t) \propto t^{2/3}$. The dust proper time τ and the coordinate time t are related as $\dot{\tau} = 1 \implies \tau(t) = t + \text{const}$. This model exhibits curvature singularity and has two disjointed solutions, representing a universe expanding from a Big Bang singularity and a universe collapsing to a Big Crunch singularity.

2.1. *Hubble Parameter and Ricci Scalar*

We are interested in the canonical expression for the Hubble parameter and the Ricci scalar. Using defining equation for the momentum conjugate to scale factor and the Hamilton's equations of motion, we get

$$\dot{a} = -\frac{p_a \mathcal{N}}{a}, \tag{5}$$

$$\ddot{a} = -\frac{p_a \dot{\mathcal{N}}}{a} - \frac{p_a^2 \mathcal{N}^2}{2a^3}. \tag{6}$$

Since we are working in comoving gauge $\mathcal{N} = 1$, the Hubble parameter takes the form

$$\mathbb{H} = \frac{\dot{a}}{a} = -a^{-2} p_a. \tag{7}$$

From (2), (5) and (6), the Ricci scalar is given by,

$$\mathcal{R} = \frac{3p_a^2}{a^4}. \tag{8}$$

Classically for dust as matter source, the Ricci scalar is $\mathcal{R} = 4/3t^2$. The flat FLRW model with dust as matter has curvature singularity at $t = 0$ when $a \sim t^{2/3} \to 0$ and $\mathcal{R} \to \infty$.

2.2. *Riemann and Kretschmann Scalar*

Riemann Scalar for this model is

$$\mathcal{R}ie = R_{\mu\nu} R^{\mu\nu} = 9\frac{(\dot{a}\dot{\mathcal{N}} - \mathcal{N}\ddot{a})^2}{a^2\mathcal{N}^6} + 3\frac{(a\mathcal{N}\ddot{a} - a\dot{a}\dot{\mathcal{N}} + 2\mathcal{N}\dot{a}^2)^2}{a^4\mathcal{N}^6} = \frac{3p_a^4}{a^8}. \tag{9}$$

Kretschmann Scalar for this model is,

$$K = R_{\mu\nu\alpha\beta} R^{\mu\nu\alpha\beta} = 12\left(\frac{(\dot{a}\dot{\mathcal{N}} - \mathcal{N}\ddot{a})^2}{\mathcal{N}^6 a^2} + \frac{\dot{a}^4}{a^4\mathcal{N}^4}\right) = \frac{15p_a^4}{a^8} = 5\mathcal{R}ie. \tag{10}$$

Classically for dust as matter, Riemann and Kretschmann scalar takes the form $\mathcal{R}ie = 16/27t^4$, and $K = 80/27t^4$. These curvature invariants also diverge at $t = 0$.

3. Quantum Cosmology

Quantization of this system is done by implementation of the constraint $\mathsf{H} \approx 0$ as supplementary condition on wave functions. Brown-Kuchař dust appears as natural clock for the quantum theory and we are essentially working with dust proper time. Wheeler Dewitt equation for this model takes the form of Schrödinger equation,

$$i\frac{\partial \Psi(R,\tau)}{\partial \tau} = \hat{H}\Psi(a,\tau), \tag{11}$$

$$\hat{H} = \hbar^2 a^{-1+p+q} \frac{d}{da} a^{-p} \frac{d}{da} a^{-q}. \tag{12}$$

Since the Hamiltonian is a product of non-commuting variables, therefore, it does not have a unique quantum counterpart and the model exhibits operator ordering ambiguity. The parameters p and q represent our freedom to choose operator ordering. The eigenvalue of Hamiltonian can be interpreted as Misner-Sharp mass which on-shell is related to the energy of the dust[a]. The self-adjoint extensions of Hamiltonian (12) are discussed in.[1]

To make the momentum operator $\hat{P}$ Hermitian on the real half line $\mathbb{R}^+$, we choose measure a^2 and the momentum operator that is symmetric with this measure $\hat{p}_a = -ia^{-1}\partial_a a$. Therefore, to accommodate hermiticity of the momentum, we have to impose the constraint $1 - p - 2q = 2$ or $p + 2q = -1$ on operator ordering parameters. Using this constraint, we can eliminate one of these parameters. It is shown in,[6] the expectation values of a general observables in a general wave packet constructed in this model is independent of parameter q and it appears as a free parameter in the model. Therefore, the above constraint does not put any restriction on the physical content of the theory. The detailed discussion about the Hermiticity and the self-adjointness of momentum operator on real half-line can be found in.[6] The positive energy stationary states with this choice are,

$$\phi^1_E(a) = \frac{2}{\sqrt{3}} E^{\frac{1}{4}} J_{\frac{2|q|}{3}}\left(\frac{2}{3}\sqrt{2E}a^{\frac{3}{2}}\right). \tag{13}$$

Which form an orthogonal set under the scalar product we have chosen, thus making them suitable for the construction of wave packet. From the positive energy modes, a unitarily evolving wave packet is constructed by choosing a normalized Poisson-like distribution

$$\psi(R,\tau) = \int_0^\infty d\sqrt{E}\phi^1_E(R)e^{iE\tau}A(\sqrt{E}), \tag{14}$$

$$A(\sqrt{E}) = \frac{\sqrt{2}\lambda^{\frac{1}{2}(\kappa+1)}}{\sqrt{\Gamma(\kappa+1)}}\sqrt{E}^{\kappa+\frac{1}{2}}e^{-\frac{\lambda}{2}E}, \tag{15}$$

where $\kappa \geq 0$ and $\lambda > 0$ are real parameters with κ being dimensionless and λ has dimensions of length or inverse of energy. For this choice of distribution, expectation value of the Hamiltonian is inversely proportional to λ. With this distribution and constraint $\kappa = 2|q|/3$, the wave packet takes the form,

$$\psi(a,\tau) = \sqrt{3}\frac{a^{|q|}}{\sqrt{\Gamma(\frac{2}{3}|q|+1)}}\left(\frac{\frac{\sqrt{2\lambda}}{3}}{\frac{\lambda}{2}-i\tau}\right)^{\frac{2}{3}|q|+1} e^{-\frac{2a^3}{9\left(\frac{\lambda}{2}-i\tau\right)}}. \tag{16}$$

Taking this constraint on the parameter makes the distribution a function of the operator ordering parameter. We can not be sure if the dependency of an observable

[a]Misner-Sharpe mass for spherically symmetric system $ds^2 = g_{ab}(z)dz^a dz^b + R^2(z)d\Omega^2$ is $M_{MS} = R(z)\left(1 - g^{ab}\partial_a R(z)\partial_b R(z)\right)/2$. For the case of FLRW mode, Misner-Sharp mass is $M_{MS} = a\dot{a}^2 r^3/2 = (4\pi r^3/3)\rho a^3 G$. The gravitational Hamiltonian is given by $H = -(3V/8\pi G)a\dot{a}^2 = -V\rho a^3$, since ρa^3 is a constant of motion and the Hamiltonian represents energy associated with the dust.

on parameter q is coming from the its dependence on the shape of the distribution or is it a genuine artifact of the operator ordering ambiguity. The signature of this parameter on the observables is discussed in[6] and we are not interested in operator ordering ambiguity in the Hamiltonian operator here. We are interested in the operator ordering ambiguity in the observables of this theory. It is shown in,[1] this model avoids singularity following DeWitt's criteria and in the current context, it represents a bouncing cosmology model.

4. Observables

In this analysis, we will follow Kuchař's proposal,[4,7,8] the observables in a time reparametrization invariant systems need not to commute with Hamiltonian constraint. Moreover in the quantum domain, we will require the Hermitian extension of operators to ensure the reality of expectation value of these observables. We will write the Hermitian extension of phase space functions that we are interested in and compute their expectation values in the wave packet (16).

4.1. *Hubble Parameter*

Corresponding to the canonical form of the Hubble parameter (7), several operator orderings for which the Hubble parameter is Hermitian can be written as,

$$F.O.1 \rightarrow \hat{\mathbb{H}}_1 = -a^{-1}\hat{p}_a a^{-1}, \tag{17}$$

$$F.O.2 \rightarrow \hat{\mathbb{H}}_2 = -\frac{1}{2}\left(a^{n-2}\hat{p}_a a^{-n} + a^{-n}\hat{p}_a a^{n-2}\right), \tag{18}$$

$$\hat{\mathbb{H}}_1\psi = \hat{\mathbb{H}}_2\psi = i\, a^{-2}\frac{\partial\psi}{\partial a} = \bar{\mathbb{H}}. \tag{19}$$

To ensure the Hermiticity of the operator, the boundary term $i\left[\psi^*\chi\right]_0^\infty$ has to vanish. It is achieved by the wavefunctions that vanishes when $a \rightarrow 0$ or $a \rightarrow \infty$. For the wave packets (16), it is the case provided $q \neq 0$.

The expectation value of the Hubble parameter for the wave packet (16) is,

$$\bar{\mathbb{H}}_1 = \langle\psi|\hat{\mathbb{H}}_1|\psi\rangle = i\int_0^\infty \psi^*(a,\tau)\frac{\partial\psi(a,\tau)}{\partial a}\, da = \frac{8\tau}{3(\lambda^2+4\tau^2)}. \tag{20}$$

In the large τ limit, i.e. $\tau^2 >> \lambda^2$, we recovers the classical value of Hubble parameter for the flat FLRW model with dust as matter.

$$\bar{\mathbb{H}}|_{\lambda\rightarrow 0} = \frac{2}{3\tau}. \tag{21}$$

The expectation value of the Hubble parameter is plotted in Fig. 1.

The Hubble parameter $\bar{\mathbb{H}}$ has global maximum at $\tau = \lambda/2$ and global minimum at $\tau = -\lambda/2$. At the point of classical singularity the Hubble parameter vanishes thus signifying a robust singularity resolution.

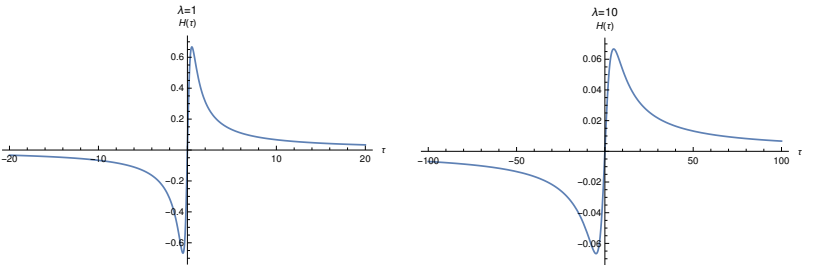

Fig. 1. Expectation value of the Hubble Parameter for different λ values.

4.2. *Ricci Scalar*

We will write general operator orderings that will make the operator corresponding to the phase space function given in Eq. (8) Hermitian with the given measure. There are two choices, normal symmetric operator ordering and Weyl ordering.

$$\hat{\mathcal{R}}_1 = 3a^{-j}\hat{p}_a a^{2j-4}\hat{p}_a a^{-j}, \tag{22}$$

$$\hat{\mathcal{R}}_2 = -\frac{3}{2}\left(a^{-j}\hat{p}_a a^{-k}\hat{p}_a a^{j+k-4} + a^{j+k-4}\hat{p}_a a^{-k}\hat{p}_a a^{-j}\right). \tag{23}$$

Here j and k are parameters that encapsulate the operator ordering ambiguity and describe our freedom in choosing operator ordering corresponding to the Ricci scalar.

For the operators to be Hermitian, the boundary term

$$-3\left[a^{-2}\left(\psi^*\frac{\partial\chi}{\partial a} - \frac{\partial\psi^*}{\partial a}\chi\right)\right]_0^\infty = 0 \tag{24}$$

has to be satisfied. For the case of the wave packet (16), the boundary term vanishes when $q > 3/2$. The expectation value of the Ricci scalar for this wave packet is,

$$\bar{\mathcal{R}}_1 = \frac{16\left(\lambda^2(3|q| + 2(j-4)(j-1)) + 4|q|(2|q|-3)\tau^2\right)}{3|q|(2|q|-3)\left(\lambda^2+4\tau^2\right)^2}, \tag{25}$$

$$\bar{\mathcal{R}}_2 = \frac{16\left(\lambda^2(3|q| - 2j(j+k-4) + 5k - 12) + 4|q|(2|q|-3)\tau^2\right)}{3|q|(2|q|-3)\left(\lambda^2+4\tau^2\right)^2}. \tag{26}$$

We see, the expectation value is well behaved regular function in the domain of parameters that ensure the Hermiticity. Again for large $|\tau|$ i.e. $\tau^2 >> \lambda^2$, we recover the classical expression for the Ricci scalar irrespective of the operator ordering chosen,

$$\bar{\mathcal{R}} = \frac{4}{3\tau^2}. \tag{27}$$

For the limit $q >> j, k$ there is no signature of the operator ordering parameters j and k in the expectation value of the Ricci scalar.

$$\bar{\mathcal{R}}_1 = \bar{\mathcal{R}}_2 = \frac{16\left(3|q|\lambda^2 + 4|q|(2|q|-3)\tau^2\right)}{3|q|(2|q|-3)\left(\lambda^2+4\tau^2\right)^2}. \tag{28}$$

The Ricci scalar in this regime has local minima at $\tau = 0$ and global maxima at $\tau = \pm\lambda/2$. Surprisingly in the large q regime, the Ricci scalar has maxima at the dust proper time, where the Hubble parameter has extrema.

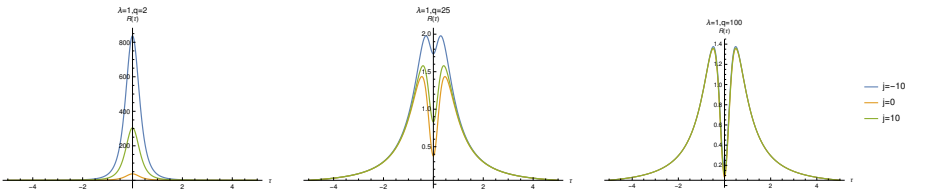

Fig. 2. Expectation value of the Ricci scalar $\bar{\mathcal{R}}_1$ for different operator orderings.

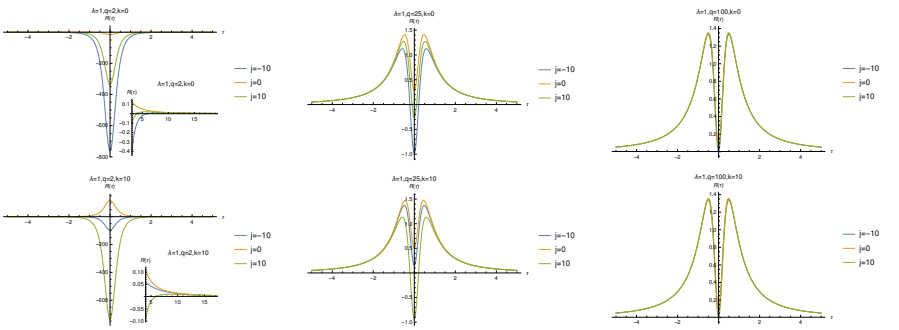

Fig. 3. Expectation value of Ricci scalar with Weyl ordering $\bar{\mathcal{R}}_2$ for different operator ordering parameters.

We have plotted the Ricci scalar for normal operator ordering in Fig. 2 and for the Weyl ordering in Fig 3. We see that the signature of the operator ordering parameters is most pronounced at the point of classical singularity i.e. at $\tau = 0$. Moreover, as we keep on increasing parameter q, the expectation value of the Ricci scalar for different operator ordering keeps on merging and for very large q, there is no signature of the operator ordering parameters. For the case of Weyl ordered Ricci scalar, the expectation value of the operator has negative values for certain parameter range.

4.3. *Riemann and Kretschmann Scalar*

Since the Kretschmann scalar is proportional to the Riemann scalar, we will write the Hermitian extensions of one of them, say, Kretschmann scalar and find the expectation value of the operator with given wave packet (16).

$$F.O.1 \to \hat{K}_1 = 15a^{-4}\hat{p}_a^4 a^{-4}, \tag{29}$$

$$F.O.2 \to \hat{K}_2 = 15\hat{p}_a^2 a^{-8}\hat{p}_a^2, \tag{30}$$

$$F.O.3 \to \hat{K}_3 = \frac{15}{2}\left(\hat{p}_a^4 a^{-8} + a^{-8}\hat{p}_a^4\right), \tag{31}$$

$$F.O.4 \to \hat{K}_4 = \frac{15}{2}\left(a^{-2}\hat{p}_a^4 a^{-6} + a^{-6}\hat{p}_a^4 a^{-2}\right). \tag{32}$$

The boundary term which needs to vanish for the Hermiticity of these operators is,

$$\Big[a^{-6}\big(\psi^*\chi''' - \psi'^*\chi'' + \psi''^*\chi' - \psi'''^*\chi - 6a^{-1}(\psi^*\chi'' - \psi''^*\chi\big) + 30a^{-2}(\psi^*\chi' - \psi'^*\chi))\Big]_0^\infty = 0 \implies |q| > \frac{9}{2} \tag{33}$$

The expectation value of the Kretschamann scalar for various operator orderings is,

$$\bar{K}_1(\tau) = \frac{1280\left(\lambda^2+4\tau^2\right)^{-4}}{27|q|(2|q|-9)(2|q|-3)}\Big(8(2|q|-9)(9|q|-20)\lambda^2\tau^2 + 3(9|q|-40)\lambda^4 + 16|q|(2|q|-9)(2|q|-3)\tau^4\Big), \tag{34}$$

$$\bar{K}_2(\tau) = \frac{1280\left(\lambda^2+4\tau^2\right)^{-4}}{27|q|(2|q|-9)(2|q|-3)(|q|-3)}\Big(3(|q|(9|q|+29)+504)\lambda^4 + 8(|q|-3)(2|q|-9)(9|q|+28)\lambda^2\tau^2 + 16(|q|-3)|q|(2|q|-9)(2|q|-3)\tau^4\Big), \tag{35}$$

$$\bar{K}_3(\tau) = \frac{1280\left(\lambda^2+4\tau^2\right)^{-4}}{27(|q|-3)|q|(2|q|-9)(2|q|-3)}\Big(3(|q|(9|q|-259)+1272)\lambda^4 + 8(|q|-3)(2|q|-9)(9|q|-116)\lambda^2\tau^2 + 16(|q|-3)|q|(2|q|-9)(2|q|-3)\tau^4\Big), \tag{36}$$

$$\bar{K}_4(\tau) = \frac{1280\left(\lambda^2+4\tau^2\right)^{-4}}{27(|q|-3)|q|(2|q|-9)(2|q|-3)}\Big(3(|q|-8)(9|q|-43)\lambda^4 + 8(|q|-3)(2|q|-9)(9|q|-44)\lambda^2\tau^2 + 16(|q|-3)|q|(2|q|-9)(2|q|-3)\tau^4\Big). \tag{37}$$

Again, the expectation value of these observables is a well behaved regular function in the domain of parameters that ensures the Hermiticity of this observable. Classical expression is recovered irrespective of the operator ordering chosen i.e., when $\tau^2 >> \lambda^2$, $\bar{K} = 80/27\tau^4$.

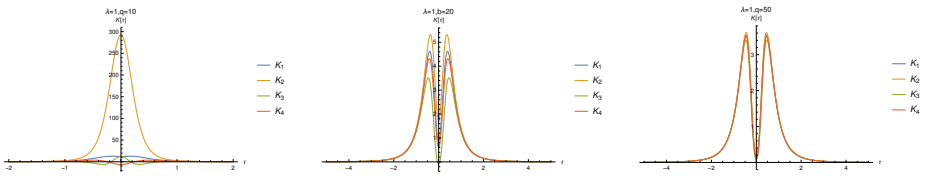

Fig. 4. Expectation value of Kretschmann scalar for various operator orderings.

We have plotted the expectation value of the Kretschmann scalar for different operator orderings. Here as well, we can see the signature of operator ordering is most pronounced at the point of classical singularity and Weyl ordered operator attains negative values for certain parameter range. Thus, the Kretschmann scalar also shows the features that are observed in the case of the Ricci scalar.

5. Discussion and Conclusion

We have studied the operator ordering ambiguity in the observables of a quantum model of cosmology with Brown-Kuchař dust as the matter source. The quantum model is singularity-free following DeWitt's criteria and it is shown that the expectation value of the scale factor is regular function with non-zero minima at the point of classical singularity and it follows classical trajectory, far away from the singularity. Thus, the quantum model represents a bouncing cosmological model which mimics classical behavior away from singularity.

We have studied the dynamics of the quantum FLRW model via the observables of the theory, Hubble parameter and curvature invariants. After writing the phase space functions for these observables, we have constructed the Hermitian extension of these observables. As these functions exhibit operator ordering ambiguity, there exists infinite many Hermitian extensions. For unitarily evolving wave packet, we have computed the expectation value of these observables. Very early in the collapsing phase and late in the expanding phase, these expectation values mimic the classical behavior irrespective of the operator ordering chosen. At the point of classical singularity, expectation value of the Hubble parameter vanishes and the Ricci scalar attains an extremum for all operator orderings, thus showing a robust singularity resolution.

This extremum value of the Ricci scalar is sensitive to the operator ordering parameters and the signature of these parameters is most pronounced at the point of singularity. The expectation value of the Ricci scalar is insensitive to this parameter away from singularity. Furthermore, in the large q regime, there is no signature of operator ordering parameter and the two maxima of Ricci scalar are at the time where the extrema of the Hubble parameter are located. For certain parameter range, the expectation value of the Weyl ordered Ricci scalar attains negative values. These features are present for the case of other curvature invariants as well.

In this paper, we generate an anisotropic solution for a static sphere filled with quark matter in the framework of self-interacting Brans-Dicke theory. For this purpose, we add an anisotropic source in the seed distribution and decouple the field equations through deformation in the radial metric function. As a result of this transformation, the field equations are disintegrated into two systems which separately include the effects of isotropic and anisotropic sources. The system related to the additional source is solved via the MIT bag model equation of state. We consider Tolman V spacetime to formulate a solution for the isotropic sector which is extended to the anisotropic domain via decoupling technique. The junction conditions at the boundary determine the unknown parameters in terms of mass and radius of the spherical object. We investigate the viability and stability of the constructed strange star model in the presence of massive scalar field corresponding to the strange star candidate PSR J1614-2230. It is concluded that the anisotropic extension is well-behaved as it fulfills the necessary requirements of a physically acceptable model.

Keywords: Brans-Dicke theory; Quark star; Gravitational decoupling.

1. Introduction

Astronomical systems (such as stellar structures, galaxies and planets) are scattered throughout the universe in the form of a cosmic web. These self-gravitating objects contain significant clues regarding the history and structure of the vast universe. Strange quark stars intriguing cosmic objects that are smaller than neutron stars and possess extremely dense cores. Researchers believe that the enormous release of radiation and energy in extremely luminous supernovae can be explained through quark stars.[1] A model that adequately describes the interactions of quarks at high density levels is still under investigation. However, in the absence of the best fit, researchers have used MIT bag model equation of state (EoS) to examine different properties of strange quark stars.[2] The statistical data obtained from GW170817[3] and GW190425[4] was used to predict the compactness and mass of quark stars. These predictions match the estimates made via the MIT bag model which strengthens the choice of this EoS. Bhar[5] used the MIT bag model to compute a solution representing strange stars in the background of Krori and Barua spacetime. The bag model has also been used to investigate the stability of quark stars by introducing radial perturbations.[6] Deb et al.[7] adopted the EoS to construct a charged stellar structure.

The task of obtaining well-behaved spacetimes corresponding to realistic models is difficult due to the non-linearity of field equations. Recently, Ovalle simplified the extraction of solutions by proposing the gravitational decoupling approach via minimal geometric deformation (MGD).[8] In this scheme, an extra source is successively added to a seed distribution (vacuum or isotropic) to incorporate intricate features of physical systems. The degree of freedom in the field equations is reduced by splitting the field equations into two arrays via a linear transformation in the radial metric function. These sets exclusively include the effects of seed and additional gravitational sources. Moreover, no energy is transferred between the two matter distributions as they are individually conserved. The respective solutions of these systems are combined to formulate a new solution. An extension of this technique has also been proposed which induces transformations in temporal as well as radial metric functions.[9]

The efficient technique of gravitational decoupling has successfully been employed to generate anisotropic solutions from well-known ansatz. The anisotropic extensions of Tolman IV have been obtained in braneworld[10] as well as general relativity (GR)[11] via MGD scheme. Isotropic configurations corresponding to Durgapal-Fuloria,[12] Krori-Barua,[13] Heintzmann[14] and Schwarzschild[15] interior solutions have been decoupled to evaluate their corresponding anisotropic versions. Contreras[16,17] deformed the metric component of (2+1)- dimensional spacetime to decouple the field equations with a cosmological constant. Singh et al.[18] derived an anisotropic spacetime by incorporating the embedding class-one condition in the decoupling approach. Hensh and Stuchlik[19] constructed an anisotropic counterpart of Tolman VII by the method of gravitational decoupling. Sharif and Ama-Tul-Mughani[20] implemented the MGD scheme to extend charged solutions to anisotropic domain in a cloud of strings. Anisotropic cosmological solutions have also been obtained by applying the MGD technique to FLRW as well as Kantowski-Sachs spacetimes.[21] Recently, Contreras et al.[22] studied axially symmetric black holes and showed that gravitational decoupling can be adopted beyond spherical symmetry.

The general theory of relativity is modified to incorporate the effects of cosmic expansion. In this regard, the family of scalar-tensor theories has gained attention. Brans-Dicke (BD) theory (a prototype of scalar-tensor theories) includes a spacetime varying scalar field $\vartheta = \frac{1}{G}$. (G is Newton's gravitational constant) along with the metric tensor to describe the effects of gravitational field.[23] A BD coupling parameter (ω_{BD}) couples the matter distribution and the massless scalar field. Different values of the tunable coupling parameter explain different cosmological scenarios. However, a conflict occurs when large values of ω_{BD} in the weak-field limit[24] do not coincide with the small values required to describe the inflationary era.[25] In order to remove the discrepancy, a potential function $V(\varsigma)$ is introduced which allots a mass to the scalar field (ς). This modification leads to self-interacting BD (SBD) theory[26] which admits all values of the coupling parameter greater than $-3/2$ for $m_\varsigma > 2 \times 10^{-25} GeV$ (m_ς denotes mass of the scalar field).[27] Recently,

MIT bag model was employed to examine the behavior of strange quark stars in the presence of a massive scalar field.[28] Some well-behaved solutions in SBD gravity as well as modified theories have been computed through gravitational decoupling technique.[29]

In this paper, we formulate two anisotropic strange star models by implementing MGD scheme on isotropic distributions in the context of SBD gravity. For this purpose, we adopt Tolman V ansatz and use the MIT bag model to investigate the viability and stability of the constructed structures. We evaluate the field equations under the effect of the additional source in section **2**. In section **3**, we deform the radial metric function to split the field equations. The anisotropic extension is checked for viability and stability in section **4**. In section **5**, the main results are discussed.

2. Self-interacting Brans-Dicke Theory

The SBD gravity is described by the action

$$S=\int\sqrt{-g}(\mathcal{R}\varsigma-\frac{\omega_{BD}}{\varsigma}\nabla^{\gamma}\nabla_{\gamma}\varsigma-V(\varsigma)+L_m+\sigma L_{\Theta})d^4x, \tag{1}$$

where relativistic units have been used. Here, $\mathcal{R}$ and L_m denote the Ricci scalar and matter lagrangian whereas $g=|g_{\gamma\delta}|$. The contribution of the anisotropic source (Θ) via the lagrangian L_{Θ} is controlled by the decoupling parameter σ. The additional gravitational source can be categorized as a scalar, vector or tensor field. The field and wave equations derived from the action (1) are written as

$$G_{\gamma\delta}=T^{(\mathrm{eff})}_{\gamma\delta}=\frac{1}{\varsigma}(T^{(m)}_{\gamma\delta}+\sigma\Theta_{\gamma\delta}+T^{\varsigma}_{\gamma\delta}), \tag{2}$$

$$\Box\varsigma=\frac{T^{(m)}+\Theta}{3+2\omega_{BD}}+\frac{1}{3+2\omega_{BD}}(\varsigma\frac{dV(\varsigma)}{d\varsigma}-2V(\varsigma)), \tag{3}$$

where $\Box\varsigma=\frac{1}{\sqrt{-g}}(\sqrt{-g}g^{\gamma\delta}\varsigma_{,\gamma})_{,\delta}$, $T^{(m)}=g^{\gamma\delta}T^{(m)}_{\gamma\delta}$ and $\Theta=g^{\gamma\delta}\Theta_{\gamma\delta}$. We consider an isotropic seed source whose energy-momentum tensor has the form

$$T^{(m)}_{\gamma\delta}=\rho u_{\gamma}u_{\delta}+p(u_{\gamma}u_{\delta}-g_{\gamma\delta}), \tag{4}$$

where p, u_{γ} and ρ represent pressure, four-velocity and energy density, respectively. The influence of massive scalar field on the physical aspects of static sphere are governed by the following energy-momentum tensor

$$T^{\varsigma}_{\gamma\delta}=\varsigma_{,\gamma;\delta}-g_{\gamma\delta}\Box\varsigma+\frac{\omega_{BD}}{\varsigma}(\varsigma_{,\gamma}\varsigma_{,\delta}-\frac{g_{\gamma\delta}\varsigma_{,\alpha}\varsigma^{,\alpha}}{2})-\frac{V(\varsigma)g_{\gamma\delta}}{2}. \tag{5}$$

The anisotropic extension is obtained by describing the internal geometry of the static sphere as

$$ds^2=e^{\phi(r)}dt^2-e^{\psi(r)}dr^2-r^2d\theta^2-r^2\sin^2\theta d\varphi^2. \tag{6}$$

The field equations, formulated in the presence of the anisotropic source, are expressed as

$$\frac{1}{r^2}-e^{-\psi}\left(\frac{1}{r^2}-\frac{\psi'}{r}\right)=\frac{1}{\varsigma}(\rho+\sigma\Theta_0^0+T_0^{0\varsigma}), \tag{7}$$

$$-\frac{1}{r^2}+e^{-\psi}\left(\frac{1}{r^2}+\frac{\phi'}{r}\right)=\frac{1}{\varsigma}(p-\sigma\Theta_1^1-T_1^{1\varsigma}), \tag{8}$$

$$\frac{e^{-\psi}}{4}\left(2\phi''+\phi'^2-\psi'\phi'+2\frac{\phi'-\psi'}{r}\right)=\frac{1}{\varsigma}(p-\sigma\Theta_2^2-T_2^{2\varsigma}), \tag{9}$$

where

$$T_0^{0\varsigma}=e^{-\psi}\left[\varsigma''+\left(\frac{2}{r}-\frac{\psi'}{2}\right)\varsigma'+\frac{\omega_{BD}}{2\varsigma}\varsigma'^2-e^{\psi}\frac{V(\varsigma)}{2}\right],$$

$$T_1^{1\varsigma}=e^{-\psi}\left[\left(\frac{2}{r}+\frac{\phi'}{2}\right)\varsigma'-\frac{\omega_{BD}}{2\varsigma}\varsigma'^2-e^{\psi}\frac{V(\varsigma)}{2})\right],$$

$$T_2^{2\varsigma}=e^{-\psi}\left[\varsigma''+\left(\frac{1}{r}-\frac{\psi'}{2}+\frac{\phi'}{2}\right)\varsigma'+\frac{\omega_{BD}}{2\varsigma}\varsigma'^2-e^{\psi}\frac{V(\varsigma)}{2}\right].$$

Here differentiation with respect to the radial coordinate is denoted by $'$. Moreover, the wave equation (3), containing information about the evolution of the massive scalar field, takes the form

$$\begin{aligned}\Box\varsigma&=-e^{-\psi}\left[\left(\frac{2}{r}-\frac{\psi'}{2}+\frac{\phi'}{2}\right)\varsigma'+\varsigma''\right]\\&=\frac{1}{3+2\omega_{BD}}\left[T^{(m)}+\Theta+\left(\varsigma\frac{dV(\varsigma)}{d\varsigma}-2V(\varsigma)\right)\right].\end{aligned} \tag{10}$$

The system of field equations (7)-(9) correspond to an anisotropic fluid distribution for $\Theta_1^1\neq\Theta_2^2$.

3. Gravitational Decoupling

Currently, the system (7)-(9) involves unknown metric potentials, state determinants, massive scalar field and anisotropic source. Thus, we require additional constraints to reduce the degrees of freedom and close the system. In this regard, the MGD technique is an efficient method for decoupling the complex field equations into simpler sets by transforming the radial metric component as

$$e^{-\psi(r)}\mapsto\lambda(r)+\sigma\nu(r), \tag{11}$$

where $\nu(r)$ is the deformation function that governs the translation in the radial metric component. The temporal metric potential is not transformed and remains unchanged. It must be noted that the linear mapping does not affect the spherical geometry of the structure. Plugging the transformation in Eqs. (7)–(9) and setting

$\sigma = 0$ yields the first set as

$$\rho = -\frac{1}{2r^2\varsigma(r)}[r^2\omega\lambda(r)\varsigma'^2(r) - r^2\varsigma(r)V(\varsigma) + r\varsigma(r)(r\lambda'(r)\varsigma'(r) + 2r\lambda(r)\varsigma''(r) + 4\lambda(r)\varsigma'(r)) + 2\varsigma^2(r)(r\lambda'(r) + \lambda(r) - 1)], \tag{12}$$

$$p = \frac{1}{r^2}[\varsigma(r)(r\lambda(r)\phi'(r) + \lambda(r) - 1)] + \frac{1}{2r\varsigma(r)}[\lambda(r)\varsigma'(r)(\varsigma(r)(r\phi'(r) + 4) - r\omega_{BD}\varsigma'(r))] - \frac{V(\varsigma)}{2}, \tag{13}$$

$$p = \frac{1}{4r\varsigma(r)}[\varsigma(r)\lambda'(r)(\varsigma(r)(r\phi'(r) + 2) + 2r\varsigma'(r)) + \lambda(r)(2\varsigma(r)\varsigma'(r) \times ((r\phi'(r) + 2) + 2r\varsigma''(r)) + \varsigma^2(r)(2r\phi''(r) + r\phi'^2(r) + 2\phi'(r)) + 2r\omega_{BD}\varsigma'^2(r)) - 2r\varsigma(r)V(\varsigma)]. \tag{14}$$

The above system corresponds to the perfect fluid configuration exclusively as the anisotropic effects are excluded. The isotropic source observes the following conservation equation

$$T_1^{1'(\text{eff})} - \frac{\phi'(r)}{2}(T_0^{0(\text{eff})} - T_1^{1(\text{eff})}) = 0. \tag{15}$$

The second set, encompassing the terms related to the additional source, is expressed as

$$\Theta_0^0 = \frac{-1}{2r^2\varsigma(r)}[r\varsigma(r)\nu'(r)(r\varsigma'(r) + 2\varsigma(r)) + \nu(r)(r^2\omega_{BD}\varsigma'^2(r) + 2r\varsigma(r) \times (r\varsigma''(r) + 2\varsigma'(r)) + 2\varsigma^2(r))], \tag{16}$$

$$\Theta_1^1 = \frac{-1}{2r^2\varsigma(r)}[\nu(r)(-r^2\omega_{BD}\varsigma'(r)^2 + r\varsigma(r)(r\phi'(r) + 4)\varsigma'(r) + 2\varsigma^2(r) \times (r\phi'(r) + 1))], \tag{17}$$

$$\Theta_2^2 = \frac{-1}{4\varsigma(r)}[2\varsigma(r)(r\nu'(r)\varsigma'(r) + \nu(r)((r\phi'(r) + 2)\varsigma'(r) + 2r\varsigma''(r))) + \varsigma^2(r)(\nu'(r)(r\phi'(r) + 2) + \nu(r)(2r\phi''(r) + r\phi'^2(r) + 2\phi'(r))) + 2r\omega_{BD}\nu(r)\varsigma'^2(r)]. \tag{18}$$

The energy and momentum of the anisotropic source is conserved as

$$\Theta_1^{1'(\text{eff})} - \frac{\phi'(r)}{2}(\Theta_0^{0(\text{eff})} - \Theta_1^{1(\text{eff})}) - \frac{2}{r}(\Theta_2^{2(\text{eff})} - \Theta_1^{1(\text{eff})}) = 0, \tag{19}$$

where

$$\Theta_0^{0(\text{eff})} = \frac{1}{\varsigma}\left(\Theta_0^0 + \frac{1}{2}\nu'(r)\varsigma'(r) + \nu(r)\varsigma''(r) + \frac{\omega_{BD}\nu(r)\varsigma'^2(r)}{2\varsigma(r)} + \frac{2\nu(r)\varsigma'(r)}{r}\right),$$

$$\Theta_1^{1(\text{eff})} = \frac{1}{\varsigma}\left(\Theta_1^1 + \frac{1}{2}\nu(r)\phi'(r)\varsigma'(r) - \frac{\omega_{BD}\nu(r)\varsigma'^2(r)}{2\varsigma(r)} + \frac{2\nu(r)\varsigma'(r)}{r}\right),$$

$$\Theta_2^{2(\text{eff})} = \frac{1}{\varsigma}\left(\Theta_2^2 + \frac{1}{2}\nu'(r)\varsigma'(r) + \frac{1}{2}\nu(r)\phi'(r)\varsigma'(r) + \nu(r)\varsigma''(r) + \frac{\omega_{BD}\nu(r)\varsigma'^2(r)}{2\varsigma(r)} + \frac{\nu(r)\varsigma'(r)}{r}\right).$$

The MGD scheme restricts the exchange of matter or energy between the two sources (seed and additional) by conserving them individually. As a consequence of disintegrating the field equations via MGD, the two systems can be solved separately. A well-behaved isotropic spacetime can specify the system (12)-(14) which minimizes the degrees of freedom as the second system contains the deformation function and components of $\Theta_{\gamma\delta}$ as undetermined variables only. In the next section, we attain a solution for the anisotropic setup by assuming a well-known ansatz along with an additional constraint.

4. Anisotropic Solution

Tolman V ansatz (one of the eight solutions proposed by Tolman) describes a spherical structure with infinite density and pressure at the center.[30] Zubair and Azmat[31] evaluated the anisotropic counterpart of Tolman V via the MGD method. Recently, Jasim et al.[32] employed this spherical solution to study charged strange stars. Tolman V spacetime is defined as

$$ds^2 = B^2 r^{2n} dt^2 - \left(\frac{1+2n-n^2}{1-(1+2n-n^2)\left(\frac{r}{F}\right)^W}\right) dr^2 - r^2 d\theta^2 - r^2 \sin^2\theta d\varphi^2, \quad (20)$$

where n, F and B are unknown constants with $W = \frac{2(1+2n-n^2)}{1+n}$. We set $\lambda = \frac{1+2n-n^2}{1-(1+2n-n^2)\left(\frac{r}{F}\right)^W}$ and determine the isotropic sector via the above spacetime. For this purpose, we evaluate the unknown parameters through the continuity of first and second fundamental forms at the junction (Σ) of interior and exterior geometries. The exterior of a static uncharged celestial object is defined via Schwarzschild metric given as

$$ds^2 = \frac{r-2M}{r} dt^2 - \frac{r}{r-2M} dr^2 - r^2 d\theta^2 - r^2 \sin^2\theta d\varphi^2, \quad (21)$$

where M is the total mass of the compact structure. The boundary conditions at $r = R$ (R is the radius of compact object)

$$(g_{\gamma\delta}^-)_\Sigma = (g_{\gamma\delta}^+)_\Sigma, \quad (p_r)_\Sigma = 0,$$
$$(\varsigma^-(r))_\Sigma = (\varsigma^+(r))_\Sigma, \quad (\varsigma'^-(r))_\Sigma = (\varsigma'^+(r))_\Sigma.$$

are utilized to determine the constants as

$$B=\frac{\sqrt{M}R^{\frac{R}{4M-2R}}}{\sqrt{-\frac{M}{2M-R}}}, \tag{22}$$

$$n=\frac{M}{R-2M}, \tag{23}$$

$$W=-\frac{2\left(M^2+2MR-R^2\right)}{2M^2-3MR+R^2}, \tag{24}$$

$$F=R\left(\frac{M^2(R-2M)}{R\left(-M^2-2MR+R^2\right)}\right)^{-\frac{1}{W}} \tag{25}$$

$$\begin{aligned}\omega_{BD}=\frac{2M-R}{8M^2((n-2)n-1)}\Bigg(&-((n-2)n-1)(2M-R)\left(\frac{R}{F}\right)^W(m_\varsigma R\\&\times(2M-R)-4)-4m_\varsigma M^2R+4m_\varsigma MR^2-m_\varsigma R^3+8Mn^3\\&-24Mn^2+8Mn+16M-8n^3R+12n^2R+16nR\Bigg).\end{aligned} \tag{26}$$

Here, the corresponding scalar field has been calculated by following the technique in.[33]

The energy density and pressure of the anisotropic analogue of Tolman V are expressed as

$$\begin{aligned}\rho=\frac{-1}{2r^2\varsigma}\Bigg(&r\varsigma\left(r\varsigma'\left(\sigma\nu'(r)+\frac{\zeta_1}{r}\right)+2\sigma\nu(r)\left(r\varsigma''+2\varsigma'\right)+2\zeta_2\left(r\varsigma''\right.\right.\\&\left.+\ 2\varsigma'\right))+2\varsigma^2\left(\sigma r\nu'(r)+\sigma\nu(r)+\zeta_1+\zeta_2-1\right)+r^2\omega_{BD}\varsigma'^2\left(\sigma\nu(r)\right.\\&\left.+\ \zeta_2\right)-r^2\varsigma V(\varsigma)\Big),\end{aligned} \tag{27}$$

$$\begin{aligned}p_r=\frac{\varsigma}{r^2}\left(\nu(r)(\sigma+2\sigma n)+\zeta_2(2n+1)-1\right)+\frac{\varsigma'\left(2(n+2)\varsigma-r\omega_{BD}\varsigma'\right)}{2r\varsigma}\\\times\left(\sigma\nu(r)+\zeta_2\right)-\frac{V(\varsigma)}{2},\end{aligned} \tag{28}$$

$$\begin{aligned}p_\perp=\frac{\varsigma}{2r^2}\Bigg(&\sigma(n+1)r\nu'(r)+2\sigma n^2\nu(r)+\frac{1}{\zeta_3^2}((n-2)n-1)\left(2n-n^2+1\right)\\&\times\ \left(2n^2-(n+1)W\right)\left(\frac{r}{F}\right)^W-2n^2\Bigg)\Bigg)+\left(\sigma\nu(r)+\zeta_2\right)\Bigg(\frac{\varsigma'}{2}\\&\times\left(\frac{\sigma\nu'(r)+\frac{\zeta_1}{r}}{\sigma\nu(r)+\zeta_2}+\frac{2n}{r}+\frac{2}{r}\right)+\varsigma''+\frac{\omega_{BD}\varsigma'^2}{2\varsigma}\Bigg)-\frac{V(\varsigma)}{2},\end{aligned} \tag{29}$$

where $\zeta_1=\frac{\left(n^2-2n-1\right)^2W\left(\frac{r}{F}\right)^W2}{\zeta_3}$, $\zeta_2=\frac{-n^2+2n+1}{\zeta_3}$ and $\zeta_3=\Big(\left(n^2-2n-1\right)\left(\frac{r}{F}\right)^W+1\Big)$ with anisotropy $\Delta=p_\perp-p_r$. The matter variables are completely specified if the deformation function is known. For this purpose, a constraint on the deformation function or appropriate EoS is applied to the anisotropic structure.

In this work, we develop an anisotropic model for strange quark stars by implementing the MIT bag model. It is hypothesized that the core of a quark star is

composed of three flavors of quarks: up (u), strange (s), and down (d). We assume that the quarks are massless and non-interacting in nature. According to the bag model, the pressure and density of quark matter read

$$p_r = \sum_f p^f - \mathcal{B}, \quad \rho = \sum_f \rho^f + \mathcal{B}, \quad f = u,\ d,\ s, \tag{30}$$

where p^f and ρ^f correspond to the pressure and density of each flavor, respectively. Kapusta[34] formulated the EoS for strange quark matter through the relation $\rho^f = 3p^f$ as

$$3p_r = \rho - 4\mathcal{B}. \tag{31}$$

Utilizing Eqs.(27) and (28) in the bag model, we obtain the following differential equation

$$\begin{aligned}&(\sigma r\nu'(r)\varsigma' + \sigma\nu(r)\,(2(3n+8)\varsigma' + 2r\varsigma'') + 2\zeta_2 r\varsigma'' + \zeta_1\varsigma' + 6n\zeta_2\varsigma'\\ &+ 16\zeta_2\varsigma' - 4rV(\varsigma) + 8r\mathcal{B}) + \frac{2\varsigma}{r}\,(\sigma r\nu'(r) + \sigma(6n+4)\nu(r) + \zeta_1\\ &+(6n+4)\zeta_2 - 4) - 2r^2\omega_{BD}\varsigma'^2\,(\sigma\nu(r) + \zeta_2) = 0,\end{aligned} \tag{32}$$

which is numerically solved along with the wave equation subject to central conditions ($\varsigma(0) = 0.2,\ \varsigma'(0) = 0$ and $\nu(0) = \nu_c$) for $V(\varsigma) = \frac{1}{2}m_\varsigma^2\varsigma^2$.

In SBD gravity, the values of coupling parameter greater than $-3/2$ are allowed for $m_\varsigma > 10^{-4}$ (in dimensionless units). Therefore, the wave equation is solved numerically for $m_\varsigma = 0.001$. Furthermore, the constants B, F, n remain unchanged for the anisotropic sphere whereas ω_{BD} is an undetermined free parameter. Thus, we choose the value of ω_{BD} as given in Eq.(26). The constants are computed by utilizing the observed mass and radii of three quark star candidates (PSR J1614-2230, Her X1 and 4U 1608-52) for $\sigma = 0.2,\ 0.9$ and $\mathcal{B} = 60MeV/fm^3$. The values of ω_{BD} and ν_c for the considered stars are given in Table **1**. It is noted that ω_{BD} attains values greater than $-3/2$ for all stellar candidates. The physical properties of the anisotropic stellar model are examined in the next section.

Table 1. Values of different parameters corresponding for $m_\varsigma = 0.001$ and $\mathcal{B} = 60MeV/fm^3$.

	PSR J1614-2230	Her X-1	4U 1608-52
$M\ (M_\odot)$	1.97	0.88	1.74
$R\ (km)$	13	7.7	9.3
ω_{BD}	9.750	15.353	6.593
$\nu_c\ (\sigma = 0.2)$	-5.1	-3.6	-6.8

4.0.1. *Physical Features of Anisotropic Model*

The metric potentials of a well-behaved solution are positive and increase monotonically.[35] The state parameters must observe a monotonically decreasing behavior

away from the center. The graphical representations of Eqs.(27)-(29) in Figure 1 reveals that the strange star model has maximum density and radial/tangential pressures in the core. Furthermore, radial pressure is zero at the surface for the considered stellar objects. It is observed from the plots of anisotropy that $p_\perp > p_r$ for 4U 1608-52 whereas anisotropy related to the remaining stars is negative, i.e., $p_\perp < p_r$. It is worthwhile to mention here that the GR analog exhibits similar behavior.[31]

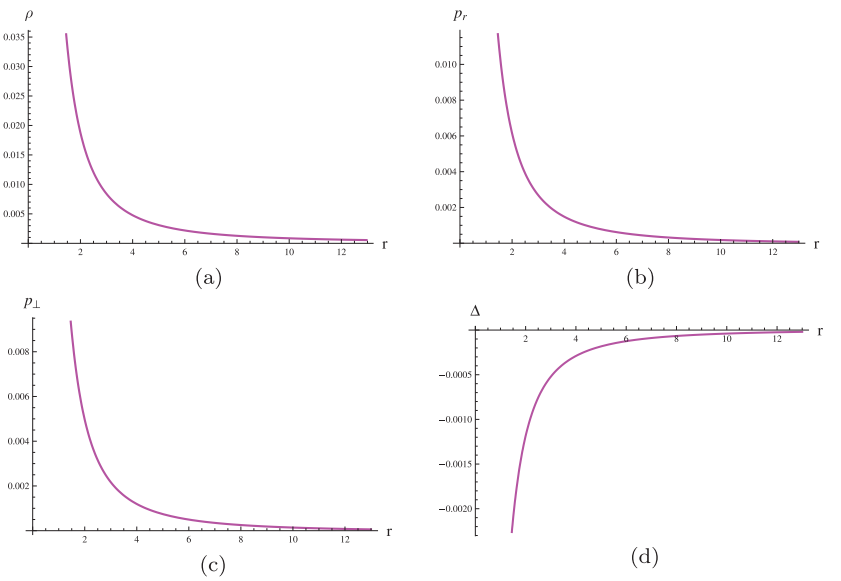

Fig. 1. Plots of (a) ρ, (b) p_r, (c) $p_\perp$ (in km^{-2}) and (d) Δ of anisotropic Tolman V solution for $\sigma = 0.2$.

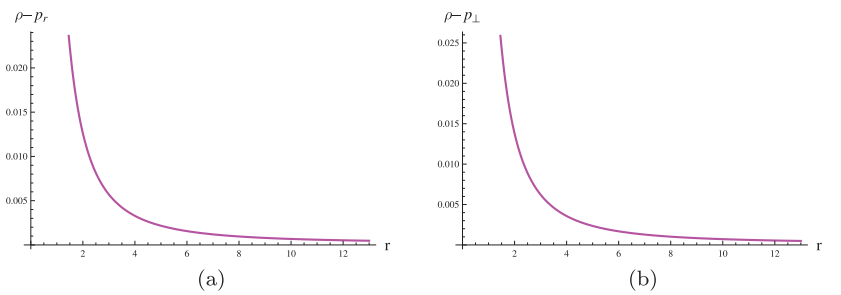

Fig. 2. (a), (b) DEC for extended Tolman V solution for $\sigma = 0.2$.

As the interior of compact stellar structures consists of normal matter, therefore the energy-momentum tensor describing the internal configuration must obey the

four energy bounds[36]

$$\begin{aligned}
&\text{null energy condition:} \quad \rho + p_r \geq 0, \quad \rho + p_\perp \geq 0,\\
&\text{weak energy condition:} \quad \rho \geq 0, \quad \rho + p_r \geq 0, \quad \rho + p_\perp \geq 0,\\
&\text{strong energy condition:} \quad \rho + p_r + 2p_\perp \geq 0,\\
&\text{dominant energy condition:} \quad \rho - p_r \geq 0, \quad \rho - p_\perp \geq 0.
\end{aligned}$$

The first three conditions require that energy density and pressure components remain positive throughout the setup. As the matter variables presented in Figure 1 fulfil this criterion, the anisotropic Tolman V is consistent with null, weak and strong energy constraints. Figure 2 indicates that the decoupled model obeys the fourth condition as well. Thus, the constructed model represents a viable quark star.

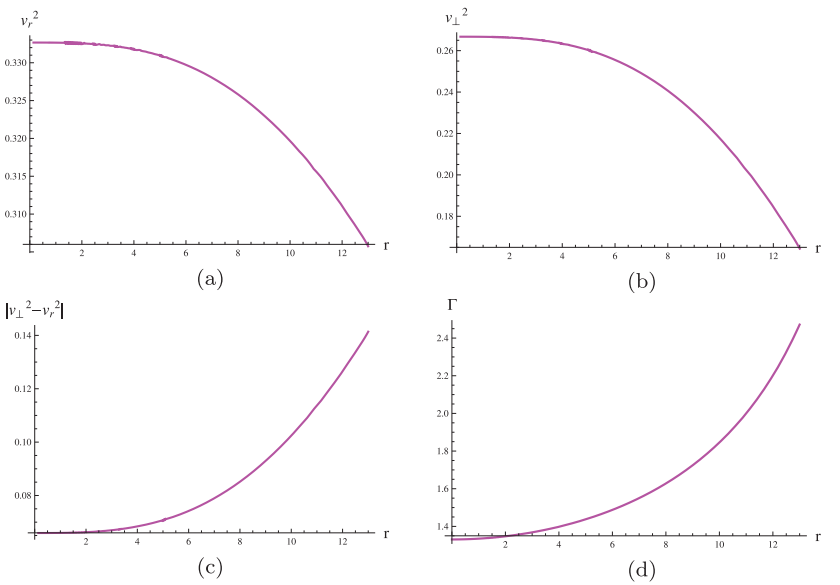

Fig. 3. Plots of (a)radial/(b) tangential velocities, (c) $|v_\perp^2 - v_r^2|$ and (d) adiabatic index of extended Tolman V solution for $\sigma = 0.2$.

The extended version of Tolman V solution is stable if it complies with the causality condition which states that velocity of light always exceeds the rate at which sound travels, i.e., $0 < v_\perp^2 < 1$ and $0 < v_r^2 < 1$ ($v_\perp^2 = \frac{dp_\perp}{d\rho}$ and $v_r^2 = \frac{dp_r}{d\rho}$ represent transverse and radial components of sound, respectively). It must be noted that the propagation of sound waves changes with a change in the medium. Figure 3 depicts that the extended solution is consistent with the causality criterion for higher as well as lower values of decoupling parameter. In order to inspect the anisotropic system for potential stability, we implement Herrera's cracking criterion. According

to this approach, if a disturbance in the equilibrium of the system leads to radial forces of different signs, the configuration cracks. The condition $0 < |v_{\perp}^2 - v_r^2| < 1$ ensures that no cracking appears within the compact sphere. This condition holds true for the current setup as shown in Figure 3.

If a stellar model obeys a stiff EoS, it is compact and difficult to compress as pressure increases greatly in response to a small change in density. Adiabatic index measures the stiffness of the EoS as

$$\Gamma = \frac{p_r + \rho}{p_r}\frac{dp_r}{d\rho} = \frac{p_r + \rho}{p_r}v_r^2.$$

The value of adiabatic index greater than $4/3$ corresponds to a stiff matter distribution.[37] The adiabatic index for $\sigma = 0.2$ is displayed in Figure 3. The generated extension of Tolman V observes the required restraint under the influence of massive scalar field.

5. Conclusions

In this work, we have extended a known isotropic solution to the anisotropic domain through the method of gravitational decoupling. Anisotropy has been induced in the isotropic matter configuration by means of an additional source. The two sources (seed and additional) have been decoupled through a linear transformation of the radial metric component. As a consequence, we have obtained two systems of differential equations. The first system includes the effects of the seed distribution only while the influence of the additional source is restricted to the second set. We have considered Tolman V spacetime to represent the first array. The system related to the anisotropic source has been solved by imposing MIT bag model on state variables of the anisotropic solution. We have numerically evaluated the wave equation for $V(\varsigma) = \frac{1}{2}m_{\varsigma}^2\varsigma^2$, $m_{\varsigma} = 0.001$ and $\sigma = 0.2$. Finally, the physical behavior of the extended model has been examined for $\mathcal{B} = 60MeV/fm^3$ through energy constraints as well as causality and cracking approaches for the star PSR J1614-2230.

The graphical analysis has shown that the state parameters observe a monotonically decreasing trend towards the surface and attain the maximum value at $r = 0$. Moreover, the anisotropy corresponding to PSR J1614-2230 is negative. Thus, radial pressure is more than the transverse component indicating a presence of attractive force within the spherical object. The extended model is composed of viable normal matter as it is consistent with the energy conditions. We have established that the constructed setup is stable as radial/tangential components of speed agree with causality and cracking criteria. The adiabatic parameter is greater than $4/3$ which indicates that the static model holds itself against inward gravitational pull for the considered values of the parameters. Thus, the strange star structure formulated via decoupling is physically realistic and stable in the presence of a massive scalar field. It is interesting to mention here that all the obtained results reduce to GR for $\varsigma =$ constant and $\omega_{BD} \to \infty$.

We show that the Nieh-Yan topological invariant breaks projective symmetry and loses its topological character in presence of non vanishing nonmetricity. The notion of the Nieh-Yan topological invariant is then extended to the generic metric-affine case, defining a generalized Nieh-Yan term, which allows to recover topologicity and projective invariance, independently. As a concrete example a class of modified theories of gravity is considered and its dynamical properties are investigated in a cosmological setting. In particular, bouncing cosmological solutions in Bianchi I models are derived. Finite time singularities affecting these solutions are analysed, showing that the geodesic completeness and the regular behavior of scalar perturbations in these space-times are not spoiled.

Keywords: Nieh-Yan, metric-affine, Bianchi I, big-bounce

1. Introduction

The theory of General Relativity (GR)[1,2] relies on the geometric interpretation of the gravitational field, described in terms of a metric tensor and a connection on

a pseudo-Riemannian manifold. Both GR and many alternative theories of gravity are based on a metric formulation, in which the connection is given by the symmetric and metric compatible Levi-Civita connection, which is completely determined by the metric and its derivatives. An alternative formulation for geometric theories of gravity consists in adopting the metric-affine paradigm, in which the metric tensor and the connection are considered as independent variables. In this approach, symmetry and metric compatibility of the connection are not imposed a priori, resulting in the presence of torsion and nonmetricity, respectively. Well known examples of metric-affine theories are Ricci based gravity,[3,4] Palatini $f(R)$ theory,[5] quadratic gravity,[6] Born-Infeld-type models,[7] general teleparallel models,[8] generalized hybrid metric-Palatini gravity[9–13] and metric-affine extension of higher order theories.[14–17]

The metric-affine approach plays a crucial role also in one of the current attempts to quantize gravity, i.e. loop quantum gravity (LQG),[18,19] where GR is reformulated in terms of a gauge $SU(2)$ connection (Ashtekar-Barbero-Immirzi connection) and its conjugate momentum, the densitized triad.[20–23] This formulation, indeed, can be derived[24] by including an additional contribution to the first order (Palatini) action of GR, namely the Nieh-Yan (NY) topological invariant[25,26] (the Holst term[27] can be used as well). The NY term was discovered in the context of Riemann-Cartan theory (where nonmetricity is set to zero) and its main property is topologicity: it reduces to a boundary term without affecting the field equations at all. This additional term is driven by the so called Immirzi parameter β,[28,29] which concurs in the definition of the Ashtekar variables and is related to a quantization ambiguity.[30] Attempts to address this issue led to the proposal of considering the Immirzi parameter as a new fundamental field,[31–33] an idea that has been later developed within several different contexts.[31,33,33–40,40–46] The promotion of such constant parameter to a dynamical field is usually pursued "by hand", substituting $\beta \to \beta(x)$ in the Lagrangian and possibly adding a potential term $V(\beta)$.

More recently, beside LQG the NY term has been studied in the context of teleparallel gravity[47] and in condensed matter physics.[48–51]

Another important property we will focus on, is projective invariance,[52,53] which has recently been shown to be of crucial importance in metric-affine theories since the breaking of this symmetry can give rise to dynamical instabilities.[54] In this regard, we want to stress that the NY term breaks this symmetry. This feature has always been neglected in literature and a revision of previous formulations seems necessary. Moreover, as will be shown in the following, the topological character of the NY term is also lost when nonmetricity is included.

The approach followed in this note is grounded on the choice of recovering these features from the very beginning in the action, without imposing any restriction on the affine connection. After a formal discussion, we will implement the gravitational model in a cosmological setting. In particular, we investigate Bianchi I models,[55–57] focusing our attention on the emergence of a classical bouncing cosmology.[42,58–64]

2. The role of nonmetricity in the Nieh-Yan term

In Einstein-Cartan theory the NY term[25,26] is explicitly defined as

$$NY \equiv \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}\left(\frac{1}{2}T^{\lambda}{}_{\mu\nu}\,T_{\lambda\rho\sigma} - R_{\mu\nu\rho\sigma}\right)\,, \tag{1}$$

where

$$R^{\rho}{}_{\mu\sigma\nu} = \partial_{\sigma}\Gamma^{\rho}{}_{\mu\nu} - \partial_{\nu}\Gamma^{\rho}{}_{\mu\sigma} + \Gamma^{\rho}{}_{\tau\sigma}\Gamma^{\tau}{}_{\mu\nu} - \Gamma^{\rho}{}_{\tau\nu}\Gamma^{\tau}{}_{\mu\sigma}, \tag{2}$$

is the Riemann tensor built with the independent connection and

$$T^{\mu}{}_{\nu\rho} = \Gamma^{\mu}{}_{\nu\rho} - \Gamma^{\mu}{}_{\rho\nu} \tag{3}$$

is the torsion tensor. The starting point of our discussion is the observation that for a non-vanishing nonmetricity tensor $Q_{\mu\nu\rho} = -\nabla_{\mu}g_{\nu\rho}$, the NY term (1) is spoilt of its topological character. Indeed, extracting the nonriemmanian part of the Riemann tensor leads to[65]

$$NY = -\frac{1}{2}\bar{\nabla}\cdot S - \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}T^{\lambda}{}_{\mu\nu}\,Q_{\rho\sigma\lambda}, \tag{4}$$

where $\bar{\nabla}_{\mu}$ is built with the Levi-Civita connection $\bar{\Gamma}^{\mu}{}_{\nu\rho}$ and

$$S_{\mu} \equiv \varepsilon_{\mu\nu\rho\sigma}T^{\nu\rho\sigma}. \tag{5}$$

Therefore, when $Q_{\rho\mu\nu} \neq 0$, the Nieh-Yan term does not simply reduce to the divergence of a vector, and the appearance of nonmetricity spoils the topologicity. Let us now consider the behavior of (1) under projective transformations of the connection, namely

$$\tilde{\Gamma}^{\rho}{}_{\mu\nu} = \Gamma^{\rho}{}_{\mu\nu} + \delta^{\rho}{}_{\mu}\xi_{\nu}, \tag{6}$$

It can easily be shown that (1) is also not invariant under projective transformations, since

$$\frac{1}{4}\varepsilon^{\mu\nu\rho\sigma}\tilde{T}^{\lambda}{}_{\mu\nu}\,\tilde{T}_{\lambda\rho\sigma} - \frac{1}{4}\varepsilon^{\mu\nu\rho\sigma}T^{\lambda}{}_{\mu\nu}\,T_{\lambda\rho\sigma} = -S_{\mu}\xi^{\mu}. \tag{7}$$

Now, by looking at (4), we point out that a newly topological Nieh-Yan term can be recovered by simply setting

$$NY^{*} \equiv NY + \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}T^{\lambda}{}_{\mu\nu}\,Q_{\rho\sigma\lambda}. \tag{8}$$

We note that projective invariance is now enclosed as well, since

$$\frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}\tilde{T}^{\lambda}{}_{\mu\nu}\,\tilde{Q}_{\rho\sigma\lambda} - \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}T^{\lambda}{}_{\mu\nu}\,Q_{\rho\sigma\lambda} = +S_{\mu}\xi^{\mu}, \tag{9}$$

which exactly cancels out (7). We stress, however, that projective invariance is not strictly related to topologicity, and suitable generalizations of (2) breaking up only with the latter can be actually formulated. Let us consider, for instance, the following modified Nieh-Yan term

$$NY_{gen} \equiv \frac{1}{2}\varepsilon^{\mu\nu\rho\sigma}\left(\frac{\lambda_1}{2}T^{\lambda}{}_{\mu\nu}\,T_{\lambda\rho\sigma} + \lambda_2\,T^{\lambda}{}_{\mu\nu}\,Q_{\rho\sigma\lambda} - R_{\mu\nu\rho\sigma}\right), \tag{10}$$

where we introduced the real parameters λ_1, λ_2. In this case the term (10) transforms under a projective transformation as

$$NY_{gen} \to NY_{gen} - (\lambda_1 - \lambda_2)\xi^\mu S_\mu, \tag{11}$$

so that by setting $\lambda_1 = \lambda_2$ we can recover again projective invariance, despite topologicity being in general violated if $\lambda_1 = \lambda_2 \neq 1$, since

$$NY_{gen} = -\frac{1}{2}\bar{\nabla}\cdot S + \frac{(\lambda_1 - 1)}{4}\varepsilon^{\mu\nu\rho\sigma}T^\lambda{}_{\mu\nu}T_{\lambda\rho\sigma} + \frac{(\lambda_2 - 1)}{2}\varepsilon^{\mu\nu\rho\sigma}T^\lambda{}_{\mu\nu}Q_{\rho\sigma\lambda}. \tag{12}$$

In the following, we will consider the general form (10), which by a suitable choice of the parameters $\lambda_{1,2}$ can reproduce all known actions usually studied in literature, as the Holst ($\lambda_1 = \lambda_2 = 0$) or the standard Nieh-Yan (4) ($\lambda_1 = 1$, $\lambda_2 = 0$) terms.

3. Generalized Nieh-Yan models

As a specific gravitational model featuring the generalized NY term we consider an action defined by a general function of two arguments, the Ricci scalar and the generalized NY term (10):

$$S_g = \frac{1}{2\kappa}\int d^4x\sqrt{-g}\,F(R, NY_{gen}), \tag{13}$$

Now, performing the transformation to the Jordan frame leads to the scalar tensor representation

$$S_g = \frac{1}{2\kappa}\int d^4x\sqrt{-g}\left(\phi R + \beta NY_{gen} - W(\phi,\beta)\right), \tag{14}$$

with $\phi \equiv \frac{\partial F}{\partial R}$, $\beta \equiv \frac{\partial F}{\partial NY_{gen}}$ and $W \equiv \phi R(\phi,\beta) + \beta NY_{gen}(\phi,\beta) - F(\phi,\beta)$.

The scalar field β can be identified with the Immirzi field, which acquires in this way a dynamical character without the need of introducing this feature by hand in the action. Moreover, this formulation offers a viable mechanism to produce an interaction term $W(\phi,\beta)$ as well. Now, the field equation for the connection are obtained varying (14) with respect to $\Gamma^\mu{}_{\nu\rho}$. For the full set of equations the reader may cosnult,[65] while here we are interest in the following contraction

$$\delta^\lambda_\nu \frac{\delta S_g}{\delta \Gamma^\lambda{}_{\nu\mu}} = 0 \tag{15}$$

which leads to

$$(\lambda_1 - \lambda_2)S^\mu = 0. \tag{16}$$

This implies that the features of the solutions depend on the parameters λ_1 and λ_2, and when projective invariance is broken ($\lambda_1 \neq \lambda_2$) one is compelled to set $S_\mu = 0$. In this case, (10) can be re-expressed as

$$NY_{gen} = -\frac{1}{2}\bar{\nabla}\cdot S - \frac{(1-\lambda_1)}{3}S^\mu T^\rho{}_{\mu\rho} - \frac{(1-\lambda_2)}{2}S^\mu Q^\rho{}_{\mu\rho}, \tag{17}$$

implying that the generalized Nieh-Yan term (10) is identically vanishing on half-shell. In other words, terms violating projective invariance are harmless along the dynamics. This can be further appreciated deriving the effective scalar tensor action stemming from (14), when the solutions of the full set of connection field equations are plugged in it. Explicit calculations (see[65] for details) lead to

$$S = \frac{1}{2\kappa}\int d^4x\sqrt{-g}\left(\phi\bar{R} + \frac{3}{2\phi}\bar{\nabla}_\mu\phi\bar{\nabla}^\mu\phi - W(\phi,\beta)\right), \tag{18}$$

where $\bar{R}$ is the Ricci scalar of the Levi-CIvita connection. This resembles the form of a Palatini $f(R)$ theory, with a potential depending on the Immirzi field as well. The equation for the latter, i.e.

$$\frac{\partial W(\phi,\beta)}{\partial\beta} = 0, \tag{19}$$

fixes its form in terms of the remaining scalar field: $\beta = \beta(\phi)$. Then, using the trace of the metric field equations, variation of (18) with respect to ϕ results in the usual structural equation featuring Palatini $f(R)$ theories,[5] i.e.

$$\left[2W(\phi,\beta) - \phi\frac{\partial W(\phi,\beta)}{\partial\phi}\right]_{\beta=\beta(\phi)} = \kappa T, \tag{20}$$

where T is the trace of the stress energy tensor of matter. This implies that the dynamics of the scalaron ϕ is frozen as well, and completely determined by T. Conditions (19) and (20) then guarantee that the scalar fields ϕ, β are not propagating degrees of freedom, and reduce to constants in vacuum, where the theory is stable and the breaking of projective invariance does not lead to ghost instabilities, in contrast to.[54]

If $\lambda_1 = \lambda_2 \equiv \lambda$, instead, the projective invariance of the model can be used to get rid of one vector degree of freedom, which can be set to zero properly choosing the vector ξ_μ. A convenient choice consists in setting $\xi_\mu = -\frac{1}{2}Q^\rho{}_{\mu\rho}$, which allows to deal only with torsion in the connection field equations. The effective action stemming from (14) then reads (see[65])

$$S = \frac{1}{2\kappa}\int d^4x\sqrt{-g}\left(\phi\bar{R} + \frac{3}{2\phi}\bar{\nabla}_\mu\phi\bar{\nabla}^\mu\phi - \frac{3\phi}{2}\frac{1}{\phi^{2\lambda}+(1-\lambda)^2\psi^2}\bar{\nabla}_\mu\psi\bar{\nabla}^\mu\psi - V(\phi,\psi)\right), \tag{21}$$

where we used the transformation $\psi \equiv \beta\phi^{\lambda-1}$ and redefined the potential as $V(\phi,\psi) = W(\phi,\psi\phi^{1-\lambda})$. In general, the Immirzi field is expected to be a well-behaved dynamical degree of freedom, since in the Einstein frame action, defined by the conformal rescaling $\tilde{g}_{\mu\nu} = \phi\, g_{\mu\nu}$, the kinetic term for the Immirzi field takes the form

$$-\frac{3}{2}\frac{\tilde{g}^{\mu\nu}\nabla_\mu\psi\nabla_\nu\psi}{\phi^{2\lambda}+(1-\lambda)^2\psi^2}. \tag{22}$$

Since $\phi^{2\lambda}+(1-\lambda)^2\psi^2 > 0$ for every value of ϕ, ψ and λ, (22) has always the correct sign and no ghost instability arise.[66]

Let us end this section with a remark on how previous results with vanishing nonmetricity can properly be recovered. In particular, the Riemann-Cartan structure of[32,33,36,37,46,67–69] can be replicated by inserting in (13) the condition of vanishing nonmetricity with a Lagrange multiplier, i.e. adding to the Lagrangian a term $l^{\rho\mu\nu}Q_{\rho\mu\nu}$, with $l^{\rho\mu\nu} = l^{\rho\nu\mu}$. Then, results of[32,33,36,37,46,67–69] are simply obtained by setting $\lambda_1 = 1$. The fact that the usual Einstein-Cartan NY invariant and related models are recovered in this way, supports the correctness of our generalization of the NY term, with respect to other possible generalizations.

4. Big bounce in Bianchi I cosmology

In this section we consider dynamical models, i.e. those described by (21), which are characterized by a dynamical Immirzi field and look for cosmological solutions in Bianchi I spacetimes. In particular, we will be interested in obtaining solutions characterized by a bouncing behavior for the universe volume, thanks to which the big bang singularity is regularized in favour of a big bounce scenario.

Let us start from the equations of motion for the metric and scalar fields which are given by

$$\bar{G}_{\mu\nu} = \frac{\kappa}{\phi}T_{\mu\nu} + \frac{1}{\phi}\left(\bar{\nabla}_\mu\bar{\nabla}_\nu - g_{\mu\nu}\bar{\Box}\right)\phi - \frac{3}{2\phi^2}\bar{\nabla}_\mu\phi\bar{\nabla}_\nu\phi + \frac{3}{2}\frac{\bar{\nabla}_\mu\psi\bar{\nabla}_\nu\psi}{\phi^{2\lambda}+(1-\lambda)^2\psi^2} + \frac{1}{2}g_{\mu\nu}\left(\frac{3(\bar{\nabla}\phi)^2}{2\phi^2} - \frac{3}{2}\frac{(\bar{\nabla}\psi)^2}{\phi^{2\lambda}+(1-\lambda)^2\psi^2} - \frac{V(\phi,\psi)}{\phi}\right), \tag{23}$$

$$2V(\phi,\psi) - \phi\frac{\partial V(\phi,\psi)}{\partial\phi} + \frac{3\lambda\phi^{2\lambda+1}}{\left(\phi^{2\lambda}+(1-\lambda)^2\psi^2\right)^2}(\bar{\nabla}\psi)^2 = \kappa T, \tag{24}$$

$$\bar{\Box}\psi - \frac{(1-\lambda)^2\psi}{\phi^{2\lambda}+(1-\lambda)^2\psi^2}(\bar{\nabla}\psi)^2 + \left(1 - \frac{2\lambda\phi^{2\lambda}}{\phi^{2\lambda}+(1-\lambda)^2\psi^2}\right)\bar{\nabla}_\mu\ln\phi\bar{\nabla}^\mu\psi = \frac{\partial V(\phi,\psi)}{3\partial\psi}. \tag{25}$$

As will be shown, cosmological solutions can be found for projective invariant models ($\lambda = 1$), and restricting to potentials of the form $V(\phi,\psi) = V(\phi)$. To this end, we consider the metric for a Bianchi I flat spacetime, i.e.

$$ds^2 = -dt^2 + a(t)^2dx^2 + b(t)^2dy^2 + c(t)^2dz^2, \tag{26}$$

which represents a homogeneous but anisotropic spacetime, with three different scale factors $a(t), b(t), c(t)$. We include matter in the form of a perfect fluid with stress energy tensor

$$T_{\mu\nu} = \mathrm{diag}(\rho, a^2p, b^2p, c^2p), \tag{27}$$

where ρ is the energy density and p the pressure. Assuming the equation of state $p = w\rho$, conservation of the stress energy tensor implies

$$\rho(t) = \frac{\mu^2}{(abc)^{w+1}}, \tag{28}$$

where μ^2 is a constant. Now, considering a Starobinsky quadratic potential[70]

$$V(\phi) = \frac{1}{\alpha}\left(\frac{\phi - 1}{2}\right)^2, \tag{29}$$

it can be shown that the equations for the scalar fields yield[a]

$$\dot{\psi} = \frac{k_0 \phi}{v}, \qquad \phi = \frac{v^2 f(v)}{6\alpha k_0^2 + v^2}, \tag{30}$$

in terms of the volume-like variable $v \equiv abc$ and the function $f(v) \equiv 1 - 2\alpha\kappa(3w - 1)\rho(v)$, while k_0 is an integration constant. Regarding the metric field equations, lengthy computations[65] allow to rewrite the tt component in the form of a modified Friedmann equation:

$$H^2 \equiv \left(\frac{\dot{v}}{3v}\right)^2 = \frac{\frac{\kappa}{3}\left(\frac{\mu_I^2}{v^2} + \frac{\rho}{\phi} + \frac{\mu_{AN}^2}{\phi^2 v^2}\right) + \frac{V(\phi)}{6\phi}}{\left(1 + \frac{3v}{2}\frac{d}{dv}\ln\phi\right)^2}, \tag{31}$$

where μ_A^2 and μ_I^2 are constants, representing the anisotropy density parameter and the energy density parameter of the Immirzi field, respectively. We note that the r.h.s is a rational function of the volume alone.

In the following we will take into account dust and radiation as matter contributions, specified by the choices $w = 0$, $\mu = \mu_D$ and $w = 1/3$, $\mu = \mu_R$ in (28), respectively. Then, bouncing solutions can be derived for $\alpha < 0$ integrating Eq. (31) for $v(t)$, which then yields the scalar fields behavior via (30).

4.1. *Vacuum case*

It is convenient to first focus on the vacuum case, where $f(v) = 1$ and $\mu_D = \mu_R = 0$. In this case we found the big bounce in the volume variable depicted in Fig. 1, where also the behavior of each scale factor is shown. We note that the volume is affected by a future finite-time *singularity*[71,72] where the Hubble function diverges, while the scale factors are always finite and nonvanishing. Such singular points will be carefully investigated in the next section studying the geodesic completeness and scalar perturbations across them. Here we just note that, in general, quantum effects of particle creation[73–76] can produce additional effective terms in the Friedman equation, able to regularize singularities of the Hubble function.

Finally, the scalar fields behaviour is shown in Fig. 2 where the field ϕ asymptotically reaches unity as $t \to \infty$, while the Immirzi field relaxes to a constant Immirzi parameter.

4.2. *Radiation and dust*

The above analysis can be extended to the non vacuum case, including the energy density of radiation and dust. A first difference concerns the late time region, since

[a] A dot denotes derivatives with respect to time.

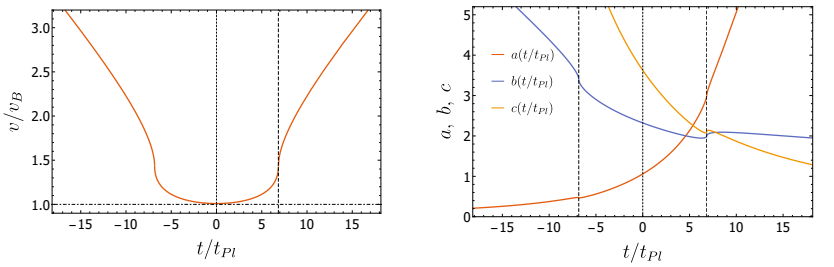

Fig. 1. Numerical solutions for $\alpha = -5/3$, $\mu_I = \sqrt{3}$, $\mu_A = 0.2\mu_I$ as a function of t/t_{Pl}. Dotted and dashed lines represent where bounce and future time singularity happen, respectively. The bounce is centered at the origin of time for convenience, and the values of the parameters are chosen in order to yield graphs that display features in a clear fashion. (a) Universe volume normalised to v_B. (b) Scale factors.

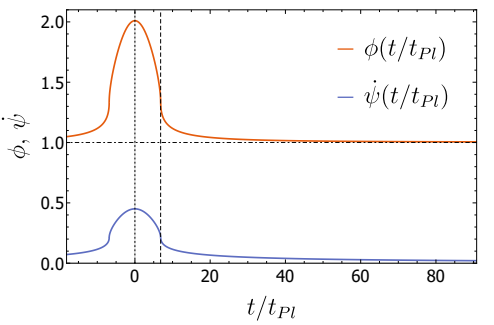

Fig. 2. Scalaron ϕ and Immirzi field derivative $\dot{\psi}$ for $\alpha = -5/3$, $\mu_I = \sqrt{3}$, $\mu_A = 0.2\mu_I$ as a function of t/t_{Pl}.

both radiation and dust are able to provide an isotropization mechanism for the universe, as is apparent studying the anisotropy degree

$$A(t) = \frac{\left(H_A^2 + H_B^2 + H_C^2\right)}{3H^2} - 1, \tag{32}$$

whose behavior is shown in Fig. 3. Regarding the universe in its early phase, instead, two different scenarios may occur, depending on the value of the parameter α. If $\bar{\alpha} < \alpha < 0$, where $\bar{\alpha} = -2\mu_I^2/\mu_D^4$, the solutions are qualitatively equivalent to the vacuum case. If $\bar{\alpha} > \alpha$, instead, we still obtain a bouncing behavior for the volume (See Fig. 4), which however is now devoid of singularities. However, now the scale factors either diverge or vanish at some critical time t_c.

5. Physical implications of curvature divergences

As described in the previous section there are two classes of solutions, characterized by a singularity in the Hubble function and non vanishing and finite scale factors

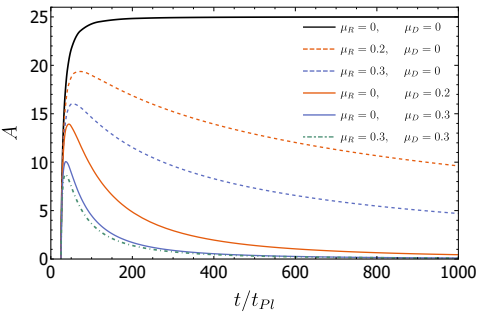

Fig. 3. Asymptotic behavior of the anisotropy degree A as a function of t/t_{Pl} after the finite time singularity for various values of μ_R, μ_D and $\alpha = -5/3$, $\mu_I = \sqrt{3}$, $\mu_A = 0.2\mu_I$.

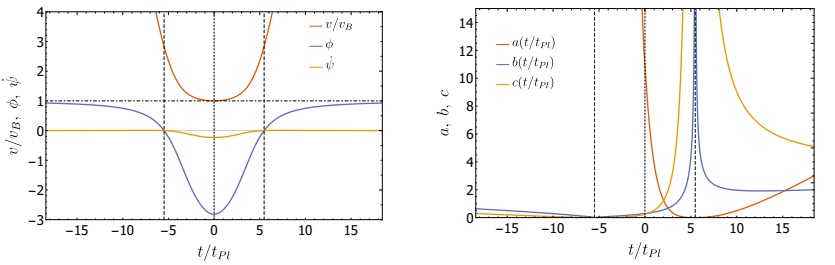

(a) (b)

Fig. 4. Numerical solutions as a function of t/t_{Pl} for $\mu_I = 0.057$, $\mu_A = 2.4$, $\mu_D = 0.365$, $\mu_R = 1.56$ and $\alpha = -8.42 < \bar{\alpha}$. The dashed lines represent where the scalaron vanishes. (a) Volume normalised to v_B, ϕ and derivative of the Immirzi field. (b) Scale factors.

(Fig. 1) or with regular Hubble function but vanishing or divergent scale factors (Fig. 4). In this section we will analyse such singularities studying the behavior of null geodesics and of scalar perturbations near the critical time t_c, at which the singularity is located.

Regarding null geodesics with tangent vector $u^\alpha = dx^\alpha/ds$, it can be shown that they admit a first integral of the form[77,78]

$$x' = \frac{k_a}{a^2}, \qquad y' = \frac{k_b}{b^2}, \qquad z' = \frac{k_c}{c^2}, \qquad t' = \left(\frac{k_a^2}{a^2} + \frac{k_b^2}{b^2} + \frac{k_c^2}{c^2}\right)^{1/2} + C_0, \tag{33}$$

where prime denotes derivative with respect to the affine parameter s and k_a, k_b, k_c and C_0 are integration constants. It follows that if $a(t)$, $b(t)$, and $c(t)$ are continuous and non-vanishing, as in Fig. 1, the tangent vector to the geodesics will be unique and well defined. Therefore, such cases are geodesically complete, a result that holds both in the anisotropic and in the isotropic case.[79]

In the other class of solutions (Fig. 4), instead, we see that the volume remains finite despite the vanishing/divergence of some scale factors. The divergence of individual scale factors does not affect the geodesics, but the vanishing of some of

them may spoil the continuity and lead to the impossibility of a unique extension across t_c. Indeed, let us consider the case in which one scale factor vanishes at some affine parameter s_c. In particular, suppose that

$$a(s) = a_0(s - s_c)^\gamma, \tag{34}$$

with $\gamma > 0$. Then, integrating the relevant equations yields

$$x(s) = x_c + \frac{k_a(s - s_c)^{1-2\gamma}}{a_0^2(1 - 2\gamma)}, \tag{35}$$

$$t(s) = t_c + C_0(s - s_c) + \frac{k_a(s - s_c)^{1-\gamma}}{a_0(1 - \gamma)}, \tag{36}$$

which are smooth if $0 < \gamma < 1/2$ and $0 < \gamma < 1$, respectively. Note that if $1/2 < \gamma < 1$, then $x(s) \xrightarrow{s \to s_c} \pm\infty$, which would imply reaching infinity in finite coordinate time. Conversely, if $0 < \gamma < 1/2$, then the geodesic path will span the range $\{t, x\} \in (-\infty, \infty)$, and the geodesics would be complete, despite the vanishing of some scale factors. However, this result is dependent on how rapidly the zero is reached, i.e. we have to determine the value of γ relative to the solutions in question. The results are shown in Fig. 5 and prove that the solution approaches zero too rapidly, corresponding to a value of γ larger than $1/2$. We are thus forced to conclude that the example shown in Fig. 4 does represent a geodesically incomplete space-time.

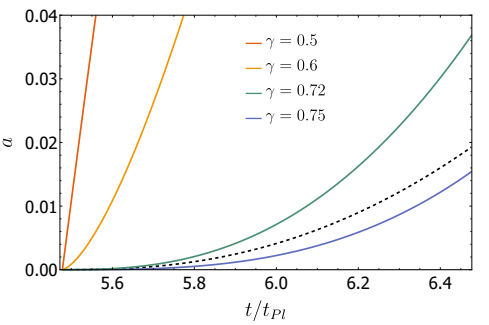

Fig. 5. Outcomes of null geodesics test for $\alpha < \bar{\alpha}$. Scale factor $a(s(t))$ for different values of γ. The dashed-black line represent the numerical solution $a(t)$ reported in Fig. 4.

We now turn the attention to the behavior of scalar field perturbations. For a scalar mode given by $\sigma_{\vec{k}}(t, \vec{x}) = \Theta(t)e^{i\vec{k}\cdot\vec{x}}$, one finds[65] an equation of the form

$$\ddot{\Theta} + h(v)\frac{\dot{v}}{v}\dot{\Theta} + \left(\frac{k_x^2}{a^2} + \frac{k_y^2}{b^2} + \frac{k_z^2}{c^2}\right)\Theta = 0\ , \tag{37}$$

where $h(v)$ represents some regular function of the volume v and $\vec{k} = (k_x, k_y, k_z)$ represents a set of constants. From this expression, we see that scalar modes are sensible to the presence of the individual scale factors a, b, and c, and of the Hubble

function $H = \dot{v}/3v$. If the scalar factors do not vanish anywhere, then any potential problems should come only from the term involving the Hubble function, which diverges in t_c. In particular, in vacuum one finds[65] the following approximate solution near the singularity

$$\Theta(t) \approx \Theta_c + \frac{\dot{\Theta}_c}{2\tilde{h}_c^2} e^{\mp 2\tilde{h}_c|t-t_c|^{1/2}} \left(1 \pm 2\tilde{h}_c|t-t_c|^{1/2}\right) , \tag{38}$$

with $\Theta_c, \dot{\Theta}_c, \tilde{h}_c$ constants, from which we see that scalar field perturbations remain bounded around t_c despite the divergence in the Hubble function. A similar result holds in presence of dust and radiation, since

$$\begin{aligned}\Theta \approx \Theta_c - \frac{\dot{\Theta}_c}{32\tilde{h}_c^4} e^{\mp 4\tilde{h}_c|t-t_c|^{1/4}} \Big(3 \pm 12\tilde{h}_c|t-t_c|^{1/4} \\ +24\tilde{h}_c^2|t-t_c|^{1/2} \pm 32\tilde{h}_c^3|t-t_c|^{3/4}\Big) ,\end{aligned} \tag{39}$$

which is easy to see to be again bounded. On the other hand, for a regular Hubble function but vanishing scale factors, equation (37) describes a harmonic oscillator with a time dependent frequency,

$$\ddot{\Theta}(t) + \frac{k_x^2}{a^2(t)}\Theta(t) \approx 0, \tag{40}$$

which diverges as $a(t) \to 0$. Therefore, for the values of $a(t)$ obtained numerically in the previous section neither geodesics nor scalar perturbations are well behaved.

6. Conclusion

We proposed a generalization of the Nieh-Yan term to metric-affine gravity, by including an additional term featuring nonmetricity and inserting two parameters (λ_1, λ_2), which allow to recover the projective invariance and the topological character, otherwise lost in presence of nonmetricity. In particular, projective invariance can be independently obtained by setting $\lambda_1 = \lambda_2 = \lambda$, whereas topologicity is only guaranteed for $\lambda = 1$.

As an explicit example, we considered a model with Lagrangian $F(R, NY_{gen})$, which re-expressed in the Jordan frame features two scalar fields. We identified these scalar degrees as the $f(R)$-like scalaron ϕ and the Immirzi field β and showed that the latter acquires dynamical character and a potential term in a more natural way than in previous treatments, where these features are introduced by hand in the action. Depending on the values of λ_1 and λ_2, we found two different scalar tensor theories. Models with $\lambda_1 \neq \lambda_2$, are non-dynamical, and the scalar fields are frozen to constant values in vacuum. In the projective invariant case ($\lambda_1 = \lambda_2$), instead, the theory is endowed with one additional dynamical degree of freedom, the Immirzi field, while the field ϕ is algebraically related to the latter via a modified structural equation.

Then, we considered in more detail the dynamical models, looking for cosmological solutions in Bianchi I spacetimes. We found numerical solutions in which the big bang singularity is replaced by a big bounce scenario, in which the universe volume undergoes a contraction up to a minimum value and then bounces back, re-expanding in another branch. The scalaron and the Immirzi field reach a maximum during the bounce and relax to constant values at later times, where the standard LQG picture, with $\phi = 1$ and a constant Immirzi parameter $\beta = \beta_0$, is recovered. Moreover, the inclusion of dust and radiation turns out to provide an isotropization mechanism at late times, a feature that is absent in the vacuum case.

Such solutions are characterized by future finite time singularities after the bounce, either in the Hubble function or in the individual scale factors. In the former case, we showed that null geodesics are still well behaved and scalar perturbations bounded, which allows us to conclude that the solution is physically acceptable. In the latter case, instead, the study of null geodesics shows that they cannot be extended across the singular point, where also scalar perturbations grow in time, leading us to regard such solutions as unphysical.

Late time cosmology with derivatives of matter Lagrangian

Shahab Shahidi

School of Physics, Damghan University, Damghan, 36716-41167, Iran
E-mail: s.shahidi@du.ac.ir

A class of modified gravity theories with higher order derivative terms of a function of the matter Lagrangian $f(L_m)$ is considered. We will consider the Newtonian limit of the theory and show that the model predicts the standard Poisson equation for a massive test particle due to the higher order nature of the derivative matter coupling. Generally the energy momentum tensor is not conserved, leading to the fifth force similar to $f(R,T)$ theories. We will however show that in the FRW background the energy-momentum tensor is conserved. Cosmological implications of this model with different functions of the matter Lagrangian f will be investigated in details and we will show that current observational data can be satisfied. Evolution of the matter density perturbation in the longitudinal gauge is also considered for dust matter sources and we will show that the observational data can be satisfied in this model.

Keywords: Modified gravity, Late time cosmology.

1. Introduction

The accelerated expansion of the universe is one of the most interesting findings of modern cosmology which is confirmed by observations.[1] Our first and standard treatment to explain this expansion is to introduce a cosmological constant Λ to the standard Einstein Hilbert action so that the Lagrangian of the gravitational theory becomes

$$\mathcal{L} = \sqrt{-g}(R - 2\Lambda + L_m), \tag{1}$$

where R is the Ricci scalar and L_m is the matter Lagrangian. Together with cold dark matter which takes care of local celestial motions, this theory could explain almost all of current observations and is well-known as the ΛCDM model for cosmology. However, the standard ΛCDM model suffers from some phenomenological and also observational issues such as the cosmological constant problem,[2] the Hubble and σ_8 tensions,[3] etc. In fact there are many attempts to explain these problems in the context of ΛCDM model. For example in,[4] the authors have tried to explain why the σ_8 tension is not a problem at all.

One of the solutions to all of the aforementioned problems is to dismiss the cosmological constant in the Lagrangian and search for a new method to describe the dynamics of accelerated universe at late times. This can be done by introducing extra degrees of freedom to the theory such as scalar-tensor[5] or vector-tensor theories,[6] or by generalizing the gravitational action itself, such as $f(R)$ gravity theories[7] or massive gravity theories.[8] Another interesting idea among these modified

gravity theories, is to introduce some non-standard couplings between gravity and matter fields. These theories include minimal couplings such as energy-momentum powered gravity[9] or non-minimal couplings such as $f(R,T)$ theories and their generalizations.[10] In figure (1) we have summarized the most important generalizations of gravitational action. The general property in non standard matter coupling theories is that the energy-momentum tensor is no longer conserved. This implies that we have a fraction of matter creation from geometry in these classes of theories which could be tested by observations.

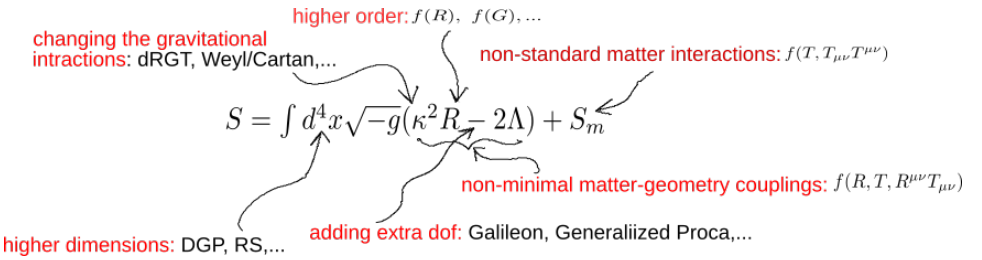

Fig. 1. Summary of modified gravity theories from the Einstein-Hilbert action.

2. The model

In this paper we introduce a new method to generalize the coupling between matter and geometry. Let us consider the evolution of the non-relativistic matter energy density with respect to the redshift z which is plotted in figure (2). One can see from this figure that the matter density is nearly flat around $z \approx 0$. This implies that the derivatives of matter density is nearly constant around present time which can mimic the cosmological constant (CC). This brings the idea that maybe derivatives of the

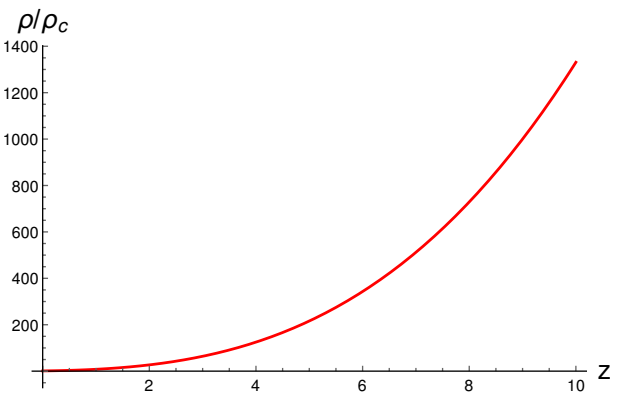

Fig. 2. The evolution of the pressure-less energy density as a function of redshift z.

matter density or matter Lagrangian could play the role of CC and be responsible for late time accelerated expansion of the universe. To explore this possibility, let us consider the action functional[11]

$$S = \int d^4x\sqrt{-g}\Big[\kappa^2(R-2\Lambda) + \alpha\,\nabla_\mu f\,\nabla^\mu f\Big] + S_m, \tag{2}$$

where $f = f(L_m)$ is an arbitrary function of the matter Lagrangian with mass dimension 1 and α is a dimensionless constant. It should be noted that the function f is a scalar field. As a result, one can consider the α-term in the action, as a canonical kinetic term for f. So, the theory (2) is a scalar tensor theory (or a simplest class of Galileon theory) where the scalar field is substituted by an energy-density valued scalar field. As we will see in the following, this rich structure allows us to explain the late time accelerated expansion of the universe. We should also note that the theory (2) is different from the so-called $f(R, L_m)$ gravity theories,[10] since in $f(R, L_m)$ theories, we have non-minimal couplings between matter and geometry but here we have a minimal derivative interaction of the matter Lagrangian.

In order to obtain the equation of motion of this model, note that the definition of the energy-momentum tensor is given by

$$T_{\mu\nu} = -\frac{2}{\sqrt{-g}}\frac{\delta(\sqrt{-g}L_m)}{\delta g^{\mu\nu}}, \tag{3}$$

which implies that

$$\delta L_m = \frac{1}{2}\big(L_m g_{\mu\nu} - T_{\mu\nu}\big)\delta g^{\mu\nu}. \tag{4}$$

As a result, one can obtain the equation of motion of the derivative matter coupling (DMC) model (2) as

$$\begin{aligned}\kappa^2(G_{\mu\nu} + \Lambda g_{\mu\nu}) + \alpha\, f'\Box f\,(T_{\mu\nu} - g_{\mu\nu}L_m)\\ + \alpha\left(\nabla_\mu f\nabla_\nu f - \frac{1}{2}g_{\mu\nu}\nabla_\alpha f\nabla^\alpha f\right) = \frac{1}{2}T_{\mu\nu},\end{aligned} \tag{5}$$

Here, prime denotes derivative with respect to the argument. As we mentioned above, the term proportional to the coupling constant α is the second Galileon equation of motion for the scalar field f.

The general behavior of the coupled matter-geometry theories is that the energy-momentum tensor is no longer conserved. In our model, one can easily obtain

$$\nabla^\mu T_{\mu\nu} = 2(T_{\mu\nu} - L_m g_{\mu\nu})\nabla^\mu \mathrm{Log}\big[1-\alpha f'\Box f\big]. \tag{6}$$

One can see that in the case $\alpha = 0$, the energy-momentum tensor becomes conserved. Here, we have to note an important property of the model. Let us assume that the matter content of the universe could be explained by a perfect fluid with Lagrangian $L_m = -\rho$ and energy-momentum tensor

$$T_{\mu\nu} = (\rho + p)u_\mu u_\nu + p g_{\mu\nu}. \tag{7}$$

In this case, the non-conservation of the energy-momentum tensor becomes

$$\nabla^{\mu}T_{\mu\nu} = -2(\rho + p)h_{\mu\nu}\,\nabla^{\mu}\mathrm{Log}\big[1-\alpha f'\,\Box f\big]. \tag{8}$$

where $h_{\mu\nu} = u_{\mu}u_{\nu} + g_{\mu\nu}$ is the projection tensor. On top of FRW space-time, the right hand side of the conservation equation (8) vanishes and we recover the conservation of the energy-momentum tensor in our model. This is however a new feature in the context of matter-geometry coupling theories.

3. Newtonian limit

Let us first consider the geodesics of the DMC model. We assume that the cosmological constant could be ignored in the low energy limit. One can easily prove that the conservation of the energy-momentum tensor (8) for a perfect fluid results in the geodesic equation of the form

$$\frac{d^2x^{\lambda}}{ds^2} + \Gamma^{\lambda}{}_{\mu\nu}u^{\mu}u^{\nu} = f^{\lambda}, \tag{9}$$

where

$$f^{\lambda} = -2h^{\lambda\nu}\nabla_{\nu}\log\Big[1 - \alpha f'\Box f\Big] - \frac{h^{\lambda\nu}\nabla_{\nu}p}{\rho + p}, \tag{10}$$

where the new vector field f^{μ} represents an extra force inserted to the particles moving in the geodesic lines. This will imply that a test particle move along a non-geodesic path. This is actually a general behavior of theories with matter-geometry coupling. In the low energy limit of the theory the metric takes the form

$$ds^2 = -(1 + 2\Phi(\vec{x}))dt^2 + (1 - 2\Phi(\vec{x}))d\vec{x}^2, \tag{11}$$

where Φ is the Newtonian potential. In this limit, only the (00) component of the energy-momentum tensor, namely ρ, is non-vanishing. If we assume that the function f in the Lagrangian is a smooth funciton and could be expanded as a power series in ρ, one obtains

$$f = \sum_{i=0}\alpha_i\rho^i.$$

As one can see from the field equation (5), f appears with at least two derivatives. As a result the derivative matter coupling terms could not contribute in the linear Newtonian approximation. We then recover the standard Poisson equation as

$$\vec{\nabla}^2\Phi(\vec{x}) = 4\pi G\rho(\vec{x}). \tag{12}$$

One should note that this result is in contrast to the general discussion on the form of Poisson equation in matter-geometry coupling theories,[12] since in that work the coupling is assumed to have a linear contribution to the field equations.

4. Cosmology

In this section, we consider the cosmological implications of the DMC model. Let us assume that the universe can be explained by a spatially flat FRW space-time with line element

$$ds^2 = a^2(t)(-dt^2 + dx^2 + dy^2 + dz^2), \tag{13}$$

where we have chosen the conformal time t with scale factor a. From the field equation (5), one can obtain the Friedmann and Raychaudhuri equations as

$$6\kappa^2 H^2 = a^2\rho - \alpha f'^2\,\dot{\rho}^2 + 2\kappa^2 a^2\Lambda, \tag{14}$$

and

$$\begin{aligned} -4\kappa^2\dot{H} - 2\kappa^2 H^2 = {} & pa^2 - 2\kappa^2 a^2\Lambda \\ & + 2\alpha f'(\rho + p)(f''\dot{\rho}^2 - f'\ddot{\rho}) \\ & - 4\alpha H(\rho + p)f'^2\dot{\rho} - 2\alpha f'^2\dot{\rho}^2. \end{aligned} \tag{15}$$

In this paper, we will consider a power-law case for the function f as $f = \gamma(-L_m/\rho_c)^n$. Defining the following dimensionless parameters as

$$\begin{aligned} & H = H_0 h, \quad \bar{\rho}_m = \frac{\rho_m}{\rho_c}, \quad \bar{\rho}_r = \frac{\rho_r}{\rho_c}, \quad \Omega_{\Lambda 0} = \frac{\Lambda}{3H_0^2}, \\ & r \equiv \bar{\rho}_m + \bar{\rho}_r, \quad \rho_c = 6\kappa^2 H_0^2, \qquad \beta = \frac{\gamma^2\alpha}{6\kappa^2}, \end{aligned} \tag{16}$$

where H_0 is the current value of the Hubble parameter and ρ_c is the critical density, the Friedmann equation reduces to

$$h^2 = a^2(r + \Omega_{\Lambda 0}) + \frac{1}{9}\beta r^{2(n-1)}\dot{r}^2. \tag{17}$$

We note that the matter sources on top of FRW universe is conserved. As a result, we obtain

$$\bar{\rho}_m = \frac{\Omega_{m0}}{a^3}, \qquad \bar{\rho}_r = \frac{\Omega_{r0}}{a^4}.$$

Transforming to the redshift coordinate, defined as

$$1 + z = \frac{1}{a},$$

and using the above equations, one obtains the dimensionless Hubble parameter as

$$(1+z)^2 h^2 = \frac{(1+z)^3\Omega_{m0} + \Omega_{\Lambda 0}}{1 + \beta(1+z)^{6n}\,\Omega_{m0}^{\;2n}}. \tag{18}$$

We should note that the dimensionless Hubble parameter h has a property $h(z = 0) = 1$. In the following, we will consider two different cases, corresponding to the vanishing CC and non-vanishing CC. In the case of vanishing CC, one obtains from the constraint $h(0) = 1$

$$\beta = (\Omega_{m0} - 1)\Omega_{m0}^{\;-2n}.$$

In the case of non-vanishing CC, one obtains

$$\Omega_{\Lambda 0} = 1 - \Omega_{m0} + \beta \Omega_{m0}^{2n}.$$

In order to obtain the best estimate on the model parameters, H_0, Ω_{m0}, n and β, we will obtain the best fit values of these parameters by confronting the model with observational data on the Hubble parameter in the redshift range $(0, 2)$.[13] In order to do this, we use the maximum likelihood analysis of the model based on the data on H_0. The likelihood function in the case of n independent data points can be defined as

$$L = L_0 e^{-\chi^2/2}, \tag{19}$$

where L_0 is the normalization constant, and χ^2 is

$$\chi^2 = \sum_i \left(\frac{O_i - T_i}{\sigma_i} \right)^2, \tag{20}$$

where i indicates the number of data, O_i are the observational values, T_i are the theoretical values and σ_i are the observational errors associated with the ith data. In the present model we have

$$L = L_0 \exp \left[-\frac{1}{2} \sum_i \left(\frac{O_i - H_0 T_i}{\sigma_i} \right)^2 \right]. \tag{21}$$

By maximizing the likelihood function, one can find the best fit values of the parameters. In the presence of the CC, one obtains

$$\begin{aligned} H_0 &= 65.91^{+3.23}_{-3.45}, \\ \Omega_{m0} &= 0.41^{+0.11}_{-0.08}, \\ \beta &= 0.004^{+0.003}_{-0.002}, \end{aligned} \tag{22}$$

where the $\pm$ values are the 1σ confidence intervals. In this case, the CC parameter $\Omega_{\Lambda 0}$ could be obtained as

$$\Omega_{\Lambda 0} = 0.59. \tag{23}$$

In figure (3), we have plotted the triangle diagram for this case. It should be noted that the parameter values for the Hubble parameter H_0 is in agreement with the ΛCDM model, indicating that the present model could not make the Hubble tension any better. We can see from the estimate (22) that the matter density Ω_0 is more than the ΛCDM value by 10 percent. Also, the CC abundance of the universe reduces up to 10 percent in this model. This in fact shows that the CC could be partially substituted by a simple derivative matter coupling. In fact, more complicated couplings could alleviate the contribution of the CC to the accelerated expansion of the universe even more.[11]

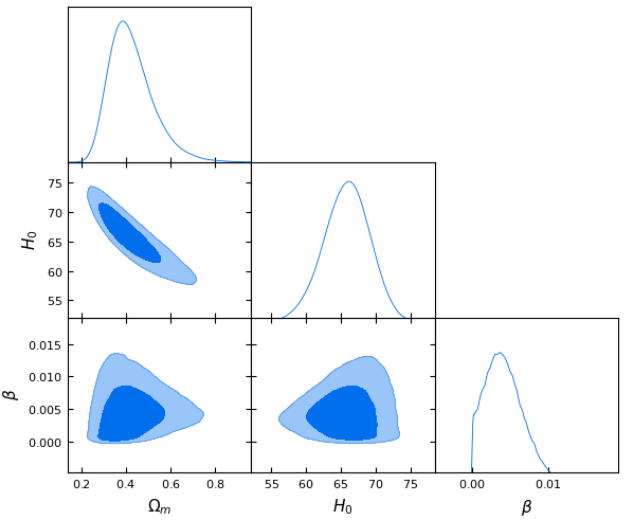

Fig. 3. The triangle diagram corresponding to 1σ intervals of the model paratmer in the case of non-vanishing CC.

Let us now consider the case of vanishing CC. In this case, all the accelerated expansion of the universe should be fully addressed by derivatives of the matter Lagrangian. The maximum likelihood analysis in this case gives

$$\begin{aligned} H_0 &= 69.32^{+3.85}_{-4.82}, \\ \Omega_{m0} &= 0.29^{+0.07}_{-0.09}, \\ n &= -0.21^{+0.11}_{-0.15}. \end{aligned} \tag{24}$$

In this case on obtains $\beta = -0.42$. In figure (4), we have plotted the triangle diagram for this case. Also, in figure (5), we have depicted the evolution of the Hubble and deceleration parameters for the best fit values of the parameters. One can see from the figures that the DMC model satisfies the observational data. In fact the Hubble parameter is a little larger than the ΛCDM value for redshifts bigger that $z \approx 0.5$. This implies that the DMC model predicts smaller universe respect to the ΛCDM model. Also, the transition from deceleration to acceleration phase is occurred later than ΛCDM model, which indicates that the universe remains in dust dominated universe more than the ΛCDM model. However, the late time observations is fully addressed in this model, thanks to the presence of derivative of matter Lagrangian.

5. Dynamical system analysis

In order to see whether the DMC model could explain the cosmic history of the universe well or not, let us consider the dynamical system analysis of the model.

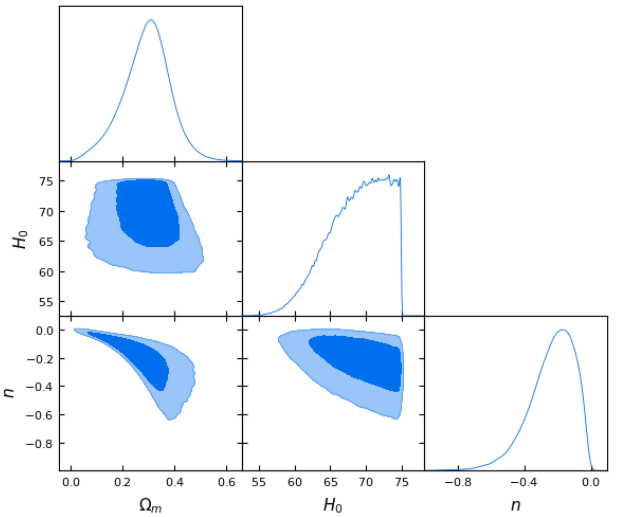

Fig. 4. The triangle diagram corresponding to 1σ intervals of the model paratmer in the case of vanishing CC.

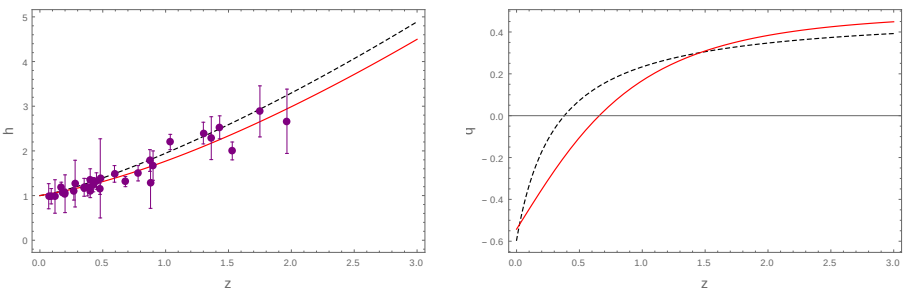

Fig. 5. The evolution of the Hubble (left) and deceleration (right) parameters as a function of redshift z for the best fit values of model parameters. The red solid line indicates the ΛCDM curve. Also, the error bars are the observational values together with their errors.[13]

We define the dynamical variables as

$$\Omega_m = \frac{\bar{\Omega}_m a^2}{h^2}, \quad \Omega_r = \frac{\bar{\Omega}_r a^2}{h^2}, \quad \Omega_h = \frac{h^2}{a^2}, \quad \Omega_\Lambda = \frac{\Omega_{\Lambda 0} a^2}{h^2}. \tag{25}$$

In the case of vanishing CC, one obtains from the Friedmann equation

$$\Omega_h = \left[\sqrt{\frac{1-\Omega_m-\Omega_r}{-\beta}} \frac{3}{(\Omega_m+\Omega_r)^{n-1}(3\Omega_m+4\Omega_r)} \right]^{\frac{1}{n}}. \tag{26}$$

In this case, we have two dynamical degrees of freedom. Also, in the case of non-vanishing CC, one obtains

$$\Omega_\Lambda = 1 - \Omega_m - \Omega_r + \frac{1}{9}\beta\,\Omega_h^{2n}(\Omega_m + \Omega_r)^{2(n-1)}(3\Omega_m + 4\Omega_r)^2, \tag{27}$$

indicating that the model has three dynamical degrees of freedom. In figure (6), we have plotted the evolution of the dust and radiation abundances and dark energy abundance defined as $\Omega_{dark} \equiv 1 - \Omega_m - \Omega_r$, as a function of $N \equiv \ln a$. The dashed lines represent the behavior of the abundances in ΛCDM model, the dotted lines indicating the DMC model with CC and the solid lines indicate the DMC model with vanishing CC. One can see from this figure, that both cases could fully describe the history of the universe as in the ΛCDM model.

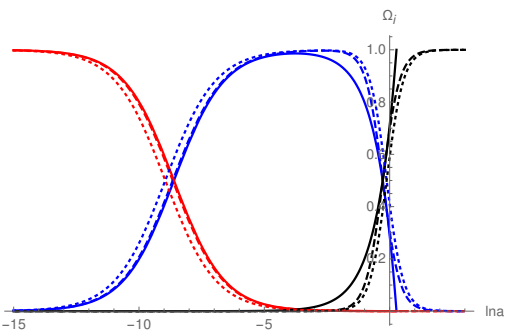

Fig. 6. The evolution of the dust (blue), radiation (red) and dark energy (black) abundances in ΛCDM model (dahsed), DMC model with CC (dotted) and DMC model with vanishing CC (solid).

In the case of vanishing CC, we have two fixed points corresponding to the radiation and dust dominated universe. In table (1), we have summarized these two fixed points. The stream plot of the evolution of the dynamical system could be seen in figure (7). In this case, there is no stable fixed point corresponds to the de Sitter acceleration of the universe. However, we have a stable manifold passing through the origin. As we get closer to the origin, the effective parameter of state of the model takes negative and larger values $\omega_{eff} < 0$ and we have more acceleration. In figure (7), we have plotted the $\omega_{eff} = -1$ curve as a solid line, indicating the

Table 1. The fixed points together with their properties for the DMC model without CC.

de Sitter expansion. In figure (6), one can see that the dark energy abundance blows up at $N \approx 0$, indicating the aforementioned property of the model in this case. As a result, in this case, the universe could begin from an unstable radiation dominated fixed point, fall into the saddle dust dominated point and end at some accelerated expanding phase.

In the case of non-vanishing CC, we have three fixed points as we have summarized in table (2). In this case, we have all the standard fixed points of the ΛCDM model. However, as one can see from the table, the stable de Sitter fixed point is in fact a fixed line, passing through the origin. We have plotted the $\Omega_h = 0$ plane of the phase space in figure (8). In this case, the history of the universe is the same as the standard ΛCDM model. This can also be seen in figure (6).

6. Conclusion

In this paper, we have considered a new possibility in the class of matter-geometry coupled theories namely, adding derivative interactions of the matter Lagrangian. We have used an arbitrary function f of the matter Lagrangian L_m which is a scalar

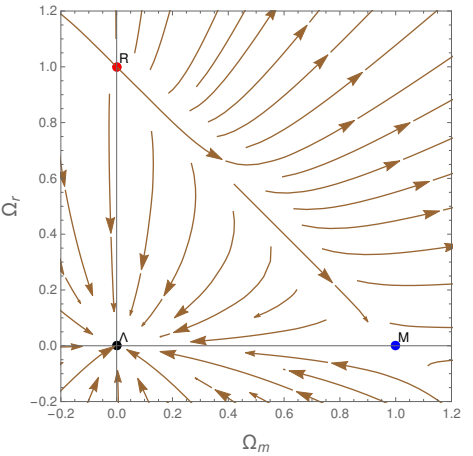

Fig. 8. The phase portrait of the dynamical system of the DMC model in the case of non-vanishing CC. The fixed points can also be seen in the figure.

field in nature, and add a canonical kinetic term of f to the action. In fact more general Galileon interactions could also be added to the theory which makes the late time behavior more reliable.

The cosmological implications of the theory in the case of vanishing and non-vanishing CC was studied in detail and we have found that CC could in part or fully be substituted by derivatives of matter Lagrangian. In the case of vanishing CC however, the cosmic history of the universe does not have a stable de Sitter fixed point and we need some higher order Galileon invariants to make the theory reliable. This was done in.[11]

In summary, we have shown in this paper that derivatives of matter Lagrangian could be considered more seriously as a reliable modified gravity theory for late times.

We analyze the Bianchi I cosmology in the presence of a massless scalar field and describe its dynamics via a semiclassical and quantum polymer approach. We investigate the morphology of the emerging Big Bounce by adopting three different sets of configurational variables: the natural Ashtekar connections, the Universe volume plus two anisotropy coordinates and a set of anisotropic volume-like coordinates (the latter two sets of variables would coincide in the case of an isotropic Universe). In the semiclassical analysis we demonstrate that the Big Bounce emerges in the dynamics for all the three sets of variables. Moreover, when the Universe volume itself is considered as a configurational variable, we have derived the polymer-modified Friedmann equation and demonstrated that the Big Bounce has a universal nature, *i.e.* the total critical energy density has a maximum value fixed by fundamental constants and the Immirzi parameter only. From a pure quantum point of view, we investigate the Bianchi I dynamics only in terms of the Ashtekar connections. In particular, we apply the Arnowitt–Deser–Misner (ADM) reduction of the variational principle and then we quantize the system. We study the resulting Schrödinger dynamics, stressing that the wave packet peak behavior over time singles out common features with the semiclassical trajectories.

Keywords: Polymer Quantum Mechanics; Polymer Cosmology; Bianchi I Universe; Ashtekar variables.

1. INTRODUCTION

The emergence of a Big Bounce in the quantum dynamics of the isotropic Universe is one of the most relevant result achieved in Loop Quantum Cosmology (LQC) as a phenomenological implication of Loop Quantum Gravity (LQG)[1,2] when applied to the cosmological sector.[3–9] Although, many criticisms have been expressed towards the LQC framework, especially regarding the lack of a real quantum description of the Big Bounce properties, the unclear equivalence between the so-called improved scheme with the original LQC formulation in the Ashtekar variables and the process through which the symmetry reduction is performed in order to properly derive LQC as the cosmological sector of LQG.[10] In this context, Polymer Quantum Mechanics (PQM)[11,12] represents a convenient mathematical instrument through which deeply

analyze bouncing cosmologies, since it is able to reproduce LQC results at least at an effective level and without entering the issues of LQG and LQC. In this work we apply PQM to the Bianchi I model in the presence of a massless scalar field and we explore both its semiclassical and quantum dynamics in different sets of configurational variables,[12] in particular the natural Ashtekar connections and two different sets of volume-like variables (the anisotropic volume-like coordinates and the Universe volume itself plus two anisotropies), following the LQC formulation in.[13,14]

The paper is structured as follows. In Sec. 2 the theory of PQM is introduced, while the original part of the paper is developed in Secs. 3–5. In particular, in Secs. 3 and 4 it is solved the semiclassical polymer dynamics of the Bianchi I model in the Ashtekar variables and in the two sets of volume-like variables respectively, then in Sec. 5 a full quantum treatment in the Ashtekar variables is developed using a Scrödinger-like formalism. Finally, in Sec. 6 some concluding remarks are commented.

2. POLYMER QUANTUM MECHANICS

PQM is a non-equivalent representation of quantum mechanics with respect to the standard Schrödinger one[12] and is based on the assumption that one or more variables of the phase space are discretized.

Firstly, we consider a set of abstract kets $|\mu\rangle$ with $\mu \in \mathbb{R}$ with the inner product $\langle\mu|\,\nu\rangle = \delta_{\mu\nu}$, where $\delta_{\mu\nu}$ is a Kronecker delta. This procedure defines the non-separable Hilbert space H_{poly} where two fundamental operators can be introduced: the *label* operator $\hat{\epsilon}$, whose action on the kets is given by $\hat{\epsilon}\,|\mu\rangle = \mu\,|\mu\rangle$, and the *shift* operator $\hat{s}(\lambda)$ ($\lambda \in \mathbb{R}$), where $\hat{s}(\lambda) = |\mu + \lambda\rangle$. The action of $\hat{s}(\lambda)$ is discontinuous since the kets are orthonormal $\forall\lambda$. In this sense, the set of kets indexed by μ is said to be discrete.

Now, we consider a one-dimensional system identified by the coordinates (q, p) and we suppose that the coordinate q has a discrete character. In the p-polarization the wave function writes as ($\hbar = 1$) $\psi_\mu(p) = \langle p|\mu\rangle = e^{ip\mu}$, the action of the operator $\hat{q}$ is differential and in particular coincident with the label operator. Its eigenvalues are precisely the μ parameters and constitute a discrete set. On the other hand, in this polarization the shift operator acts in a multiplicative way as

$$\hat{s}(\lambda)\psi_\mu(p) = e^{i\lambda p}e^{i\mu p} = \psi_{(\mu+\lambda)}(p)\,. \tag{1}$$

As already mentioned, its action is discontinuous; therefore, we must conclude that the operator $\hat{p}$ does not exist since it is not possible to obtain a discontinuous operator from the exponentiation of a Hermitian one. Similar conclusions are reached by analyzing the structure of the q-polarization. Indeed, defining the variable q as discrete implies the non-existence of the operator $\hat{p}$, which must be regularized in order to deal with a well-defined dynamics. In order to overcome this issue, we introduce a regular graph $\gamma_{\mu_0} = \{q \in \mathbb{R}\,|\,q = n\mu_0, \forall n \in \mathbb{Z}\}$, *i.e.* a numerable set of

equidistant points whose spacing is given by the scale μ_0, and we restrict the action of the shift operator $e^{i\lambda p}$ by imposing $\lambda = n\mu_0$ in order to remain in the lattice. Its action is well-defined, so we use it to approximate any function of p in the following way:

$$p \approx \frac{1}{\mu_0} \sin(\mu_0 p) = \frac{1}{2i\mu_0} \left(e^{i\mu_0 p} - e^{-i\mu_0 p} \right) . \tag{2}$$

We notice that this approximation is good for $\mu_0 p \ll 1$. Under this hypothesis, the action of the regularized $\hat{p}$ operator is

$$\hat{p}_{\mu_0} |\mu_n\rangle = -\frac{i}{2\mu_0} (|\mu_{n+1}\rangle - |\mu_{n-1}\rangle) . \tag{3}$$

In the original part of the paper we will apply this picture to the configurational variables describing the Bianchi I cosmology. The interest we have in using a representation of quantum mechanics characterized by a discrete configurational variable relies in investigating cut-off effects on geometrical quantities and hence on the cosmological dynamics.

3. SEMICLASSICAL POLYMER DYNAMICS OF THE BIANCHI I MODEL IN THE ASHTEKAR VARIABLES

In this section we firstly investigate the semiclassical polymer dynamics of the Bianchi I model in terms of the Ashtekar variables. The phase space is six-dimensional and it is expressed through the canonical couple (c_i, p_j), which link with the scale factors a_i and their velocities is

$$p_i = |\epsilon_{ijk} a_j a_k| \text{sign}(a_i) , \qquad c_i = \gamma \dot{a}_i , \tag{4}$$

with $i = 1, 2, 3$ and $\{c_i, p_j\} = \kappa\gamma\delta_{ij}$. In order to implement the polymer paradigm, we proceed by imposing the polymer substitution for the Ashtekar connections

$$c_i \to \frac{1}{\mu_i} sin(\mu_i c_i) , \tag{5}$$

so the polymer Hamiltonian constraint with a massless scalar field takes the form

$$\mathcal{H}_{poly} = -\frac{1}{\kappa\gamma^2 V} \sum_{i \neq j} \frac{\sin(\mu_i c_i) p_i \sin(\mu_j c_j) p_j}{\mu_i \mu_j} + \frac{p_\phi^2}{2V} = 0 , \tag{6}$$

where $i, j = 1, 2, 3$ and $V = \sqrt{p_1 p_2 p_3}$. This way, we have chosen to define the variables p_i on three independent polymer lattices (with spacing μ_i respectively) due to their geometrical character. We also choose ϕ as the internal time, so N is fixed by the gauge $N = \frac{\sqrt{p_1 p_2 p_3}}{p_\phi}$, so that the equations of motion in the polymer representation are:

$$\begin{cases} \dfrac{dp_i}{d\phi} = -\dfrac{p_i \cos(\mu_i c_i)}{\gamma p_\phi} \left[\dfrac{p_j}{\mu_j} \sin(\mu_j c_j) + \dfrac{p_k}{\mu_k} \sin(\mu_k c_k) \right] \\ \dfrac{dc_i}{d\phi} = \dfrac{\sin(\mu_i c_i)}{\gamma \mu_i p_\phi} \left[\dfrac{p_j}{\mu_j} \sin(\mu_j c_j) + \dfrac{p_k}{\mu_k} \sin(\mu_k c_k) \right] \end{cases} \tag{7}$$

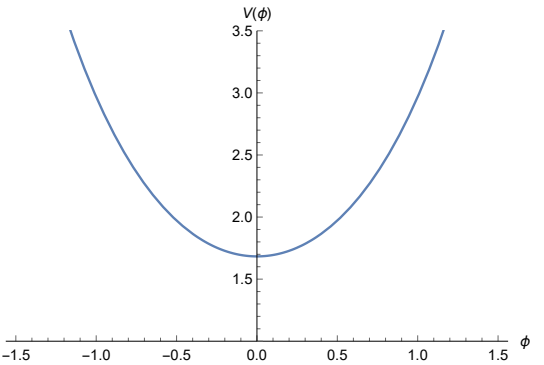

Fig. 1. Polymer trajectory of the Universe volume $V = \sqrt{p_1 p_2 p_3}$ in function of time ϕ: the Big Bounce replaces the initial singularity of the Bianchi I model.

for $i, j, k = 1, 2, 3$, $i \neq j \neq k$. By identifying proper constants of motion, the equations in (7) can be decoupled and the system can be analytically solved. In particular, in Fig. 1 it is shown the behavior of the Universe volume $V(\phi) = \sqrt{p_1(\phi)p_2(\phi)p_3(\phi)}$ as function of ϕ. The resulting trajectory highlights that a semi-classical Big Bounce replaces the classical Big Bang in the polymer framework.

4. SEMICLASSICAL POLYMER DYNAMICS OF THE BIANCHI I MODEL IN THE VOLUME-LIKE VARIABLES

In this section we study the dynamics of the Bianchi I Universe for a new choice of variables. In particular, the anisotropic character of the Bianchi I model leads to the possibility of considering two different sets of volume-like variables, that coincide in the case of the isotropic model.

4.1. *Analysis in the anisotropic volume-like variables:* (V_1, V_2, V_3)

Firstly, we consider three equivalent generalized coordinates which correspond to the proper Universe volume in the isotropic limit only:[14]

$$V_i = \mathrm{sign}(p_i)|p_i|^{\frac{3}{2}}\,, \qquad \eta_i = \frac{2c_i}{3\sqrt{|p_i|}}\,, \tag{8}$$

where η_i for $i = 1, 2, 3$ are the conjugate momenta and the new symplectic structure for the system is characterized by the Poisson brackets $\{\eta_i, V_j\} = \kappa\gamma\delta_{ij}$.

After that the canonical transformation has been performed, we obtain the polymer Hamiltonian constraint in the new variables by using the polymer substitution for the momenta η_i, since the variables V_i live on the corresponding polymer lattices. It reads as

$$\mathcal{H}_{poly} = -\frac{9}{4\kappa\gamma^2 V}\sum_{i\neq j}\frac{V_i \sin(\mu_i\eta_i)V_j \sin(\mu_j\eta_j)}{\mu_i\mu_j} + \frac{p_\phi^2}{2V} = 0\,, \tag{9}$$

where $i,j=1,2,3$ and $V=(V_1V_2V_3)^{\frac{1}{3}}$. Analogously, we impose $N=\frac{V}{p_\phi}$ due to the choice of ϕ as relational time, so the Hamilton equations describing the dynamics are

$$\begin{cases} \dfrac{dV_i}{d\phi} = -\dfrac{9V_i\cos(\mu_i\eta_i)}{4\gamma p_\phi}\left[\dfrac{V_j}{\mu_j}\sin(\mu_j\eta_j)+\dfrac{V_k}{\mu_k}\sin(\mu_k\eta_k)\right] \\ \dfrac{d\eta_i}{d\phi} = \dfrac{9\sin(\mu_i\eta_i)}{4\gamma\mu_1 p_\phi}\left[\dfrac{V_j}{\mu_j}\sin(\mu_j\eta_j)+\dfrac{V_k}{\mu_k}\sin(\mu_k\eta_k)\right] \end{cases} \tag{10}$$

for $i\neq j\neq k$. In analogy with the previous treatment, we can identify proper constants of motion that decouple the system (10) along the three directions.

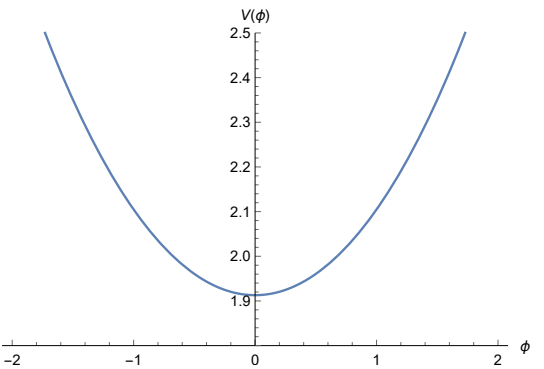

Fig. 2. Semiclassical polymer trajectory of the Universe volume $V=(V_1V_2V_3)^{1/3}$ as function of ϕ.

By taking general initial conditions according to (9), analytical solutions for the anisotropic volume coordinates can be gained. In particular, the Universe volume as function of ϕ reads as $V(\phi)=(V_1(\phi)V_2(\phi)V_3(\phi))^{1/3}$ and its behavior is shown in Fig. 2. The Big Bounce clearly appears as a polymer regularization effect instead of the classical Big Bang.

4.2. *Analysis in the volume variables:* (v,λ_1,λ_2)

In the new set of volume variables ($\lambda_i=\mathrm{sign}(p_i)\sqrt{|p_i|}$, $v=\lambda_1\lambda_2\lambda_3$) the Universe volume itself v is considered and $\eta_{1,2}=2\sqrt{p_{1,2}}c_{1,2}$, $\eta_3=2\sqrt{\frac{p_3}{p_1p_2}}c_3$ are the conjugate momenta. The Poisson brackets are conserved ($\{\eta_i,\lambda_j\}=\kappa\gamma\delta_{ij}$ for $i\neq j$, $i,j=1,2$ and $\{\eta_3,v\}=\kappa\gamma$) and the semiclassical polymer Hamiltonian takes the form

$$\mathcal{H}_{poly}=-\frac{1}{4\kappa\gamma^2V}\Big(\sum_{i=1,2}\frac{\lambda_i\sin(\mu_i\eta_i)v\sin(\mu_3\eta_3)}{\mu_i\mu_3}+\frac{\lambda_1\sin(\mu_1\eta_1)\lambda_2\sin(\mu_2\eta_2)}{\mu_1\mu_2}\Big)+\frac{p_\phi^2}{2V}=0, \tag{11}$$

where the canonical transformation has been performed before the implementation of the semiclassical polymer paradigm on the variables η_i, as in the previous subsection. Analogously, we derive the Hamilton equations for the couple of variables (v, η_3)

$$\begin{cases} \dfrac{dv}{d\phi} = -\dfrac{v\cos(\mu_3\eta_3)}{4\gamma p_\phi}\left[\dfrac{\lambda_1}{\mu_1}\sin(\mu_1\eta_1) + \dfrac{\lambda_2}{\mu_2}\sin(\mu_2\eta_2)\right] \\ \dfrac{d\eta_3}{d\phi} = \dfrac{\sin(\mu_3\eta_3)}{4\gamma\mu_3 p_\phi}\left[\dfrac{\lambda_1}{\mu_1}\sin(\mu_1\eta_1) + \dfrac{\lambda_2}{\mu_2}\sin(\mu_2\eta_2)\right] \end{cases} \tag{12}$$

and also for the conjugate variables (λ_1, η_1), (λ_2, η_2)

$$\begin{cases} \dfrac{d\lambda_i}{d\phi} = -\dfrac{\lambda_i\cos(\mu_i\eta_i)}{4\gamma p_\phi}\left[\dfrac{v}{\mu_3}\sin(\mu_3\eta_3) + \dfrac{\lambda_j}{\mu_j}\sin(\mu_j\eta_j)\right] \\ \dfrac{d\eta_i}{d\phi} = \dfrac{\sin(\mu_i\eta_i)}{4\gamma\mu_i p_\phi}\left[\dfrac{v}{\mu_3}\sin(\mu_3\eta_3) + \dfrac{\lambda_j}{\mu_j}\sin(\mu_j\eta_j)\right] \end{cases} \tag{13}$$

where we have used $N = \frac{V}{p_\phi}$ in order to derive the dynamics of the model in function of the relational time ϕ.

Once fixed the initial conditions on the variables (λ_1, η_1), (λ_2, η_2), (v, η_3) according to (11), we can solve this system analytically since the 3D-motion is decoupled in three one-dimensional trajectories, thanks to the use of constants of motion analogous to those ones of the previous cases. In particular, the analytical solution for the Universe volume $v(\phi)$ clearly resembles a bouncing behavior, as shown in Fig. 3. Also, by choosing a particular shape for these constants of motion, we find the following convenient form for the polymer-modified Friedmann equation of the Bianchi I model in the proper volume variables:

$$H^2 = \frac{\kappa}{54}\frac{p_\phi^2 + \bar{\mathcal{K}}^2}{v^2}\left[1 - \frac{4\kappa\gamma^2\mu^2}{3}\left(\frac{p_\phi^2 + \bar{\mathcal{K}}^2}{2v^2}\right)\right], \quad \bar{\mathcal{K}} = \frac{\mathcal{K}}{\sqrt{2\kappa\gamma^2}}, \tag{14}$$

where we have fixed $\mu_1 = \mu_2 = \mu_3 = \mu$ without loss of generality. In (14), the additional term $\bar{\mathcal{K}}^2/2v^2$ reasonably mimics the energy-like contribution of the

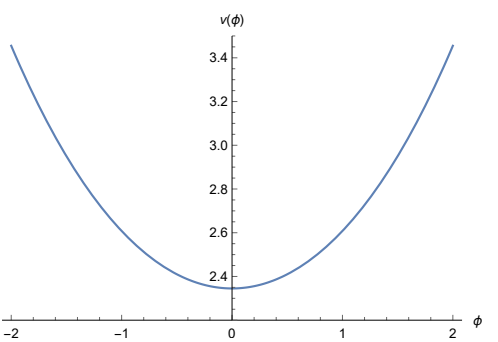

Fig. 3. Semiclassical polymer trajectory of the Universe volume $v(\phi)$.

anisotropies to the total energy density ($\mathcal{K}$ is an arbitrary constant) and the total critical energy density results to be

$$\rho_{crit}^{tot} = \frac{3}{4\kappa\gamma^2\mu^2}\,, \tag{15}$$

so it has universal features since it is independent from the initial conditions on the motion. By concluding, thanks to equation (14) we have inferred the physical properties of the critical point, showing that taking the Universe volume itself as a configurational variable makes the Big Bounce acquire universal physical properties.

5. QUANTUM ANALYSIS

The purpose of this section is studying the Bianchi I model in the Ashtekar variables at a quantum level by applying the Dirac quantization. Firstly, we perform an ADM reduction of the variational principle at a semiclassical level in order to deal with a Schrödinger-like formalism. More specifically, after choosing the scalar field ϕ as the temporal parameter, we derive the ADM-Hamiltonian by solving the scalar constraint (6) with respect to the momentum associated to the scalar field:

$$p_\phi \equiv \mathcal{H}_{ADM} = \sqrt{\Theta}\,, \quad \Theta = \frac{2}{\kappa\gamma^2}\sum_{i\neq j}\frac{\sin(\mu_i c_i)p_i\sin(\mu_j c_j)p_j}{\mu_i\mu_j}\,, \tag{16}$$

where $i,j = 1,2,3$. We choose the positive root in order to guarantee the positive character of the lapse function (see Sec. 3). Now we promote the ADM-Hamiltonian to a quantum operator, obtaining the following Schrödinger-like equation:

$$-i\partial_\phi\Psi = \sqrt{\hat{\Theta}}\Psi\,, \quad \sqrt{\hat{\Theta}} = \Big[\frac{2}{\kappa^2\gamma^2}\Big(\partial_{x_1}\partial_{x_2} + \partial_{x_1}\partial_{x_3} + \partial_{x_2}\partial_{x_3}\Big)\Big]^{1/2}\,, \tag{17}$$

where we have used the substitution $x_i = \ln\left[\tan\left(\frac{\mu c_i}{2}\right)\right] + \bar{x}_i$. The associated probability density is $\mathcal{P}(\vec{x},\phi) = \Psi^*(\vec{x},\phi)\Psi(\vec{x},\phi)$, where

$$\begin{aligned}\Psi(\vec{x},\phi) = \int_{-\infty}^{\infty} dk_1\,dk_2\,dk_3\prod_{i=1}^{3}\exp\left[-\frac{(k_i-\mu_{k_i})^2}{2\sigma_{k_i}^2}\right] \\ \times\, e^{i(k_1x_1+k_2x_2+k_3x_3+\sqrt{2|k_1k_2+k_1k_3+k_2k_3|}\phi)}\,.\end{aligned} \tag{18}$$

Now we can analyze the quantum dynamics of (18) by following the peak of the probability density $\mathcal{P}$ over time, in order to verify the consistency between the information carried by the quantum wave packet of the Bianchi I model and the semiclassical solutions provided in Sec. 3 when the Ashtekar variables are considered. In Fig. 4 some different sections of the probability density $\mathcal{P}$ at different values of ϕ are shown. As we can see, their spreading behavior over time is evident, as well as their gaussian-like shape. Also, in Fig. 5 the position of the peaks of $\mathcal{P}$ are represented by the red dots and have also been fitted by means of a linear interpolation. The resulting fitting functions are represented by the red dashed straight lines, while the semiclassical trajectories by the continuous straight ones. In particular,

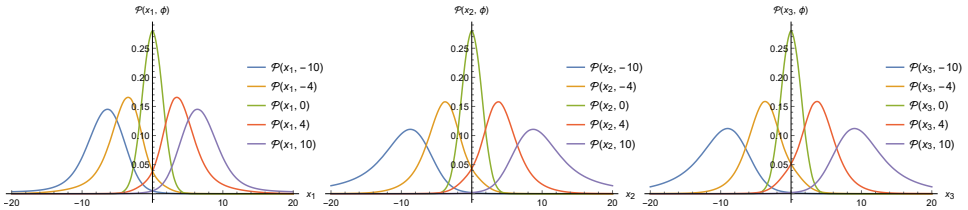

Fig. 4. The normalized sections $\mathcal{P}(x_i, \phi)$ are shown in sequence for $i = 1, 2, 3$ respectively at different times (here $\mu_{k_1} = \mu_{k_2} = \mu_{k_3} = 0, \sigma_{k_1} = \sigma_{k_2} = \sigma_{k_3} = 1/2$). Their spreading behavior over time is evident together with the gaussian-like shape.

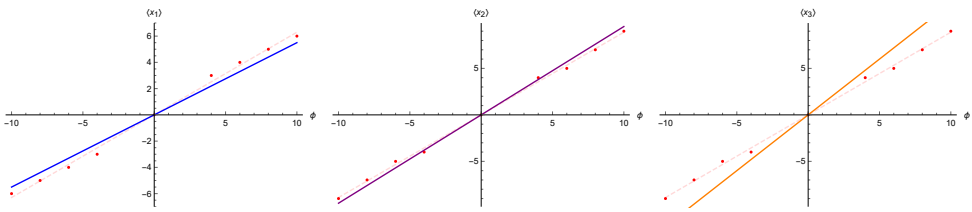

Fig. 5. The three pictures show the position of the peaks of $\mathcal{P}(x_i, \phi)$ for $i = 1, 2, 3$ respectively in function of time ϕ (red dots). The resulting fitting functions (red dashed straight lines) overlap the semiclassical trajectories (continuous lines) with a confidence level of three standard deviations.

the slope of the fitting straight lines is consistent with the semiclassical one with a confidence level of three standard deviations for all the three coordinates. Therefore, we conclude that there is a good correspondence between the quantum behavior of the Universe wave function and the solutions of the semiclassical dynamics.

6. CONCLUDING REMARKS

In this paper we analyzed the polymer semiclassical and quantum dynamics of the Bianchi I model with a massless scalar field in the Ashtekar variables and in two sets of volume-like ones. In the polymer semiclassical analysis we obtained a bouncing behavior in all the three sets of variables. Also, a polymer-modified Friedmann equation of the Bianchi I model has been derived when the Universe volume itself is considered as a configurational variable. This way, the proper expression of the total critical energy density has been provided, giving a complete picture of the Big Bounce and showing its universal features, *i.e.* its dependence from fundamental constants and parameters only. Finally, by performing an ADM reduction of the variational problem, we passed to a Schrödinger-like formalism and then we implemented the canonical quantization in the Ashtekar variables. In particular, the study of the probability density behavior has outlined a good correspondence between the dynamics of the quantum Universe wave packet and the corresponding semiclassical trajectories. In conclusion, due to the role of the Bianchi I model in constructing the general cosmological solution, this study acquires a great relevance in order to understand the properties of the primordial Universe.

A quantum state in a Bianchi II model is studied as it approaches the cosmological singularity, by means of the evolution of its moments. Classically this system presents a transition between two Bianchi I models. This phenomenon is described by a very specific and well-known transition law, which is derived based on the conservation of certain physical quantities. In the quantum theory fluctuations, as well as higher-order quantum moments, of the different variables arise. Consequently, these constants of motion are modified and hence also the transition rule. We focus on the so-called locally rotationally symmetric and vacuum case, as a first step towards a more complete study. Indeed, the future goal of this research line is to generalize this analysis to the Bianchi IX spacetime, which can be seen as a succession of Bianchi II models. Ultimately, these results will shed light on the role played by quantum effects in the BKL conjecture.

Keywords: Bianchi II; local rotational symmetry (LRS); quantum Bianchi spacetime; Bianchi transition.

1. Introduction

Close to a spacelike singularity, it is conjectured that the classical dynamics of any universe follows a chaotic behavior, according to Belinski-Khalatnikov-Lifshitz (BKL).[1] In this scenario, the dynamics of each point is decoupled from the rest and can be described by a Bianchi IX spacetime, which can be understood as a succession of Bianchi II models.[1] This model is much easier to analyze than the full Bianchi IX dynamics, and therefore provides a good first step to study the full BKL scenario. More precisely, as it was described in Misner's seminal work,[2] in the Bianchi II model the system undergoes a single transition between two Bianchi I models. However, close to the singularity quantum effects are expected to become relevant, and thus, in the present work we will analyze how they modify this classical transition.

2. Classical Model

A Bianchi II model is a type of spatially homogeneous but anisotropic four-dimensional spacetime. If we follow the usual 3+1 decomposition in order to describe

the model canonically, the vacuum Hamiltonian constraint of this system is found to be

$$\mathcal{C} = \frac{1}{2} e^{-3\alpha} \left(-p_\alpha^2 + p_-^2 + p_+^2 \right) + e^{\alpha - 8\beta_+} = 0, \tag{1}$$

where α describes the spatial volume and $\beta_\pm$ are the shape parameters that encode the spatial anisotropy of the spacetime. These are the so-called Misner variables and p_α and $p_\pm$ are their corresponding conjugate momenta. If α is chosen as the internal time, the physical Hamiltonian of the system takes the subsequent form:

$$H := \ -p_\alpha = \left(p_+^2 + p_-^2 + 2e^{4\alpha - 8\beta_+} \right)^{1/2}. \tag{2}$$

This is the most general vacuum description but, in order to further simplify the problem, we will remove one of the shape parameters by imposing $\beta_- = 0 = p_-$, which is known as the *locally rotationally symmetric* (LRS) case. Consequently, the Hamiltonian (2) is reduced to:

$$H = \left(p^2 + 2e^{4\alpha - 8\beta} \right)^{1/2}, \tag{3}$$

where, for compactness, $\beta := \beta_+$ and $p := p_+$ have been defined.

This model presents a singularity, even in the particular LRS case, precisely when $\alpha \to -\infty$. Hence, we will be interested in studying the evolution towards this limit. For this purpose, the first step is to obtain the equations of motion:

$$\dot{\beta} = \frac{p}{H}, \tag{4}$$

$$\dot{p} = \frac{8}{H} e^{4\alpha - 8\beta}, \tag{5}$$

where the dot represents the derivative with respect to the internal time α. From (4)-(5) we note that, when the exponential term $e^{4\alpha - 8\beta}$ is negligible, the equations of motion can easily be solved. Under such an assumption, p would be a constant of motion and, in this sense, the system would follow a free dynamics, whereas the shape-parameter β would be a linear function of α:

$$\beta = \text{sign}(p)\alpha + c, \tag{6}$$

with an integration constant c. During this period the system is equivalent to a LRS vacuum Bianchi I –or Kasner– solution. This Kasner regime is completely characterized by the values of the constants of motion p and c. As illustrated in Fig. 1 and Fig. 2, if we begin the evolution towards the singularity in one of these regimes, with $p > 0$ and at large values of α, the shape parameter β follows the linear behavior as given in (6) until the exponential term $e^{4\alpha - 8\beta}$ ceases to be negligible. At that point, a transition happens and the system enters in another Kasner regime.

In order to study this transition, a useful procedure is to exploit the conserved quantities of the system. The mentioned constants of motions are found to be the following:

$$R_1 := 2H - p, \tag{7}$$

$$R_2 := e^{2(\alpha+\beta)}(H - p). \tag{8}$$

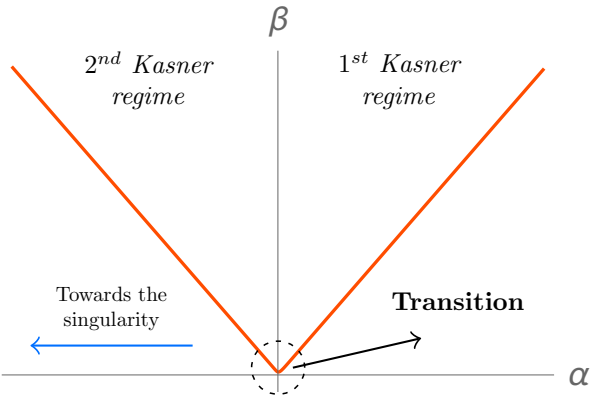

Fig. 1. Classical evolution of the variable β with respect to α, where $p > 0$ for large values of α and β.

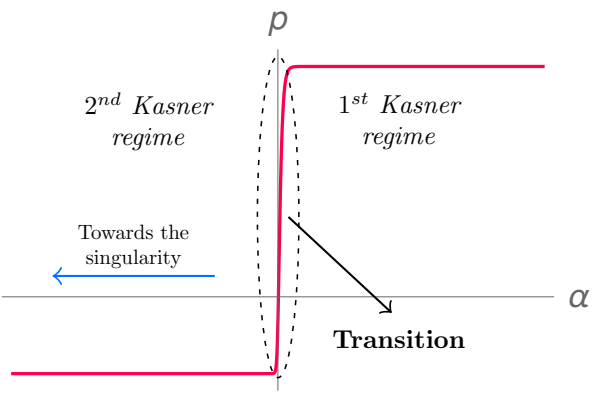

Fig. 2. Classical evolution of the variable p with respect to α, where $p > 0$ for large values of α and β.

If we evaluate these quantities in the initial and final states and equate them, we obtain a system of two equations, which relate the parameters of the first Kasner epoch $(\overline{c}, \overline{p})$ with those of the second one $(\widetilde{c}, \widetilde{p})$. Thus, after solving it we obtain the law that describes the transition between the two Kasner regimes, namely:

$$\widetilde{p} = -\frac{1}{3}\overline{p}, \tag{9}$$

$$\widetilde{c} = -3\overline{c} - \frac{1}{2}\ln\left(\frac{2}{3}\overline{p}^3\right). \tag{10}$$

3. Quantum Transition Rules

Once that we have provided a canonical description of the classical model, we are ready to develop the quantum analysis. The quantum dynamics is governed by the

following Hamiltonian operator, which is defined from the classical one and chosen to be Weyl-ordered, that is, with a totally symmetric ordering of the basic operators:

$$\hat{H}(\hat{p},\hat{\beta}) = \left(\hat{p}^2 + 2e^{4\alpha-8\hat{\beta}}\right)^{1/2}_{\text{Weyl}}. \tag{11}$$

Then, instead of studying the evolution of the wave function itself, we follow a formalism developed for quantum cosmology and quantum mechanics in general, which is based on the moment decomposition of the wave function.[4] Thus, according to this formalism, the system is fully described by the expectation values of the basic variables,

$$\beta := \langle\hat{\beta}\rangle, \quad p = \langle\hat{p}\rangle, \tag{12}$$

as well as the following infinite set of quantum moments:

$$\Delta(\beta^i p^j) := \langle(\hat{\beta}-\beta)^i(\hat{p}-p)^j\rangle_{\text{Weyl}} \quad (i,j\in\mathbb{N}). \tag{13}$$

The sum of the indices $i+j$ will be referred as the order of the corresponding moment. The evolution of these variables is ruled by a quantum effective Hamiltonian H_Q, that is defined as the expectation value of $\hat{H}$. By performing a Taylor expansion around the expectation values of $\hat{\beta}$ and $\hat{p}$, it can be written as the following infinite series:

$$\begin{aligned} H_Q &= \left\langle \hat{H}(\hat{p},\hat{\beta})\right\rangle \\ &= H(\beta,p) + \sum_{i+j=2}^{\infty} \frac{1}{i!j!}\frac{\partial^{i+j}H(\beta,p)}{\partial\beta^i\partial p^j}\Delta(\beta^i p^j), \end{aligned} \tag{14}$$

where $H(\beta,p)$ is the classical Hamiltonian (3). This effective Hamiltonian H_Q encodes the complete dynamical information of the system. Indeed, the equations of motion for the variables of the system –β, p and $\Delta(\beta^i p^j)$– are obtained by computing their Poisson brackets with H_Q:

$$\frac{d\beta}{d\alpha} = \{\beta, H_Q\} = \frac{\partial H_Q}{\partial p}, \tag{15}$$

$$\frac{dp}{d\alpha} = \{p, H_Q\} = -\frac{\partial H_Q}{\partial \beta}, \tag{16}$$

$$\begin{aligned} \frac{d\Delta(\beta^i p^j)}{d\alpha} &= \{\Delta(\beta^i p^j), H_Q\} \\ &= \sum_{m,n=0}^{+\infty} \frac{1}{m!n!}\frac{\partial^{m+n}H(\beta,p)}{\partial\beta^m\partial p^n}\{\Delta(\beta^i p^j), \Delta(\beta^m p^n)\}, \end{aligned} \tag{17}$$

where the Poisson brackets between expectation values are defined in the usual way in terms of the commutator, that is, $\{\langle\hat{A}\rangle, \langle\hat{B}\rangle\} := -i\langle[\hat{A},\hat{B}]\rangle/\hbar$. Let us emphasize

that this evolution of the variables is completely equivalent to that given by the Schrödinger picture in terms of the wave function.

We observe that the classical Hamiltonian H defined in (3) is not polynomial, which means that the series in (14) is indeed infinite and it is not truncated at certain order. Thus, the equations of motion (15)-(17) form an infinite system of coupled equations. Therefore, in order to study and compute the dynamics explicitly, a cut-off must be introduced. That is, we will consider all the moments of order higher than a certain value N to be vanishing:

$$\Delta(\beta^i p^j) \approx 0 \quad \text{for} \quad i + j > N. \tag{18}$$

In fact, such a truncation corresponds to considering a semiclassical regime, where the quantum state is peaked on a classical trajectory and hence the high-order moments are negligible.

However, even if we apply a cut-off, instead of solving the coupled system of equations for any value of α, we will focus on the so-called Kasner regimes, as we have done in the classical analysis. During these periods, the equations of motion take the form

$$\frac{d\beta}{d\alpha} \approx \text{sign}(p), \quad \frac{dp}{d\alpha} \approx 0, \quad \frac{d\Delta(\beta^i p^j)}{d\alpha} \approx 0, \tag{19}$$

which are immediate to solve:

$$\beta \approx \text{sign}(p)\alpha + c, \tag{20}$$

$$p \approx const., \tag{21}$$

$$\Delta(\beta^i p^j) \approx const., \tag{22}$$

with an integration constant c. Comparing these results with the classical ones, we observe that the behavior of p and β in these states remains identical in the quantum analysis. Moreover, the moments hold a constant value. In summary, the parameters that characterize each quantum Kasner epoch will be, as in the classical case, the constants c and p, along with the infinite constant set of moments $\Delta(\beta^i p^j)$. Then, in order to analyze the transition between two of these quantum Kasner regimes, we will once again exploit the constants of motion. In this quantum scenario, the conserved quantities are found to be the expectation values $\langle \hat{R}_1 \rangle$ and $\langle \hat{R}_2 \rangle$, where $\hat{R}_1$ and $\hat{R}_2$ are the operator counterpart of the classical conserved quantities (7) and (8). In fact, any of the following combinations is also a constant of motion:

$$\langle \hat{R}_i^n \hat{R}_j^m \rangle = const., \quad \text{for} \quad m, n \in \mathbb{N} \text{ and } i, j \in \{1, 2\}. \tag{23}$$

Nonetheless, as a technical subtlety, it must be mentioned that the choice of ordering of these operators is far from trivial: one must find the proper ordering so that they are conserved. Furthermore, at higher orders in moments, there may appear some terms that go with some explicit powers of $\hbar$. A more detailed discussion about these issues can be found in.[3]

Based on the classical results, we will consider that we have an initial Kasner regime characterized by the parameters $(\overline{c}, \overline{p}, \overline{\Delta(\beta^i p^j)})$ and that, as we approach the singularity, another such regime is reached described by the parameters $(\widetilde{c}, \widetilde{p}, \widetilde{\Delta(\beta^i p^j)})$. Hence, if we evaluate the constants of motion in these two states and equate them, we obtain a system of algebraic equations that relate the different parameters. After solving this system, we get the quantum transition law, which takes the following form:

$$\widetilde{p} = -\frac{1}{3}\overline{p}, \tag{24}$$

$$\widetilde{c} = -3\overline{c} - \frac{1}{2}\ln\left(\frac{2\overline{p}^2}{3}\right) + \sum_{n=2}^{N} \frac{(-1)^n}{n\overline{p}^n}\overline{\Delta(p^n)}, \tag{25}$$

$$\widetilde{\Delta(\beta^m p^n)} = \sum_{l=0}^{N-(m+n)} \sum_{k=0}^{m} \frac{a_{mnkl}}{\overline{p}^{m+l-k}} \overline{\Delta(\beta^k p^{m+n+l-k})} \tag{26}$$

$$+ \sum_{r=2}^{N-2} \sum_{k=0}^{m-1} \sum_{l=l_{min}}^{l_{max}} \frac{b_{mnklr}}{\overline{p}^{m+r+l-k}} \overline{\Delta(p^r)}\ \overline{\Delta(\beta^k p^{m+n+l-k})} + \sum_{k=1}^{\lfloor N/4 \rfloor} \frac{c_{mnk}}{\overline{p}^{2k-n}} \hbar^{2k},$$

where N denotes the order of the truncation. On the one hand, as can be seen from (24), the transition law for p remains identical as the classical one. However, we do obtain some quantum corrections for the transition law of β, as can be seen by comparing (10) with (25). Nevertheless, as expected, if all the moments are set to zero we recover the classical transition law. On the other hand, the transition law for the moments can be written in the compact form (26), with certain numerical coefficients a_{mnkl}, b_{mnklr} and c_{mnk}. Up to fifth order in moments, we have obtained the explicit expression of these coefficients and we refer the reader to[3] for the detailed expressions. If we analyze this formula in detail, we observe that it is linear in all of the moments except for some quadratic terms that contain pure moments of p. Moreover, regardless of the order of the truncation, there is a strong dependence on the index m of the shape parameter β of the corresponding moment. In particular, this index determines which initial moments will directly affect the value of a given final moment. For instance, the value of $\widetilde{\Delta(p^n)}$ (which corresponds to $m = 0$) only depends on the initial pure p-moments $\overline{\Delta(p^n)}$. Nevertheless, the value of $\widetilde{\Delta(\beta p^n)}$, that is $m = 1$, depends not only on pure p-moments, but also on $\overline{\Delta(\beta p^n)}$. In general, the value of the final moment $\widetilde{\Delta(\beta^m p^n)}$ will depend on the initial moments $\overline{\Delta(\beta^j p^i)}$ with $j \leq m$.

4. Quantum Dynamics

Once we have studied the asymptotic characteristics of this model in the Kasner regimes, we complete it by performing a numerical analysis to examine in detail its

dynamical evolution. For this purpose, we have chosen an initial Gaussian state, namely

$$\overline{\Delta(\beta^{2m}p^{2n})} = 2^{-2(m+n)}\hbar^{2m}\sigma^{2(n-m)}\frac{(2m)!(2n)!}{m!n!}, \tag{27}$$

for $\forall m, n \in \mathbb{N}$, and vanishing otherwise. As expected, the numerical study shows that starting from high values of α and evolving towards lower ones, the system follows the Kasner dynamics until it undergoes a transition, which happens near $\alpha = 0$. This transition takes place in a very small period of time and then the system reaches its final equilibrium value –the final Kasner regime– very quickly.

Regarding the evolution of the expectation values p and β, we remark that they remain almost identical as in the classical case, that is, as depicted in Fig. 1 and Fig. 2. In fact, only in a very close zoom into the transition (near $\alpha = 0$) we can appreciate a slight modification in their evolution: quantum effects slightly increase the value of p and β during the transition.

Moreover, the evolution of the moments show that during the initial Kasner regime they hold a constant value, at certain point they begin to perform strong oscillations and then quickly relax to their final constant value, which characterizes the coherent state during the final Kasner regime. The precise dynamics of the moments are quite complicate but, if we look into the transition in more detail, some general features can be detected. For instance, we remark that the higher the index of p, the earlier the moments reach their final equilibrium value. Furthermore, we observe that the lower the order of a given moment, the sooner it starts to oscillate and with a larger amplitude, which is in agreement with the semiclassical hierarchy of moments we are assuming. More specifically, at each given order the pure fluctuations of p show the biggest amplitudes. In addition, moments with at least one odd index, *i.e.*, the initially vanishing ones, present more oscillations.

It is particularly interesting to observe that the moments that were vanishing in the initial Kasner epoch –due to the choice of the Gaussian state– are not vanishing in the final one, due to the mentioned oscillations. This is indeed an expected outcome according to the transition laws (26). However, it means that even when we choose an initial state where there are no correlations between β and p, the transition will generate correlations for the final state. In particular, all the initial vanishing moments are activated in a similar way: as they approach the transition they experience an excitation and start to grow exponentially, until they begin to oscillate.

5. Conclusions

In summary, we have described the quantum LRS Bianchi II model making use of a decomposition of the wave function into its infinite set of moments. For the classical case, we have obtained the explicit constants of motion for the full dynamics, and thus we have completely integrated the equations of motion. For the quantum case,

making use of the conserved quantities (23), we have been able to obtain the exact quantum transition law for every variable (24)-(26) up to fifth-order in moments. Furthermore, by performing a numerical analysis of the model, we have studied the dynamical part of the evolution. In particular we have focused on the region where the transition takes place, and we have derived some general features of the behavior of the different variables. The follow-up of this work is to remove the LRS symmetry and to study the most general Bianchi II model. Then, the next step will be to extend the analysis to the full Bianchi IX model, and ultimately, to obtain the quantum corrections to the BKL transitions.

The hypercomplex medium as storage of physical equations

Alexander P. Yefremov

Institute of Gravitation and Cosmology, RUDN University,
6 Miklukho-Maklay Street, Moscow, 117198 Russian Federation,
E-mail: efremov-ap@rudn.ru
www.rudn.ru

Using the quaternion framework (Q-math), we show that the specific mathematical equations born in "quaternion medium" in physical units become known physical laws. In particular, it is shown how one can discover immanently hidden "geometric physical laws": Cartesian frames, equations of electrodynamics, Q-vector formulation of the relativity theory. One can also find the linked logical chain between laws of quantum, classical, and relativistic mechanics.

Keywords: Hypercomplex numbers; Quaternions; Fundamental equations.

1. Introduction: Hypercomplex Numbers

We draw attention to the mathematics of hypercomplex (HC) numbers, which, by analogy with differential geometry so fruitful for modern physics, can serve as an exceptionally rich environment. The HC math set comprises, first of all, four "good" algebras of real, complex, quaternion (Q) and octonion numbers; the Frobenius-Hurwitz theorem states that these are the fundamental division algebras admitting the identities of squares (Table 1).

Table 1. Classical "good" HC algebras

Algebra of numbers	Symbol	Number of units (real, imaginary)	Coefficients at units	Multiplication	Division, identity of squares
Real	R	$2^0 = 1$ (1, 0)	real	commutative, associative	+
Complex	C	$2^1 = 2$ (1, 1)	real	commutative, associative	+
Quaternion	Q, H	$2^2 = 4$ (1, 3)	real	non-commut., associative	+
Octonion	O	$2^3 = 8$ (1, 7)	real	non-commut., non-assoc.	+

"Close in spirit" algebras of "not good" HC numbers: double (perplex, split-complex), dual, biquaternion numbers (all having zero dividers) must be also mentioned here because their units can be structured similarly to the units of "good" numbers.

These sets of HC numbers, together with their adjacent domains (spinor elements and related groups), deserve to be considered not only as suitable or helpful mathematical instruments but also as an environment in which physical laws (once discovered empirically or heuristically) turn out to be immanently contained.

Without loss of generality here we make an accent on the still associative but non-commutative algebra of quaternion (Q-) numbers. Nonetheless, under the term "Q-math set" we imply the Q-numbers, biquaternion (BQ) numbers, specific Q-spinor set, and relevant invariance groups. Due to Heaviside and Gibbs with their palliative vector algebra, the Q-math set was unfairly abandoned in XX century though rarely emerging just as an exotic math tool (see e.g. Ref. 1). However, firstly incidental findings and later systematic investigations demonstrated that the Q-set contains many geometric images and equations closely related to fundamental physics. Here is a brief review of the revealed Q-math – physical coincidences.

2. First Physical Findings in Q-Math

Discovered by W.R.Hamilton in 1843, Q-numbers are built on one real scalar unit 1 (normally omitted in formulas), and three non-commuting imaginary vector units $\mathbf{i},\ \mathbf{j},\ \mathbf{k} \equiv \mathbf{q}_n$; coefficients at the units a, b_n are real

$$q = a + b_1 i + b_2 j + b_3 k \equiv a + b_n \mathbf{q}_n. \tag{1}$$

The multiplication law for the units has the form

$$\mathbf{q}_k \mathbf{q}_n = -\delta_{kn} + \varepsilon_{knj}\mathbf{q}_j, \quad 1 \cdot \mathbf{q}_n = \mathbf{q}_n \cdot 1, \tag{2}$$

$\delta_{kn}, \varepsilon_{knj}$ are 3D Kronecker and Levi-Civita tensors, index summation rule is implied. This algebra appeared to be near as "good" as that of complex numbers. With the definition of conjugation $\bar{q} = a - b_n \mathbf{q}_n$ a Q-number may be endowed the norm $\|q\| \equiv q\bar{q} = \bar{q}q = a^2 + b_n b_n$, then the algebra admits division $(q_2/q_1)_{left} = \bar{q}_1 q_2 / \|q_1\|$ (right and left as multiplication) and comprises the identity of four squares $\|q_1 q_2\| = \|q_1\|\,\|q_2\|$.

2.1. *Cartesian frame*

Hamilton was the first to realize that Q-imaginary units automatically behave like three vectors initializing an orthogonal frame which was empirically postulated by Descartes two hundred years before; in fact, this observation appeared to be the first Q-math – Physics coincidence. However, the scalar unit until recently had no clear geometric image (see below).

2.2. *Electrodynamics*

The next finding occurs a century later. Nearly abandoned quaternions (due to the predominance of the "vector algebra"), nonetheless had their faithful supporters. One of them Rudolf Fueter considered ways to build a theory of functions of quaternion variables. In 1937 he published a series of papers (e.g., Ref. 2) where a Cauchi-Riemann-type differentiability condition

$$d_u \mathbf{F} \equiv \left(\frac{i}{c}\frac{\partial}{dt} - \mathbf{q}_n \frac{\partial}{dx_n} \right) \mathbf{F} = 0 \tag{3}$$

for a vector BQ-function $\mathbf{F}(u) = (H_k + iE_k)\mathbf{q}_k$ of a BQ-variable $u = -ict + x_n\mathbf{q}_n$ was postulated. It was a great surprise to reveal that Eq. (3) written in the form of "imaginary" and "real" parts (in the C-algebra sense)

$$d_u\mathbf{F} = \underbrace{\frac{i}{c}\frac{\partial H_k}{\partial t}\mathbf{q}_k - i\frac{\partial E_k}{\partial x_k} + \frac{\partial E_k}{\partial x_n}\varepsilon_{knj}\mathbf{q}_j}_{\text{"imaginary" part}} + \underbrace{\frac{1}{c}\frac{\partial E_k}{\partial t}\mathbf{q}_k + \frac{\partial H_k}{\partial x_k} - \frac{\partial H_k}{\partial x_n}\varepsilon_{knj}\mathbf{q}_j}_{\text{"real" part}}$$

eventually (in the Q-algebra sense) decays into four real equations which exactly coincide with the vacuum Maxwell equations of electrodynamics.

2.3. *Pauli basis for Q-algebra*

Here we must recall one more event concerning Q-math non-directly, but very important. In 1927 Pauli suggested his mechanical equation for a charged quantum particle in an exterior magnetic field. To describe spin-magnetic field interaction he heuristically introduced three traceless 2×2-matrices with determinants equal to -1. Later analysis showed that these matrices multiplied by $-i$ together with the unit 2×2-matrix form a set of Q-units identically obeying the product rule (2)

$$1 = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},\ \mathbf{q}_1 = -i\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},\ \mathbf{q}_2 = -i\begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix},\ \mathbf{q}_3 = -i\begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \qquad (4)$$

It is important to note that representation (4) is the simplest one but not unique.

3. Form-Invariance of Q-Multiplication and Q-Spaces

Within the last three decades, the interest in Q-math has grown greatly; in current databases, one finds hundreds of relevant pure math investigations as well as Q-number links with physics (see e.g. Ref. 3). The first natural aspect of this research concerns the stability of the multiplication law (Eq. (2)) under changers of the imaginary (vector) Q-units $\mathbf{q}_n$, i.e., under changes of the geometry of the Q-frames. A simple analysis shows[4] that Eq. (2) keeps its form under transformations of the vector Q-units by the vector group SO(3,C) or by $1:2$ isomorphic to it the spinor (reflection) group SL(2,C)

$$\mathbf{q}_{n'} = O_{n'm}\mathbf{q}_m \to O \in SO(3,C); \quad \mathbf{q}_{n'} = U\mathbf{q}_n U^{-1} \to U \in SL(2,C). \qquad (5)$$

In general case each group has 6 independent parameters, implying natural isomorphism with the Lorentz group. Three real parameters just rotate the frame in the 3D space; three imaginary parameters perform respective hyperbolic rotations (though specific since only the 3D frame's vectors are involved).

The Q-units derivatives by the parameters Φ_ξ can be defined as

$$d\mathbf{q}_k(\Phi_\xi) = \omega_{\xi\,kn}\mathbf{q}_n\,d\Phi_\xi, \qquad (6)$$

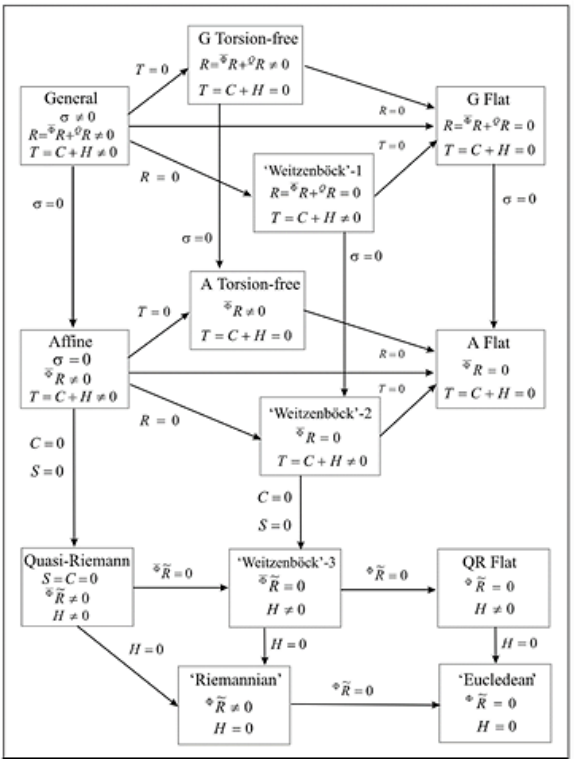

Fig. 1. Q-space of general type with full affine connection (Riemann + contortion + non-metricity) and full Q-connection (proper + Q-nonmetricity) generates at least 13 variants of different Q-spaces.

with $\omega_{\xi\,kn}$ being some coefficients skew in vector indices. If the parameters are functions of space-time coordinates x^{α}, then the Q-unit derivatives acquire the form

$$\frac{d\mathbf{q}_k}{dx^{\alpha}} = \frac{d\Phi_{\xi}}{dx^{\alpha}}\omega_{\xi\,kn}\mathbf{q}_n \equiv \Omega_{\alpha\,kn}\mathbf{q}_n; \tag{7}$$

$\Omega_{\alpha kn}$ can be associated with a connection of a specific vector space each point of which is an initial point of a Q-frame. This additional geometric property can be endowed to any space-time (e.g., already curved), thus making it a Q-enriched differential manifold with supplementary components of affine connection (therefore, curvature).[5]

For instance, apart from "standard" Riemann, Cartan, and non-metricity terms, the Q-space geometry can include respective proper Q-connection (giving zero curvature), Q-torsion, and Q-non-metricity. This gives a greatly wider scheme of the space geometry classification, hence greater possibilities to formulate generalized versions of relativistic theories of gravity comprising models with distributed polarized sources (Fig. 1).

4. Equations of Mechanics in Quaternion Frames

4.1. *Representation of Newton's dynamic equation in rotating Q-frames*

For real parameters $\Phi_\xi(t)$ of the subgroup $SO(3,R) \in SO(3,C)$ dependent only on time provide one gets a special type of the Q-connection components which in this case are physically equivalent to angular velocities of the Q-frame space rotations $\Omega_{kn} \equiv \dot{\Phi}_\xi \omega_{\xi\, kn}$. Together with the Q-vector form-invariance conditions $\mathbf{r} \equiv x_{\tilde{k}} \mathbf{q}_{\tilde{k}} = x_n\, \mathbf{q}_n$, $\mathbf{f} \equiv f_{\tilde{k}} \mathbf{q}_{\tilde{k}} = f_n\, \mathbf{q}_n$(specific force), this helps to rewrite "inertial" Newton's dynamic equation $\frac{d^2}{dt^2}\,(x_{\tilde{k}} \mathbf{q}_{\tilde{k}}) = f_{\tilde{k}}\, \mathbf{q}_{\tilde{k}}$ in an arbitrarily rotating Q-frame $\mathbf{q}_n(t)$

$$\ddot{\mathbf{r}} = \mathbf{f}. \tag{8}$$

The Q-vector components of Eq. (8) are

$$\ddot{x}_k + 2\dot{x}_n \Omega_{nk} + x_n \dot{\Omega}_{nk} + x_n \Omega_{nm} \Omega_{mk} = f_k; \tag{9}$$

its form in the traditional vector notations is

$$\ddot{\mathbf{r}} + 2[\mathbf{\Omega} \times \mathbf{v}] + [\dot{\mathbf{\Omega}} \times \mathbf{r}] + [\mathbf{\Omega} \times [\mathbf{r} \times \mathbf{\Omega}]] = \mathbf{f}.$$

Equation (8) fits for any arbitrarily complex rotations of the reference system; in particular, it describes very well the dynamics of bodies observed from the so-called chasing frames.[4]

4.2. *BQ-vector version of the theory of relativity*

Full group $SO(3,C)$ preserve form-invariance of the following "time + space" BQ-vector

$$dz = (idt\, e_k + dx_k)\, \mathbf{q}_k, \quad e_k e_k = 1, \quad e_k dx_k = 0, \tag{10}$$

which can be regarded as a specific "quaternion square root" from the space-time interval of special relativity $dz^2 = dt^2 - dr^2$. This gives a chance to build a specific BQ-vector relativity theory (Fig. 2), with the basic correlation given by Eq. (10) and the generalized "rotational equation"

$$\Sigma' = O\, \Sigma, \quad \Sigma \equiv \{\mathbf{q}_k\}, \quad O \in SO(3,C);$$

this "rotational relativity" gives all effects of Einstein's Special Relativity, but a different model of the universe, which in this case is (3+3)D. However, the most suitable (and fruitful) theory is for solving problems with non-inertial frames, directly giving solutions for the so-called hyperbolic motion, Thomas precession, linear relativistic oscillator, and relativistic shift of planets' satellites.[6,7] As well, this theory straightly admits a format of Newton-type dynamic equation for relativistic particles.[8]

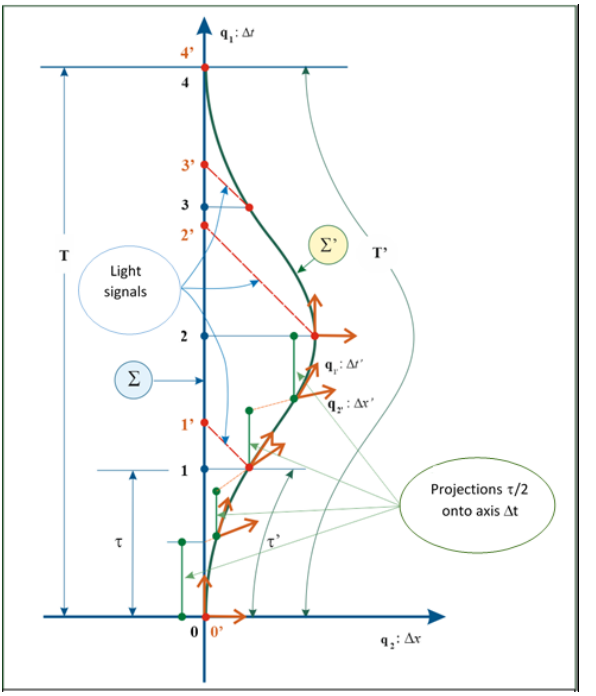

Fig. 2. Minkowski diagram for relativistic harmonic oscillator (1 cycle).

5. Q-Math Version of Pregeometry and a Matrix Image of the Complex Number

In search for the nature of quantum physics, J. A. Wheeler heuristically suggested a concept of pregeometry which "breaks loose all mention of geometry and distance".[9]

5.1. *Spectral theorem and fractal surface "under 3D Q-geometry"*

Within Q-math this concept of pregeometry can be in a way associated with a specific fractal surface (with dimensionality 1/2), being a type of subspace of 3D geometric space generated by Q-triad $\mathbf{q}_n$ (Fig. 3).

An area of the fractal surface (2D-cell) is formed by two vectors, a dyad, which originates as a bi-orthogonal basis of vectors $\{\psi^+,\ \psi^-\}$ and convectors $\{\varphi^+,\ \varphi^-\}$ within the framework of the spectral theorem since vector Q-units can be represented as simple non-degenerate matrices. In particular, the fractal dyad vectors may appear as right and left eigenvectors of one vector Q-unit. Unexpectedly it turned out that all four quaternion units are, in fact, structured, since they can be built from only one set of a Q-unit's eigenvectors (and co-vectors) as bilinear tensor

products

$$\mathbf{q}_1 = -i(\psi^+\varphi^+ + \psi^-\varphi^-), \quad \mathbf{q}_2 = \psi^+\varphi^- - \psi^-\varphi^+,$$
$$\mathbf{q}_3 = i(\psi^+\varphi^+ - \psi^-\varphi^-); \quad 1 = \psi^+\varphi^+ + \psi^-\varphi^-. \tag{11}$$

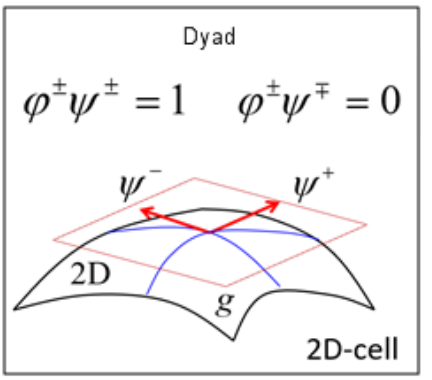

Fig. 3. A fractal surface domain.

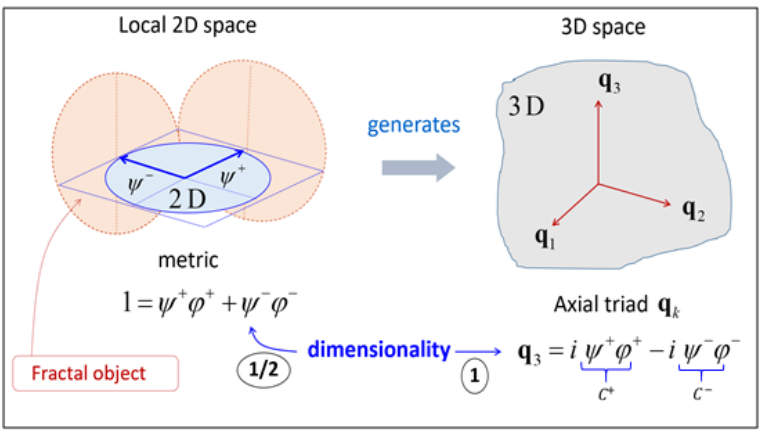

Fig. 4. Elements of a fractal surface generate volume of 3D space.

The first three equalities of Eq. (11) state that a domain of the 3D space formed by axial vector Q-triad $\mathbf{q}_n$ is a composed structure whose elements are vectors $\{\psi^+, \psi^-\}$ and convectors $\{\varphi^+, \varphi^-\}$ forming a local area of the fractal surface. Thus, the local volume of three-dimensional space associated with the triad of unit quaternionic axial vectors is, in fact, a derived geometric object, the true elements

of which are two vectors (co-vectors) of the fractal dyad. It is possible to say that an invisible 2D fractal space (a pre-geometric surface) generates a 3D geometric space (Fig. 4).

In its turn, the last equality of Eq. (11) demonstrates that the scalar unit, in this case, the unit diagonal 2×2-matrix (in Cartesian components)

$$\psi^{+(A)}\psi^{+}{}_{(B)} + \psi^{-(A)}\psi^{-}{}_{(B)} = \delta^{A}_{B}$$
$$\Rightarrow \begin{pmatrix}0\\1\end{pmatrix}(0\ 1) + \begin{pmatrix}1\\0\end{pmatrix}(1\ 0) = \begin{pmatrix}0\ 0\\0\ 1\end{pmatrix} + \begin{pmatrix}1\ 0\\0\ 0\end{pmatrix} = \begin{pmatrix}1\ 0\\0\ 1\end{pmatrix} = 1,$$

is nothing but metric tensor of the fractal surface; thus, the scalar unit may be said to acquire its not geometric but pregeometric meaning.

Another significant observation in this context is that it is precisely due to the structural decomposition of Q-units in Eq. (11) that the law of multiplication of the Q-algebra keeps its form under $SL(2, C)$ transformations. In this case, each dyad vector (co-vector) is subject to a direct $\psi' = U\psi$ (inverse $\varphi' = \varphi U^{-1}$) transformation of this group or its subgroup.

5.2. *Conic-gearing model of the complex number*

One of the pure math consequences of the existence of the Q-unit's structure is the appearance of an original matrix model of the complex number previously imaged on the complex plane or the Riemann sphere.[10]

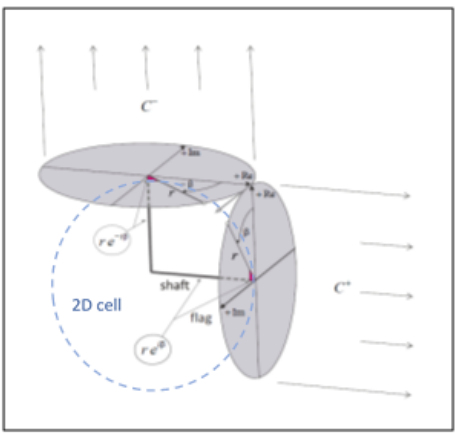

Fig. 5. C-number as a conic-gearing couple on a 2D-cell.

Indeed, if only two units are in the game (e.g., 1, $\mathbf{q}_3$), then any complex number can be represented as $z = x + iy \equiv x \cdot 1 + y \cdot \mathbf{q}_3$, $a, b \in R$; this number belongs to the C-algebra commutative in multiplication. Applying to the units the decomposition

in Eq. (11) one gets

$$z = (x + iy)\psi^+\varphi^+ + (x - iy)\psi^-\varphi^-.$$

This number can be rewritten in the polar coordinates

$$z = r\left(e^{i\beta}C^+ + e^{-i\beta}C^-\right), \tag{12}$$

here $C^\pm \equiv \psi^\pm\varphi^\pm$ are the projectors, idempotent, and mutually orthogonal matrices. Equation (12) has a clear geometric image. It models a type of conic-gearing couple, one gear orthogonal to another touching in a point (Fig. 5). Each gear has the shaft equal to r; a rotation of one gear by angle β forces another one to rotate by the angle $-\beta$. This picture conformally changes with the change of the number's modulus. Besides, its projectors C^+ and C^- determine the same orthogonal directions as the dyad vectors ψ^+ and ψ^-, so, in a way this model can be used to visualize the behavior of a 2D-cell under variations of the phase angle. Below we use it in this sense.

6. "General Theory of Particle Mechanics"

6.1. *Q-algebra stability under transformations of the fractal structure*

The next question to answer is which transformations of a fractal surface leave the algebra validity. The simplest mapping is a multiplication of the initially constant dyad by an arbitrary complex number

$$\Psi^+ = \lambda\,\psi^+, \quad \Psi^- = \lambda^*\psi^-; \quad \lambda \equiv \sigma e^{i\alpha} \tag{13}$$

thus, introducing the phase change α and the 2D-cell's conformal stretching factor σ (Fig. 6). Under mapping (13) new 3D vectors (and the scalar too) built according to the pattern (11) lose their property of unity, e.g., $\Psi^+\Phi^+ + \Psi^-\Phi^- = \lambda\lambda^*(\psi^+\varphi^+ + \psi^-\varphi^-) \neq 1$.

To cure the algebra, we, first, assume that the mapping parameters are functions of a scalar θ and coordinates ξ_n of an abstract math phase $\alpha(\theta, \xi)$, $\sigma(\theta, \xi)$, then define a normalizing integral over a volume of the space

$$f(\theta) \equiv \int_V \lambda\lambda^*\, d^3\xi = 1, \tag{14}$$

and finely, renormalize new vectors and the scalar, e.g., as $1' = f(\theta)\,(\psi^+\varphi^+ + \psi^-\varphi^-) = 1$. Further on, we demand that this normalization last "forever" (in the sense of parameter θ)

$$\partial_\theta \int_{V_\xi} \lambda\lambda^* dV_\xi = 0; \tag{15}$$

this gives a differential condition of the algebra stability (a continuity-type equation)

$$\partial_\theta(\lambda\lambda^*) + \nabla(\lambda\lambda^*\mathbf{k}) = 0; \tag{16}$$

with $\mathbf{k}$ being a 3D vector. We can choose this vector arbitrarily.

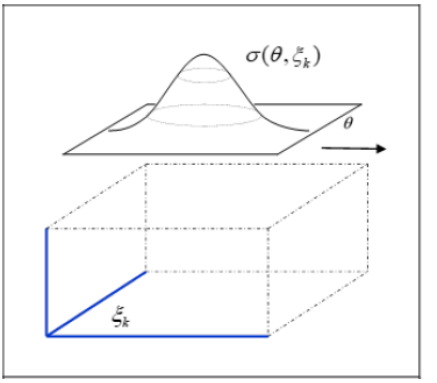

Fig. 6. σ-factor over an abstract space.

6.2. *Quantum mechanics*

If the free vector indicates the direction of the phase increase (behaves as a propagator) $k_n = \partial_n \alpha$, then the algebra stability condition given by Eq. (16) fractalizes and acquires the form

$$\left[\partial_\theta - \frac{i}{2}\left(\partial_n \partial_n - 2W\right)\right]\lambda \; = 0, \tag{17}$$

where W is an arbitrary scalar function. All magnitudes and operators entering Eq. (17) are pure mathematical (abstract), hence, measured in no units. It is natural to introduce micro-world units' standards, e.g., the Compton length $\varepsilon \equiv \hbar/(mc)$ and respective time $\tau \equiv \hbar/(mc^2)$. Then the abstract coordinates and scalar parameter are transformed as $\xi_n \to x_n/\varepsilon,\ \theta \to t/\tau$ and the fractal algebra stability condition in Eq. (17) takes the precise form of the Schrodinger equation

$$\left(i\hbar\,\partial_t + \frac{\hbar^2}{2m}\nabla^2 - U(x_n,t)\right)\lambda = 0 \tag{18}$$

the free function acquiring the meaning of the potential energy $U \equiv mc^2 W$.

In a more complex case, the propagator can depend also on a vector field $k_n = \partial_n \alpha + A_n$, this requires the use of the matrix dyad (e.g., of positive parity $\varphi,\ \psi$) and the Clifford-type metric $g_{mn} \equiv (\mathbf{p}_m \mathbf{p}_n + \mathbf{p}_n \mathbf{p}_m)/2$, $\mathbf{p}_k \equiv i\mathbf{q}_k$. Then the continuity-type stability condition takes the form $\partial_\theta(\varphi\psi) + g_{mn}\partial_m[\varphi\psi\,(\partial_n\alpha + A_n)] = 0$, while its fractal mathematical version is

$$\left[i\partial_\theta - \frac{1}{2}(-i\partial_k + A_k)(-i\partial_k + A_k) - \frac{1}{2}\mathbf{p}_k B_k - W\right]\psi = 0, \quad B_n \equiv \varepsilon_{kmn}\partial_k A_m; \tag{19}$$

written in physical units (on the base of the micro-world units' standards) Eq. (19) becomes exactly the Pauli equation for quantum-mechanical charged particle in the exterior magnetic field.[11] Thus, investigation of fractal pregeometry helps to deduce the basic quantum mechanical equations purely out of mathematical considerations.

6.3. *Non-static solution for H-atom*

The suggested approach hints to look for non-standard solutions to the quantum mechanical equation. As an example, we mention a non-static solution for the hydrogen atom where instead of Schrodinger's static ansatz for the wave function $\lambda = \sigma(r)e^{-\alpha(t)}$ a stationary function is assumed: $\lambda = \sigma(r,t)e^{i(k\varphi-\omega t)}$, with the same Coulomb potential $U = q^2/r$. In this case, the quantization follows from the normalization condition (so that no special cutting of a series is needed), while the result of the quantization precisely gives formulas of the Bohr H-atom heuristic model $m\,\Omega_n r_n^2 = n\hbar$, $\Omega_n = 2\omega/n = mq^4/(2n^2\hbar^3)$. In this stationary solution, the electron is not a point; its density is harmonically distributed along a circular orbit, and this configuration revolves around the nucleus with a constant angular velocity.[12]

6.4. *From quantum to analytical mechanics*

Decomposition of the math Schrodinger equation (Eq. (17)) into real and imaginary parts leads to a couple of the Bohm-type equations,[13] the first one providing conservation of the conformal factor $\partial_\theta\sigma + \partial_k\sigma\,\partial_k\alpha + \sigma\,\partial_k\partial_k\alpha = 0$, the second (more complicated) dealing with the "phase dynamics"

$$\partial_\theta\alpha + \frac{1}{2}\,(\partial_n\alpha)\,(\partial_n\alpha) + W_{\rm ex} + W_{\rm int} - \frac{1}{2}\partial_n\partial_n\sigma/\sigma = 0. \tag{20}$$

Separation functions of Eq. (20) into fast (σ, $W_{\rm int}$) and slow ones (α, $W_{\rm ex}$) gives a Helmholtz-type equation for the interior distribution of the σ-factor "density" onto the 2D-cell surface, while the "slow" equation

$$\partial_\theta\alpha + \frac{1}{2}\,(\partial_n\alpha)\,(\partial_n\alpha) + W_{\rm ex} = 0 \tag{21}$$

in the physical units and under assumption $S = \alpha\,\hbar$ takes the exact form of the Hamilton-Jacobi equation of the analytical mechanics

$$\partial_t S + \frac{(\partial_n S)(\partial_n S)}{2m} + U_{\rm ex} = 0, \quad U_{\rm ex} = mc^2 W_{\rm ex}. \tag{22}$$

Thus, the classical action function can be shown directly linked to the fractal 2D-cell's phase measured in values of Planck constant. Then, using evident math steps, we automatically arrive at the Lagrangian format (kinematic energy minus potential energy) heuristically handpicked for the Newtonian dynamics.[14] In this approach, an elementary object of mechanics, a particle, turns out to have two images (Fig. 7), a fractal one – a 2D-cell loaded with a fractal mass density and oscillating within its real and complex sectors, and a geometric one – a point-like massive particle rotating about one 3D-axis with the angular velocity twice greater in modulus than the angular frequency of the 2D-cell's oscillation.

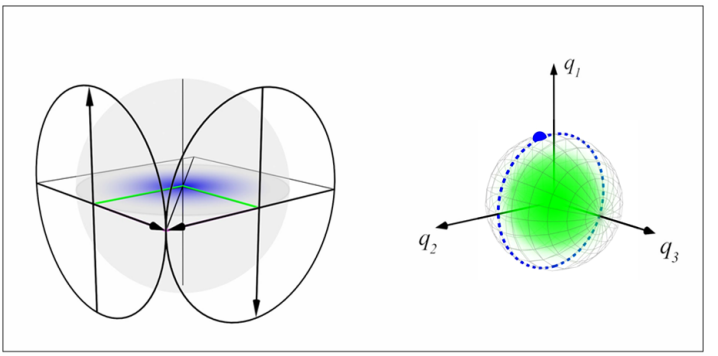

Fig. 7. Particle's 2D and 3D models.

6.5. *From analytical to relativistic mechanics*

The last model leads to an original derivation of the action function for the classical relativistic particle. We consider a point-like object of the characteristic size ε (length standard) moving in 3D space with velocity u and rotating about one axis with angular velocity Ω (twice as great as its 2D-cell analog's oscillation frequency), see Fig. 8.

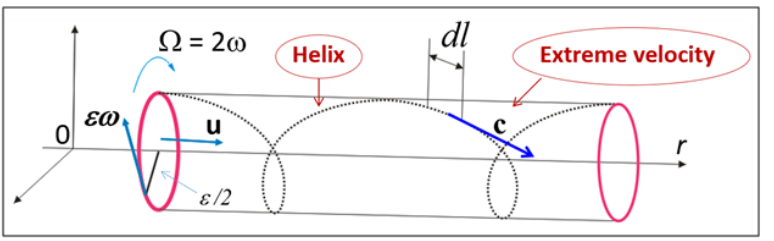

Fig. 8. Derivation of the action function for a relativistic particle.

A bordering point of this object, hence, depicts in the space a helix line; the only assumption for this model is that the velocity modulus of the bordering point is always equal to the fundamental velocity c. We compute a square of the helix' line element

$$dl^2 = c^2 dt^2 = \varepsilon^2 d\alpha^2 + u^2 dt^2$$

and find from here the phase change for the time interval $[t_1, t_2]$

$$\alpha = \pm \frac{c}{\varepsilon} \int_{t_1}^{t_2} \sqrt{1 - \frac{u^2}{c^2}}\, dt, \tag{23}$$

the signs indicate the right or left helicity. Choosing the sign minus (left helicity) and taking into account the correlation $\alpha = S/\hbar$ we rewrite Eq. (23) in the physical units to obtain

$$S = \alpha\,\hbar = -mc^2 \int_{t_1}^{t_2} \sqrt{1 - \frac{u^2}{c^2}}\, dt, \tag{24}$$

which precisely coincides with the mechanical action of the relativistic particle (previously introduced heuristically). It can be shown that reduction of Eq. (24) (written in differential form) to the non-relativistic case automatically establishes relations between classical and quantum quantities, thus linking the free particle 2D model as a De Broglie wave, the particle's rest energy linked to the permanent oscillation of the 2D cell.

6.6. *The map of the general theory of particle mechanics*

Thus, a profound investigation of the Q-math environment helps to distinguish in it a series of pure mathematical equations similar in the form to those merging from the physical experiment or found by great researchers "in a flash of a genius". Written in proper physical units these equations become the undisputed laws of quantum, classical and relativistic mechanics. The logical chain of this "general theory of particle mechanics" can be represented in the form of the following schematic map (see Fig. 9).

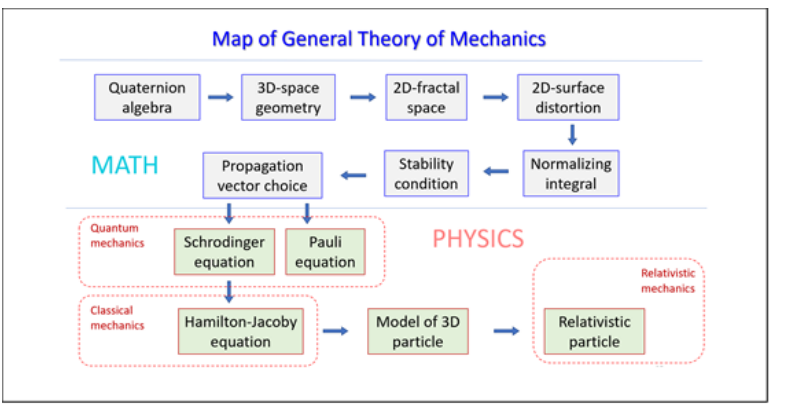

Fig. 9. Map of general theory of mechanics.

7. Conclusion and Perspectives

We demonstrated that the specific mathematical equations born in "quaternion medium" in physical units become known physical laws; briefly we remind the results. Q-math environment comprises 3D geometric and 2D pre-geometric (fractal)

domains. In the geometric domain, one discovers immanently hidden "geometric physical laws": Cartesian frames, equations of electrodynamics, Q-vector version of the relativity theory ("Rotational Relativity") giving the same effects as the special relativity. In the fractal domain, one finds the linked logical chain laws of quantum mechanics, classical mechanics, and relativistic mechanics. These coincidences are hardly incidental; moreover, they suggest new ways to move the theory ahead.

Among possible directions, one can pay attention to the following (at least three) aspects. (i) Coupling affine differential manifold with the rotational relativity gives a chance to build a new type of Q-vector gravity. (ii) Such a gravity model is known to be naturally split into spinor-type structures[15] which can reconcile relativistic gravity with quantum physics. (iii) Gauge fields, in particular, electromagnetic and Yang-Mills potentials seem to be promising objects to investigate their geometric and fractal structures within Q-math medium approaches.

The Maxwell-Bopp-Landé-Thomas-Podolsky-Einstein system for a static point source

Érik Amorim
Department Mathematik, Universität zu Köln,
Cologne, Germany
E-mail: edeamori@math.uni-koeln.de

We discuss the existence of a static, spherically symmetric spacetime that is the solution of the Einstein field equations coupled with an electric field obeying the equations of electromagnetism of Maxwell-Bopp-Landé-Thomas-Podolsky for a static point charge. Contrary to what happens with the Reissner-Weyl-Nordström spacetime, the electric field energy is finite, just as for this same theory on a background flat spacetime.

Keywords: Bopp-Podolsky, Field self-energy

1. Introduction

The problem of the *self-force* in electrodynamics consists of finding an expression for the force that the electromagnetic field generated by a charged point particle exerts on the particle itself. The possibility to write well-posed classical systems of equations for the joint evolution of electromagnetic (EM) fields and their sources, without resorting to *ad hoc* field averaging or bare mass renormalization at point charges, requires working with laws of electromagnetism such that the energy-momentum density of the electromagnetic field generated by charged particles is locally integrable, which is not the case for the usual Maxwell equations. There are generalized EM theories that were proposed specifically to address this problem, one of them being the so-called *Bopp-Podolsky* theory, which we will call **Bopp-Landé-Thomas-Podolsky** or **BLTP** theory. Using this theory, Kiessling and Tahvildar-Zadeh[1] have recently shown how to formulate a well-posed system for the joint evolution of point particles and their EM fields in *flat-space*, that is, the Minkowski spacetime of Special Relativity. Local integrability of the field energy-momentum at the location of the particles is essential in their work, hence why it is important to work with generalizations of the usual Maxwell equations. But the non-linearities in the Einstein field equations pose serious obstacles to generalizing this study to the theory of General Relativity.

The present work is a small first step towards extending this framework to General Relativity. It reports on a recent result by the author from his PhD thesis (Ref. 2) concerning the existence of a finite-energy solution to the Einstein equations for the spacetime of a single, static point charge whose electric field obeys the equations in Bopp-Podolsky theory.

2. Problem description

The usual Maxwell equations or **Maxwell-Maxwell system** for the EM fields $\boldsymbol{E}, \boldsymbol{B}, \boldsymbol{D}, \boldsymbol{H}$ of a static point particle of charge Q sitting at position $\boldsymbol{x} = 0$ in flat-space consists of the **pre-metric Maxwell equations**

$$\begin{cases} \nabla \cdot \boldsymbol{B} = 0 \\ \nabla \times \boldsymbol{E} + \dfrac{1}{c}\dfrac{\partial \boldsymbol{B}}{\partial t} = 0 \end{cases} , \qquad \begin{cases} \nabla \cdot \boldsymbol{D} = 4\pi Q \delta_0 \\ \nabla \times \boldsymbol{H} - \dfrac{1}{c}\dfrac{\partial \boldsymbol{D}}{\partial t} = 0 \end{cases} , \tag{1}$$

where δ_0 is the Dirac Delta, together with the **Maxwell vacuum law**, which specifies $\boldsymbol{D} = \boldsymbol{E}$ and $\boldsymbol{H} = \boldsymbol{B}$. Upon solving this system, one finds $\boldsymbol{B} = \boldsymbol{H} = \boldsymbol{0}$ and

$$\boldsymbol{D}(\boldsymbol{r}) = \boldsymbol{E}(\boldsymbol{r}) = -\varphi'(r)\boldsymbol{e}_{\boldsymbol{r}} = \frac{Q}{r^2}\boldsymbol{e}_{\boldsymbol{r}} \ ,$$

for $r = \|(x, y, z)\| = \|\boldsymbol{r}\|$ and $\boldsymbol{e}_{\boldsymbol{r}} = r^{-1}\boldsymbol{r}$, and where the *electric potential* φ is the so-called *Coulomb potential*

$$\varphi(r) = \frac{Q}{r} \ .$$

But plugging these fields into the standard integral formula for the electric field energy (set $\varkappa^{-2} = 0$ in (4) and (5) ahead) produces an integral that diverges at the location $\boldsymbol{x} = 0$ of the point charge.

In the 1940's, a modification of the above system was proposed. We call it the **Maxwell-BLTP** system, in honor of its original proponents Bopp,[3] Landé and Thomas,[4] and Podolsky.[5] The pre-metric equations (1) remain the same, but the **BLTP vacuum law** stipulates a modified relation between the electric and magnetic fields:

$$\begin{cases} \boldsymbol{D} = \boldsymbol{E} - \varkappa^{-2}\Box \boldsymbol{E} \\ \boldsymbol{H} = \boldsymbol{B} - \varkappa^{-2}\Box \boldsymbol{B} \end{cases} \tag{2}$$

where $\Box = -c^{-2}\partial_t + \Delta$ is the wave operator and $\varkappa > 0$ is a postulated large parameter of Nature with dimension of inverse length. Note that $\varkappa = \infty$ recovers the Maxwell-Maxwell system. The solution of (1) and (2) has $\boldsymbol{B} = \boldsymbol{H} = \boldsymbol{0}$ and

$$\boldsymbol{D}(\boldsymbol{r}) = \frac{Q}{r^2}\boldsymbol{e}_{\boldsymbol{r}} \ , \quad \boldsymbol{E}(\boldsymbol{r}) = -\varphi'(r)\boldsymbol{e}_{\boldsymbol{r}} \ ,$$

for the electric potential being

$$\varphi(r) = \frac{Q(1 - e^{-\varkappa r})}{r} \ . \tag{3}$$

We remark that φ is continuous at $r = 0$ and everywhere bounded. The exponential term in it is a small correction to the Coulomb potential for large values of r, while also ensuring that $\varphi(r)$ remains bounded for small r. The field energy density, which in this static case works out to be

$$\varepsilon_{\text{BLTP}} = \frac{1}{8\pi}\left(\boldsymbol{E} \cdot \boldsymbol{D} - \frac{1}{2}(|\boldsymbol{E}|^2 - \varkappa^{-2}(\nabla \cdot \boldsymbol{E})^2)\right) \ , \tag{4}$$

yields a finite value for the total field energy $\mathcal{E}$ when integrated:

$$\mathcal{E} := \int_{\mathbb{R}^3} \varepsilon_{\mathrm{BLTP}} \, \mathrm{d}V = \frac{Q\varphi(0)}{2} = \frac{Q^2 \varkappa}{2} \ . \tag{5}$$

Now suppose we "switch on gravity," that is, we seek solutions of the Einstein field equations of General Relativity for a static, spherically symmetric spacetime with a naked timelike singularity representing a single point charge at rest. The underlying manifold is $\mathbb{R}^4$ minus a line, with a global spherical coordinate system (ct, r, θ, ϕ). This universe is devoid of matter away from the particle, but the latter generates electromagnetic fields that can be calculated at any point and contribute to the stress-energy tensor $T_{\mu\nu}$, which is the source term in the Einstein equations. In the case of EM theories arising from a Lagrangian, which is the case for both the Maxwell-Maxwell and Maxwell-BLTP theories, one calculates $T_{\mu\nu}$ via the standard procedure of considering variations of the matter action with respect to the metric. A globally defined electric potential $\varphi(r)$ satisfying $\lim_{r\to\infty} \varphi(r) = 0$ enters this long calculation and must be considered an unknown of the system. We refer the reader to Ref. 2 for the details. The other two unknowns of the problem appear in the metric, which can be written in the general form

$$\mathrm{d}s^2 = -c^2 \frac{\psi(r)}{\zeta(r)} \mathrm{d}t^2 + \zeta(r) \mathrm{d}r^2 + r^2(\mathrm{d}\theta^2 + \sin^2\theta \mathrm{d}\phi^2) \ ,$$

where r is the area-radius coordinate and $\psi(r), \zeta(r)$ are unknown. In order for the spacetime to be asymptotically flat away from the singularity, we look for solutions satisfying

$$\lim_{r\to\infty} \psi(r) = \lim_{r\to\infty} \zeta(r) = 1 \ . \tag{6}$$

In place of φ, we will consider as the third unknown of the problem the function

$$w(r) := \frac{r^2 \varphi'(r)}{\psi(r)} + Q \ . \tag{7}$$

One can think of w as measuring how much the electric potential deviates from the Coulomb potential. Physically meaningful solutions should satisfy

$$\lim_{r\to\infty} w(r) = 0 \tag{8}$$

so that the laws of EM away from the point charge become the usual Maxwell laws.

Using the Lagrangian of the Maxwell-Maxwell theory in the above framework, it is well-known that the solution of the Einstein equations is the *Reissner-Weyl-Nordström solution*, which we abbreviate as **RWN solution**:

$$\psi^{(\mathrm{RWN})}(r) = 1 \ , \quad \zeta_M^{(\mathrm{RWN})}(r) = \left(1 - \frac{2GM}{c^2 r} + \frac{GQ^2}{c^4 r^2}\right)^{-1} \ , \quad w^{(\mathrm{RWN})}(r) = 0 \ ,$$

with G being the gravitational constant and M a free parameter that turns out to be the *ADM mass* of the spacetime. However, just like in flat-space, it can be calculated from the stress-energy tensor that the electric field energy integral (set

$\varkappa^{-2} = 0$ in (11) ahead) diverges around the singularity. This means that the field self-energy of the particle is infinite.

Using instead the Lagrangian of the Maxwell-BLTP theory, the Einstein equations reduce to the **Maxwell-BLTP-Einstein system**. In units where $c = Q = \varkappa = 1$, it reads

$$\begin{cases} \psi' = -\dfrac{\varepsilon\psi}{r^3}(w')^2 \ , \\ \\ \zeta' = \dfrac{\zeta(1-\zeta)}{r} + \dfrac{\varepsilon}{r^3}\left(\zeta^2 - \zeta^2 w^2 - (w')^2\zeta\right) \ , \\ \\ w'' = \left(\dfrac{3-\zeta}{r} + \dfrac{\varepsilon\zeta}{r^3}(1-w^2)\right) w' + \zeta w \ . \end{cases} \tag{9}$$

where the dimensionless parameter ε takes the role of Newton's G, that is, it stands for $\varepsilon := GQ^2\varkappa^2/c^4$. Even if $\varkappa$ is as large as physically reasonable — the inverse of the Planck length, — we find that ε is of order 10^{-20} for Q being the charge of an electron. Therefore it makes sense to study the solutions of system (9) as a perturbation of those corresponding to the $\varepsilon = 0$ case, which we call the **flat-space solution**:

$$\psi^{(\mathrm{flat})}(r) = 1 \ , \quad \zeta^{(\mathrm{flat})}(r) = 1 \ , \quad w^{(\mathrm{flat})}(r) = (1+r)e^{-r} \ , \tag{10}$$

where $w^{(\mathrm{flat})}$ was obtained from (7) and (3). The integral for the electric field energy, reinstating the constants $c, Q, \varkappa$, can be calculated to be

$$\mathcal{E} = \frac{1}{2}\int_0^\infty \frac{\psi}{r^2}\left(Q^2 - w^2 - \frac{1}{\varkappa^2}\cdot\frac{(w')^2}{\zeta}\right)\mathrm{d}r \tag{11}$$

(performed on any constant-time hypersurface).

The goal of this work is to prove that a finite-energy solution to system (9) exists and to study the nature of its singularity at $r = 0$. For the lack of a better name, the ensuing spacetime will be referred to as the **M-BLTP spacetime**.

Remark 2.1. For any value of $\varkappa \leq \infty$, the RWN solution (2) also solves the version of system (9) with the constants $c, G, \varkappa$ reintroduced, but it is an undesirable solution because of the divergence of the energy integral. A recent result by Cuzinatto[6] et al. shows that RWN is in fact the only physically meaningful exterior solution of this system in case the spacetime contains a black hole — that is, if the coordinate system is only valid on a domain of the form $r \in (r_0, \infty)$ for $r_0 > 0$. So it is remarkable that another solution can exist if the domain is taken to be $r \in (0, \infty)$, as it is for us.

3. Main result

The main theorem proved in Ref. 2 can be paraphrased as follows:

Theorem 3.1. There exists $\varepsilon_* \in (0,1)$ such that, for all $\varepsilon \in [0, \varepsilon_*]$, the Maxwell-BLTP-Einstein system (9) of a static point charge admits a solution $(\psi_\varepsilon, \zeta_\varepsilon, w_\varepsilon)$ for $r \in (0, \infty)$ satisfying the asymptotic properties (6), (8) and the condition $\mathcal{E} < \infty$, where $\mathcal{E}$ is given in (11). Furthermore, the behavior of the solution for large r is

$$\psi_\varepsilon(r) = 1 + O(e^{-r}) \ , \quad \zeta_\varepsilon(r) = \zeta_M^{(\mathrm{RWN})}(r) + O(e^{-r}) \ , \quad w_\varepsilon(r) = O(e^{-r}) \ ,$$

and that for small r is

$$\psi_\varepsilon(r) = O(e^{-Y\varepsilon}) \ , \quad \zeta_\varepsilon(r) = X + O(r^2) \ , \quad w_\varepsilon(r) = 1 + O(r^2) \ ,$$

where the parameters M, X, Y are determined by ε, with $X \in [1, 1.1)$ and $Y \in (0.9, 1]$. Additionally, pointwise at any $r > 0$, we have

$$\lim_{\varepsilon \to 0} (\psi_\varepsilon(r), \zeta_\varepsilon(r), w_\varepsilon(r)) = (\psi^{(\mathrm{flat})}(r), \zeta^{(\mathrm{flat})}(r), w^{(\mathrm{flat})}(r)) \ . \tag{12}$$

We give an outline of the proof:

- First it is shown that, for any fixed $r_0 > 0$, a family of solutions exists on $[r_0, \infty)$ satisfying the asymptotic conditions (6), (8) as long as $\varepsilon > 0$ is small enough. This family is parametrized by (and continuous in) two arbitrary real parameters μ and α, the first one being related to the ADM mass. The method consists of writing the solution as a power series in ε starting from the $\varepsilon = 0$ flat-space solution, and then employing a novel technique for estimating the growth of the coefficients in order to get a lower bound for the radius of convergence. Also note that conditions (6), (8) already imply the finiteness of the energy integral (11) away from $r = 0$.
- Next a suitable rewriting of the system is found that casts its study, for small r, as a first-order, 4-dimensional autonomous dynamical system around a hyperbolic equilibrium point P. The 2-dimensional unstable manifold $\mathcal{W}$ of P is analytic and consists of a continuous 1-parameter family (we call σ the parameter) of solutions which, in the original variables, corresponds to solutions satisfying the condition

  $$\lim_{r \to 0} \frac{\psi(r)(w(r) - 1)}{r^2} \in \mathbb{R} \ . \tag{13}$$

  This is proven to imply $\mathcal{E} < \infty$. More than that, it also implies $\mathcal{E} = Q\varphi(0)/2$, as in flat-space. The estimation technique mentioned above, this time adapted for power series in two real variables, enables the computation of points in $\mathcal{W}$ to arbitrarily small error.
- With the above work, we can construct, in a suitable 4-dimensional space $\{(x, y, z, r)\}$, a 3-dimensional hypersurface $\mathcal{Z}$ corresponding to solutions satisfying the desirable asymptotic conditions for large r, and a 2-dimensional surface $\mathcal{W}$ corresponding to solutions satisfying sufficient asymptotic conditions for small r to guarantee a finite $\mathcal{E}$. To complete the proof, one needs to show that $\mathcal{W}$ and $\mathcal{Z}$ intersect. To this end we consider the 3-dimensional

hypersurface $r = r_0$ of (x, y, z, r)-space. Intersected with it, $\mathcal{W}$ becomes a continuous curve $\mathcal{W}_0$ and $\mathcal{Z}$ becomes a continuous surface $\mathcal{Z}_0$. By looking at the x, y, z coordinates of points on $\mathcal{W}_0$ and $\mathcal{Z}_0$ as continuous functions of their parameters σ, μ, α, and by considering that a point intersection exists when $\varepsilon = 0$, the *Poincaré-Miranda theorem* can be applied to ensure that this point intersection still exists for small $\varepsilon > 0$. It corresponds to one solution over $r \in (0, \infty)$ for the chosen value of ε.

4. Properties of the solution

We conclude by analyzing some important properties of the M-BLTP spacetime and reporting on current work in progress related to recent results in the same vein.

4.1. *Bare mass*

There is another well-known modification of the Maxwell-Maxwell equations which also deals with the problem of infinite field energy-momentum of a point particle in flat-space. Originally proposed by Born,[7] it is part of what nowadays is commonly called *Born-Infeld electrodynamics*. It was then first observed by Hoffmann[8] that, under this formulation of EM, the singularity of the static, spherically symmetric spacetime of a resting point charge is milder than that of the RWN spacetime, in the sense that the blowup of certain curvature scalars at $r = 0$ is less severe in it. In Ref. 9, a class of electrostatic, spherically symmetric spacetimes that generalize that of Hoffmann is studied in much the same way as we did here for the BLTP laws. We call these *Hoffmann spacetimes*. An important quantity considered in that work is the so-called *mass-function* $m(r)$, which is defined by its relation to the second metric coefficient:

$$\zeta(r) = \left(1 - \frac{2Gm(r)}{c^2 r}\right)^{-1} . \tag{14}$$

The ADM mass is given by $m(\infty) := \lim_{r\to\infty} m(r)$, while the number $m(0) := \lim_{r\to 0} m(r)$ is called the **bare mass** of the spacetime. It is observed that $m(0) \in (-\infty, 0)$ for the class of Hoffmann spacetimes, and that this finite, negative bare mass contributes to the electric field energy to provide the entire mass/energy content of the spacetime:

$$\mathcal{E} = c^2(m(\infty) - m(0)) .$$

But the methods of that work are fundamentally distinct from ours. The metric coefficients of the Hoffmann spacetimes can be explicitly solved by quadrature, partly due to the helpful fact that they satisfy $g_{tt}g_{rr} = -1$. This is not the case for the M-BLTP spacetime, turning even the question of existence of a solution into a completely different and more challenging task for us. Nevertheless, one can prove that the curvature blowup of the M-BLTP spacetime is just as mild as that of the

Hoffmann spacetimes, but, contrary to the latter, the following relation holds in the former:

$$\mathcal{E} > c^2(m(\infty) - m(0)) \ .$$

This suggests that $m(0)$ doesn't have a simple interpretation in the M-BLTP spacetime as a bare mass located at the point charge.

4.2. *Equations of motion*

In Ref. 10, a weak form of the twice-contracted second Bianchi identity for static, spherically symmetric spacetimes with a "singularity worldline" is studied. Sufficient conditions for it to hold are found for when $\psi \equiv 1$ and $m(0) < 0$. Considering how the classical Bianchi identities imply the local conservation laws $\nabla_\mu T^{\mu\nu} = 0$ (equations of motion of the matter/fields), the importance of this work to the scope of our project is that it provides a rigorous formulation of an equation of motion for a spacetime singularity, such as a point charge in the way that it is modeled in our spacetime. However, we find that the M-BLTP spacetime satisfies $\psi(r) > 1$ and $m(0) = 0$, which means that this work would not be directly applicable to study the motion of point-charge-singularities in GR under the BLTP laws of electromagnetism. More work in this topic will be needed when considering spacetimes containing two or more point charges that obey the BLTP laws.

4.3. *Further solutions*

Our existence proof obtains a solution whose ADM mass parameter $M = m(\infty)$ is determined by the value of ε. Physically it should be the case that M can be chosen *a priori*, independently from ε, so that point charges of arbitrary mass can be modeled. So the question arises whether we are missing more solutions to system (9). One point where our existence proof has potentially missed other solutions is clear: we have imposed condition (13), which is sufficient but not necessary for a finite energy. It also turns out that this condition implies $m(0) = 0$, but, considering what happens in the Hoffmann spacetimes, it is not unreasonable to expect that other solutions with $m(0) < 0$ and a finite energy might exist. If this turns out to be true, then, in the proof outline above, the curve $\mathcal{W}_0$ corresponding to suitable solutions for small r could potentially be turned into a surface with parameters σ and $m(0)$, which would intersect the surface $\mathcal{Z}_0$ in more than just one point. That is, one would expect a whole 1-parameter family of solutions over $r \in (0, \infty)$, allowing for a free parameter such as M. This is currently being studied by the author.

Acknowledgments

The author would like to thank his PhD advisors Michael Kiessling and Shadi Tahvildar-Zadeh for all the valuable discussions throughout his course of studies at Rutgers University and for the opportunity to present this work during the 16th Marcel Grossmann Meeting.

On recent developments in the theory of relativistic dissipative fluids

V. Hoang

San Antonio, Texas 78249 (USA)
E-mail: duynguyenvu.hoang@utsa.edu

I give an overview about recent results on the well-posedness and breakdown of solutions for relativistic fluid equations.

Keywords: Relativistic dissipation, fluids, quark-gluon plasma, neutron star merger, causality, blowup of solutions

1. Relativistic fluids and heavy-ion collisions

The study of the quark-gluon plasma is provides a window into fundamental physics 10^{-6} seconds after the big bang.[1] On Earth, this state of matter is produced in collisions between heavy nuclei at relativistic speeds, creating a strongly interacting mixture of quarks and gluons. Current state-of-the art modeling of the quark-gluon plasma[1] is based on relativistic fluid equations, showing that the plasma behaves very much like an expanding liquid drop. Dissipative effects[1–3] have to be taken into account to make theoretical predictions match experimental data. Dissipative effects may also be relevant for the study of neutron star mergers.[4]

In Einstein's theory of relativity, a Lorentzian manifold (M, g) is taken as a model for spacetime. M can be thought of as the set of all events in the universe, characterized by *where and when* they happen. For simplicity consider a flat spacetime $M = \mathbb{R}^4 = \{x^\alpha := (x^0, \dots, x^3)\}$, where $x^0 = ct$ is the time coordinate and c the speed of light. The Minkowski metric $g = \mathrm{diag}(-1, 1, 1, 1)$ describes distances of events between one another. We use standard tensor notation throughout (repeated greek indices summed from 0 to 3, latin indices from 1 to 3). For a textbook introduction, see Refs. 5–7.

The basic fields in a relativistic fluid description are (e, n, u^α), where the total energy density e, the particle number density n and the four-velocity $u^\alpha = \frac{1}{\sqrt{1-|\vec{v}|^2/c^2}}\left(1, \frac{\vec{v}}{c}\right)$ all depend on x^α. The four-velocity replaces the ordinary three-dimensional velocity $\vec{v}$ of a fluid and is a time-like vector satisfying $g_{\mu\nu}u^\mu u^\nu = -1$. We first review the perfect fluid equations:

$$\begin{aligned}
&\text{relativistic Euler/momentum equation:} \quad (e+p)\dot{u}^\beta = -(g^{\beta\alpha} + u^\beta u^\alpha)\nabla_\alpha p \\
&\text{conservation of energy:} \quad \dot{e} + (e+p)\nabla_\alpha u^\alpha = 0 \\
&\text{conservation of particle number:} \quad \nabla_\alpha(nu^\alpha) = 0 \\
&\text{equation of state/pressure equation:} \quad p = p(e, n)
\end{aligned} \tag{1}$$

where a dot $\dot{f} = u^\alpha \nabla_\alpha f$ denotes the relativistic material derivative. The momentum equation is analogous to Newton's second law $m \cdot a = F$, as $(e+p)$ corresponds to relativistic mass density, $a^\beta := u^\alpha \nabla_\alpha u^\beta = \dot{u}^\beta$ is the acceleration and the gradient of the pressure is a force. Additionally the projection operator $h^{\beta\alpha} := g^{\beta\alpha} + u^\beta u^\alpha$ appears in the relativistic version. In the formal limit $c \to \infty$, the velocity field $\vec{v}$ will satisfy the non-relativistic Euler equation for perfect fluids with rest mass density ρ

$$\rho \left(\partial_t v^i + v^j \partial_j v^i \right) = -g^{ij} \partial_j p. \tag{2}$$

The usual way to derive the fluid equations (1) is to define the energy momentum tensor

$$T^{\mu\nu} = (e+p) u^\mu u^\nu + p g^{\mu\nu} \tag{3}$$

and to postulate the conservation of energy and momentum $\nabla_\mu T^{\mu\nu} = 0$. This formulation goes back to the work of Einstein and Schwarzschild.[8,9] The first and second equation of (1) are equivalent to $\nabla_\mu T^{\mu\nu} = 0$. While the relativistic Euler equations are a rich source of mathematical problems, they constitute a highly idealized description of a fluid. A physically more complete description includes dissipative processes such as viscosity, diffusion and heat conduction.

To model dissipative effects of viscosity and heat conduction, the energy-momentum tensor is extended to

$$T^{\mu\nu} = (e + p + \Pi) u^\mu u^\nu + (p + \Pi) g^{\mu\nu} + \pi^{\mu\nu} + q^\mu u^\nu + q^\nu u^\mu, \tag{4}$$

where q^ν is the heat-flux vector, Π the bulk viscosity, and $\pi^{\mu\nu}$ the tensor of shear viscosity. These quantities satisfy the orthogonality and symmetry constraints

$$q^\nu u_\nu = 0, \quad \pi^{\mu\nu} u_\mu = 0, \quad \pi^{\mu\nu} = \pi^{\nu\mu}, \quad \pi^{\mu\nu} g_{\mu\nu} = 0. \tag{5}$$

The equations of motion that result from conservation of energy, momentum and particle number are now

$$\begin{aligned}
&\text{momentum:} \quad (e+p+\Pi)\dot{u}_\mu + h^\nu_\mu \nabla_\nu (p+\Pi) + h^\alpha_\mu \nabla_\nu \pi^\nu_\alpha \\
&\qquad\qquad + h_{\nu\mu} \dot{q}^\nu + \left(\nabla_\nu u_\mu + \nabla_\alpha u^\alpha h_{\mu\nu} \right) q^\nu = 0 \\
&\text{energy:} \quad \dot{e} + (e+p+\Pi) \nabla_\mu u^\mu + q_\mu \dot{u}^\mu + \nabla_\mu q^\mu + \pi^{\mu\nu} \sigma_{\mu\nu} = 0 \\
&\text{particles:} \quad \nabla_\alpha (n u^\alpha) = 0 \\
&\text{equation of state:} \quad p = p(e, n)
\end{aligned} \tag{6}$$

To complete the system, additional dynamical equations for $(\Pi, q^\nu, \pi^{\mu\nu})$ have to be postulated. A large body of literature (see Ref. 7 and references therein) has been devoted to finding suitable dynamical equations for these quantities.

For a fluid with a single species of particles, i.e. excluding mixtures and chemical reactions, these evolution equations in the Israel-Stewart model take the form

$$\begin{aligned} \tau_0\dot{\Pi} + \Pi + \zeta\nabla_\alpha u^\alpha + \left[\frac{1}{2}\zeta T\nabla_\alpha\left(\frac{\tau_0}{\zeta T}u^\alpha\right)\Pi\right] &= 0 \\ \tau_1 h^\lambda_\nu \dot{q}_\lambda + q_\nu = -\kappa T(h^\lambda_\nu\nabla_\lambda \ln T + a_\nu) - \left[\frac{1}{2}\kappa T^2\nabla_\alpha\left(\frac{\tau_1}{\kappa T^2}u^\alpha\right)q_\nu\right] \\ \tau_2 h^\alpha_\mu h^\beta_\nu \dot{\pi}_{\alpha\beta} + \pi_{\mu\nu} = -2\eta\sigma_{\mu\nu} - \left[\frac{1}{2}\eta T\nabla_\gamma\left(\frac{\tau_2}{\eta T}u^\gamma\right)\pi_{\mu\nu}\right] \end{aligned} \tag{7}$$

The appearance of the relaxation times $\tau_0, \tau_1, \tau_2 > 0$ is crucial for the stability and well-posedness of the model. The physical meaning of variables and various transport coefficients is as follows:

- Π bulk viscous pressure (isotropic force from fluid element shrinking/expanding).
- $\pi^{\mu\nu}$ shear viscous stresses (anisotropic force from transverse fluid layer movement).
- $p = p(e, n)$ hydrostatic pressure (isotropic gas pressure)
- e total energy density (rest energy density + internal energy density)
- n particle density (measures particles per volume)
- T absolute temperature
- $\zeta > 0, \eta > 0$ bulk/shear viscosity coefficient
- $\kappa > 0$ heat conductivity coefficient $\tau_0, \tau_1, \tau_2 > 0$ characteristic relaxation times for $\Pi, q^\nu, \pi^{\mu\nu}$
- $\sigma_{\mu\nu}$ kinematic shear tensor $\sigma_{\mu\nu} = h^\alpha_\mu h^\beta_\nu \frac{1}{2}(\nabla_\beta u_\alpha + \nabla_\alpha u_\beta)$, distortion of fluid element

I will refer to the set of equations (6), (7) as the full Israel-Stewart (IS) model. To see the mathematical structure of the equations (7) more clearly, the *truncated IS model*[7] (p. 302) is introduced. In (7) the divergence-type terms are dropped, leading to

$$\begin{aligned} \tau_0\dot{\Pi} + \Pi &= -\zeta\nabla_\alpha u^\alpha, \\ \tau_1 h^\lambda_\nu \dot{q}_\lambda + q_\nu &= -\kappa T(h^\lambda_\nu\nabla_\lambda \ln T + a_\nu), \\ \tau_2 h^\alpha_\mu h^\beta_\nu \dot{\pi}_{\alpha\beta} + \pi_{\mu\nu} &= -2\eta\sigma_{\mu\nu} \end{aligned} \tag{8}$$

A formal non-relativistic limit $c \to \infty$, $\tau_i \to 0$ of (6), (8) recovers the classical compressible Navier-Stokes equations.[7] The equations (7) can be derived using a systematic procedure starting from the second law to thermodynamics (entropy production) (see Ref. 7). The full IS model can also be motivated by considerations from kinetic theory, which aims to derive macroscopic fluid equations by a moment expansion process (see Refs. 10–14).

The first dissipative relativistic fluid theories were formulated by Eckart[15] and Landau-Lifshitz.[16] These models are more direct covariant analogues of the non-relativistic Navier-Stokes equations. Consequently the equations of motion have a

parabolic character and information can propagate at infinite speed, violating the most basic requirement of relativity.[17] In addition, the Eckart model can exhibit catastrophic instabilities.[18–20] As a reaction to these undesired properties, the IS model was developed in Refs. 21–25, with an initial contribution by Müller.[26] Partial differential operators with the property of finite speed of propagation are called *hyperbolic*[27] and the IS model is conjectured to have the even stronger property of *causality*. Causality requires both finite speed of propagation and that changes in initial data propagate at sub-light speeds, i.e. that the values of $(e, n, \Pi, u^\mu, q^\nu, \pi^{\mu\nu})$ at any point (t_0, x_0) depend only on the initial data given on the domain of dependence, i.e. inside the past-directed light cone.

The following heuristic argument illustrates why (7) should lead to finite speed of propagation: Consider the following modification of Fourier's law of heat conduction

$$\tau_0 \partial_t \vec{q} + \vec{q} = -\kappa \nabla T \tag{9}$$

with $\vec{q}(t, \cdot) : \mathbb{R}^3 \to \mathbb{R}^3$ being the three-dimensional heat flux. Assuming that the temperature T is proportional to the internal energy of the fluid and using conservation of energy leads to

$$\tau_0 \partial_t^2 T + \partial_t T - \kappa \Delta T = 0, \tag{10}$$

a generalized form of the heat equation, which is recovered upon setting $\tau_0 = 0$. (10) for $\tau_0 > 0$ is the telegraph equation[28] which has finite speed of propagation. The idea is therefore that the presence of relaxation times τ_i in (7) will have a similar effect and guarantee finite speed of propagation.

2. Local-wellposedness

The local well-posedness problems for the full and truncated systems (6),(7) (or (6), (8)) is still open. In Ref. 29, local-wellposedness and causality was shown for a related system used in heavy-ion collisions:

$$\begin{aligned}
u^\alpha \nabla_\alpha e + (e + P + \Pi) \nabla_\alpha u^\alpha + \pi^\alpha_\mu \nabla_\alpha u^\mu &= 0, \\
(e + P + \Pi) u^\beta \nabla_\beta u_\alpha + c_s^2 h^\beta_\alpha \nabla_\beta e + h^\beta_\alpha \nabla_\beta \Pi + h^\beta_\alpha \nabla_\mu \pi^\mu_\beta &= 0, \\
\tau_\Pi u^\mu \nabla_\mu \Pi + \Pi &= -\zeta \nabla_\mu u^\mu - \delta_{\Pi\Pi} \Pi \nabla_\mu u^\mu - \lambda_{\Pi\pi} \pi^{\mu\nu} \sigma_{\mu\nu}, \\
\tau_\pi h^{\mu\nu}_{\alpha\beta} u^\lambda \nabla_\lambda \pi^{\alpha\beta} + \pi^{\mu\nu} &= -2\eta \sigma^{\mu\nu} - \delta_{\pi\pi} \pi^{\mu\nu} \nabla_\alpha u^\alpha - \tau_{\pi\pi} \pi^{\langle\mu}_\alpha \sigma^{\nu\rangle\alpha} - \lambda_{\pi\Pi} \Pi \sigma^{\mu\nu},
\end{aligned} \tag{11}$$

which introduces new relaxation times and system coefficients $\tau_\pi, \lambda_{\pi\Pi}, \ldots$ etc. This system contains shear/bulk viscosity but no heat conduction. The equations for shear and bulk viscosity differ somewhat from the Israel-Stewart model, but follow the same general idea of introducing a relaxation mechanism.

Theorem 2.1. *Consider the Cauchy problem for equations* (11) *in Minkowski space, with initial data* $\mathring{\Psi} = (\mathring{e}, \mathring{u}^\nu, \mathring{\Pi}, \mathring{\pi}^{\mu\nu})$ *given on* $\{t = 0\}$. *There is an open set of inital data satisfying the constraints and that* $\mathring{\Psi} \in \mathcal{G}^\delta(\{t = 0\})$, *where* $1 \leq \delta < 20/19$. *Then, there exist a* $T > 0$ *and a unique* $\Psi = (e, u^\nu, \Pi, \pi^{\mu\nu})$ *defined on* $[0, T) \times \mathbb{R}^3$

such that Ψ *is a solution in* $[0,T)\times\mathbb{R}^3$ *and* $\Psi = \mathring{\Psi}$ *on* $\{t=0\}$. *Moreover, the solution* Ψ *is causal (i.e. domain of influence of initial data is contained in forward light-cones).*

The set of admissible initial data is physically reasonable and can be described by a set of inequalities involving ε, Π and the eigenvalues of π^μ_ν. The notation $\mathcal{G}^\delta(\{t=0\})$ refers to a Gevrey-type space, and we refer to Ref. 29 for more details.

3. Breakdown of solutions

Solutions to nonlinear partial differential equations may have a finite lifespan, the most elementary example being Burgers' equation.[30] For suitable C^∞ initial data, solutions develop a shock, i.e. a singularity in the first derivative after a finite time. A deeper question can also be asked: What precisely happens at breakdown time? Do derivatives or the fields themselves become infinite? For perfect relativistic fluids there exists a well-developed theory that proves shock formation[31–33] giving a detailed picture of the quantities that actually blow up. These results are very deep and rely on hidden geometric-analytic structures in the perfect fluid equations, which allow their formulation as quasilinear second-order covariant wave equations. It is a hard unsolved problem how to generalize these delicate hidden structures to dissipative fluids. Considering the available mathematical technology, asking for a detailed description of the singularity in the dissipative case seems to be out of reach for now. The investigation of these matters is clearly in its beginning stages, and in Ref.[34] we establish a first blowup result for a viscous dissipative fluid with only bulk viscosity (no shear viscosity or heat conduction). The basic ideas are based on the work by Sideris[35] and for relativistic fluids based on Guo-Tahvildar-Zadeh,[36] who developed a robust technique to show breakdown of smooth solutions for compressible fluids using the fundamental conservation $\nabla_\mu T^{\mu\nu} = 0$. Novel aspects of this method continue being discovered.[34,37] At the core of this technique lies a type of virial identity involving the second moment of the energy density, from which differential inequalities are derived, leading to the blowup via a contradiction argument.

Theorem 3.1. *Consider the viscous equations with bulk viscosity (without shear viscosity) with given smooth constitutive functions* p, ζ, τ_0. *Assume that*

$$\mathcal{C} := \int_0^\infty \frac{1}{n} \sup_{\rho\geq 0} \frac{\zeta(\rho,n)}{\tau_0(\rho,n)}\, dn < \infty$$

and make further (mild) technical assumptions of the equation of state $p = p(e,n)$. *There exists a smooth initial data* $(\mathring{\rho}, \mathring{n}, \mathring{\Pi}, \mathring{\mathbf{u}})$ *with large velocities such that the local smooth solution breaks down in finite time.*

A detailed discussion of the model and the assumptions on equations of state and bulk viscosity can be found in Ref. 34. The viscous case requires novel estimates

for Π. From its evolution, we have $\dot{\Pi} \sim \nabla_\alpha u^\alpha$, but the quantity $\nabla_\alpha u^\alpha$ is very hard to control in a non-constructive blowup proof. Instead, we use a hidden structure in the equations, namely an auxiliary transport equation in ρ, n, Π allowing us to get estimates for Π.

4. Conclusion

Including dissipation into models of relativistic fluids is necessary for a complete macroscopic description, as effects such as viscosity and heat conduction are ubiquitous in nature. Investigating dissipative effects in relativity has a long history, yet there is a gap in knowledge considering many fundamental questions about existence, uniqueness, blowup and decay properties of solutions. First breakthroughs have been made but many important problems remain open, for example to show well-posedness and singularity formation for the Israel-Stewart model (6), (7).

Adiabatic solutions in general relativity as null geodesics on the space of boundary diffeomorphisms

Emine Şeyma Kutluk

Physics Department, Middle East Technical University, Ankara, 06800, Turkey

We use Weinberg's trick for adiabatic modes, in a Manton approximation for general relativity on manifolds with spatial boundary. This results in a description of the slow-time dependent solutions as null geodesics on the space of boundary diffeomorphisms, with respect to a metric we prove to be composed solely of the boundary data. We show how the solutions in the bulk space is determined with the constraints of general relativity.

To give our description a larger perspective, we furthermore identify our resulting Lagrangian as a generalized version of the covariantized Lagrangian for continuum mechanics. We study the cases of 3+1 and 2+1 dimensions and show for the solutions we propose, the Hamiltonian constraint becomes the real homogeneous Monge-Ampere equation in the special case of two spatial dimensions.

Keywords: Adiabatic Solutions; Large Gauge Symmetries; Manton Approximation; Soft Modes; Moduli Space; Geometric Continuum Mechanics

1. Introduction and Summary

Asymptotic symmetries and soft theorems has been a topic that drew much attention in the last decade. Starting from 2013, Strominger have shown[1–3] that soft theorems arise as Ward identities of asymptotic space-time and/or gauge symmetries. Since then many new versions of soft theorems have been suggested.

Independently of this line of research, in quantum cosmology people have been studying similar Ward identities.[4–6] These studies heavily relies on Weinberg's argument for the existence of adiabatic modes on a generic cosmological background.[7]

We use a similar argument for general relativity in a Manton approximation.[8,9] Manton approximation tells one slow time trajectories on the space of static and minimum energy solutions, called the vacua, are good approximate solutions. In our approach we take the vacua to be gauge transformations of a reference metric; then introduce the time dependency in a way that the resulting trajectory is no longer a redundant gauge transformation-as was the case in Weinberg's argument. We study what becomes of the Lagrangian and the equations of motion for these trajectories, and see

- Lagrangian solely depends on the quantities on the boundary of spatial slices,
- constraints of general relativity serves to determine the bulk metric from its boundary values,

- solutions are geodesics on the space of vacua, which are further required to be null due to the Hamiltonian constraint.

Trajectories on diffeomorphism groups were previously used to describe the motion of ideal fluids[10] (see also Ref. 11), where they are described as geodesics with respect to a metric. We covariantize this description,[9] and show that our aforementioned solutions correspond to a specific choice of a generalized metric.

As particular examples we study solutions produced from a flat metric on 3-dimensional ball and also general two dimensional enclosed surface. We show how Hamiltonian constraint enforces coupling of two independent towers in the former and how it reduces down to homogeneous-real Monge Ampere equation in the latter case.

2. A Manton Approximation for General Relativity

2.1. *Setup*

We start by reviewing the Manton approximation[12] (see also Refs. 13, 14). Let us have a set of fields $\phi^I(t,x)$, on a spacetime described by the coordinates (t,x). Let us describe our system with a *natural* action

$$S = \int \left(\frac{1}{2} g_{IJ}(\phi)\, \dot{\phi}^I \dot{\phi}^J - V(\phi) \right) dV^{d+1} \tag{1}$$

where dV^{d+1}, with a slight abuse of notation, denotes the Riemannian volume form for a metric on the $d+1$ dimensional space-time manifold. Let us consider the configuration space, i.e. the space of static fields, called $\mathcal{F}$.

Assume that the potential have a continuous set of minima called $\mathcal{E}$; more specifically, in the configuration space let there be a submanifold such that

$$(\partial_I V)(\varphi^I) = 0 \quad \text{where} \quad \varphi^I \in \mathcal{E} \ . \tag{2}$$

Note that these static fields are solutions to equations of motion for the type of theory we are considering, since the equation of motion is given by

$$g_{IK}\left(\ddot{\phi}^I + \Gamma^I_{MJ} \dot{\phi}^M \dot{\phi}^J \right) = -\partial_K V \ . \tag{3}$$

Now the metric g_{IJ} will induce a metric on $\mathcal{E}$. The Manton approximation tells us that a *geodesic* on $\mathcal{E}$ with respect to this metric, that is slow in time, is a good approximate solution and the motion off $\mathcal{E}$ can be ignored.

Now we want to apply this procedure to general relativity. For this we need a Lagrangian for general relativity that is of the natural form. This can be achieved by considering a spacetime manifold in the form of $\mathbb{R} \times M$ with the ADM action, and then choosing Gaussian normal coordinates (GNC) where $g_{00} = -1, g_{0i} = 0$. Then, renaming the spatial part of the metric as $h_{ij} = g_{ij}$ the action we have is

$$S = \frac{1}{2} \int \mathrm{g}_h(\dot{h}_{ij}, \dot{h}_{kl})\, dt - \int V[h]\, dt \tag{4}$$

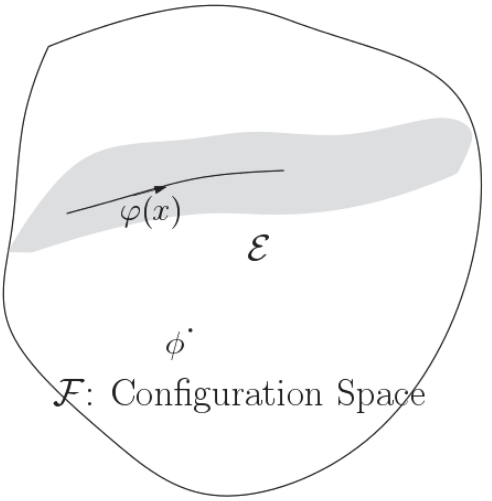

Fig. 1. Configuration space and the space of minima

where

$$\mathrm{g}_h(\delta_1 h, \delta_2 h) = \frac{1}{2}\int_M \left(h^{ik}h^{jl} - h^{ij}h^{kl}\right)\delta_1 h_{ij}\delta_2 h_{kl}\, dV^d \ , \tag{5}$$

$$V[h] = -\int_M R(h)\, dV^d \ . \tag{6}$$

Here dV^d is the Riemannian volume form and $R(h)$ Ricci scalar for h.g_h will be the metric on the configuration space. Note that since g_{00}, g_{0i}, generally known as lapse and shift, are Lagrange multipliers which we have fixed; constraints of GR

$$\nabla^i\left(\dot{h}_{ij} - h^{kl}\dot{h}_{kl}h_{ij}\right) = 0\,, \tag{7}$$

$$R(h) + \frac{1}{2}h^{ij}h^{kl}\dot{h}_{i[j}\dot{h}_{k]l} = 0\,, \tag{8}$$

needs to be imposed externally from now on.

To implement the Manton approximation, we now need to identify the set of static solutions that extremize the theory. Note that the potential is not bounded from below, so there will be no minimal energy. However it will have an extrema:

$$\delta V|_{\bar{h}} = 0 \to \quad R_{ij}(\bar{h}) = 0 \ . \tag{9}$$

So the Ricci flat metrics $\bar{h}$ and their gauge transformations will compose the space of static set of extrema of the action. For our investigation we focus on a single reference metric and its gauge transformations, i.e. we define the static extrema $\mathcal{E}$ to be composed of metrics

$$\hbar = \psi \cdot \bar{h} \ , \tag{10}$$

i.e. a Ricci flat metric and its gauge transformations. Remember we have chosen a gauge, thus the remaining gauge transformations are not full set of diffeomorphisms. They turn out to be two sets that can be written as

$$\psi_\chi = \left(0, \chi^i(x)\right) \ , \tag{11}$$

$$\psi_\alpha = \left(\alpha(x), \partial_j \alpha(x) \int_0^t h^{ij}(t', x) dt'\right) . \tag{12}$$

First of these are simply the spatial diffeomorphisms, whereas the second type are a form of local boost- they are the transformations that take a choice of "initial" hypersurface to another one when choosing GNC, see Ref. 14 for more details. Local boosts are field-dependent transformations, and thus they do not form a proper algebra- reflecting the fact that constraints of general relativity do not form a proper algebra.[a] Moreover they are not static as what a Manton description tells a vacuum ought to be. Because of these reasons we restrict our attention to spatial diffeomorphisms and define $\mathcal{E}$ as the space of metrics produced by spatial gauge transformations of the flat metric.

So we take $\mathcal{E}$ to be the set of spatial metrics that are -spatial- gauge transformations of a spatial reference metric, i.e.

$$h = \phi^* \bar{h} \ . \tag{13}$$

Written in a coordinate basis this reads as

$$h^z_{ij}(x) = \frac{\partial \phi^{\underline{k}}(x, z)}{\partial x^i} \frac{\partial \phi^{\underline{m}}(x, z)}{\partial x^j} \bar{h}_{\underline{km}} \tag{14}$$

where z parametrizes the gauge transformations. The dynamics is then described as a motion on this space:

$$h^z_{ij}(x, t) = \frac{\partial \phi^{\underline{k}}(x, z(t))}{\partial x^i} \frac{\partial \phi^{\underline{m}}(x, z(t))}{\partial x^j} \bar{h}_{\underline{km}} \ , \tag{15}$$

or

$$h(t) = \phi_t^* \bar{h} \ . \tag{16}$$

Note here the "trickiness": Once we introduce the time dependency this way, what we are doing is not a coordinate/gauge transformation in the full spacetime.

Let us illustrate this with a simple example in 3+1 dimensions. Take reference spatial metric to be the flat metric $\bar{h}_{ij} = \delta_{ij}$. Consider the transformations

$$\phi^i_t = a(t) x^i \ . \tag{17}$$

For these transformations our ansatz will produce the spacetime metric

$$ds^2 = -dt^2 + a^2(t)(dx^2 + dy^2 + dz^2) \ . \tag{18}$$

[a] Commutators of constraints of general relativity gives what is called an algebroid, see Ref. 15 and Ref. 16 for further discussion.

This illustrates very clearly that our ansatz gives us physically new solutions, for this case the spatially flat FRW spacetime.[b]

2.2. *Motion as a Geodesic on the Space of Boundary Diffeomorphisms*

In the last subsection we have proposed solutions to Einstein equations in GNC where

$$h(t) = \phi_t^* \bar{h} \ . \tag{19}$$

Now we would like to check whether these solve the Einstein equations or if they should satisfy further conditions. Note that our free variable is the diffeomorphism $\phi(t, x)$ here. We start by first checking the constraint equations that we have started imposing externally after we have eliminated the Lagrange multipliers. First we observe for our solutions Eq. (19) we have

$$\dot{h}_{ij} = \nabla_i \xi_j + \nabla_j \xi_i \qquad \text{where} \qquad \xi^i := \dot{\phi}^{\underline{k}} \frac{\partial x^i}{\partial \phi^{\underline{k}}} \qquad \text{so that} \qquad K_{ij} = \nabla_{(i} \xi_{j)} \ . \tag{20}$$

Here ∇ is the covariant derivative belonging to h. Using this and the fact $R_{ij}(h) = R_{ij}(\bar{h}) = 0$, momentum constraint becomes

$$\mathcal{P}_j(\xi) = \nabla^i \nabla_{[i} \xi_{j]} = 0 \ , \tag{21}$$

whereas Hamiltonian constraint is

$$\mathcal{H}(\xi) = (\nabla_i \xi^i)^2 - \nabla_{(i} \xi_{j)} \nabla^i \xi^j = 0 \ . \tag{22}$$

Furthermore the dynamics will be determined with the reduced Lagrangian, where one plugs Eq. (19) in Eq. (4). For our solutions the potential is zero whereas the kinetic term is the length of $\dot{h}$ with respect to the metric

$$\mathrm{g}_h(\delta_1 h, \delta_2 h) = \frac{1}{2} \int_M \left(\nabla_{(i} \xi_{1j)} \nabla^i \xi_2^j - (\nabla_i \xi_1^i)(\nabla_i \xi_2^i) \right) dV^d \ . \tag{23}$$

This is the metric Eq. (5) on the configuration space pulled back to the space of vacua. As we have noted, solutions to the dynamical equation of the above action will be geodesics on the space of vacua with respect to this metric. Then we see *Hamiltonian constraint restricts these geodesics to be null.*

Now note that each spatial slice is diffeomorphic to the reference slice, so everything can be re-expressed in coordinates where the spatial metric is equal to reference metric i.e. defining

$$\sigma := \phi_{t*} \xi \tag{24}$$

[b]This will not solve vacuum Einstein equations, but this is not relevant for the point made here.

constraint equations and the metric on the vacua space can be rewritten as

$$\mathcal{P}_j(\sigma) = \bar{\nabla}^i \bar{\nabla}_{[i}\sigma_{j]} = 0 \ , \tag{25}$$

$$\mathcal{H}(\sigma) = (\bar{\nabla}_i \sigma^i)^2 - \bar{\nabla}_{(i}\sigma_{j)} \bar{\nabla}^i \sigma^j = 0 \ , \tag{26}$$

$$\mathrm{g}_h(\delta_1 h, \delta_2 h) = \frac{1}{2} \int_M \left(\bar{\nabla}_{(i}\sigma_{1j)} \bar{\nabla}^i \sigma_2^j - (\bar{\nabla}_i \sigma_1^i)(\bar{\nabla}_i \sigma_2^i) \right) dV^d(\bar{h}). \tag{27}$$

We will use this coordinate frame for ease of calculation. Note that coordinate transformation to this frame will be different for each spatial slice.

Now we proceed to showing that the metric on the space of vacua, Eq. (27), is composed of the boundary data. For this we would like to decompose things into parts tangent and normal to the boundary ∂M, so we simply write everything in the basis $\{n, e^a\}$ where n is the unique normalized vector field orthogonal to ∂M and e^a is a orthogonal basis tangent to ∂M.[c] Now if one uses the momentum constraint Eq. (25) within Eq. (27), and assume vector field σ to be boundary preserving i.e.

$$n_i \sigma^i \big|_{\partial M} = 0 \ , \tag{28}$$

one can see that

$$\mathrm{g}_h(\sigma_{(1)}, \sigma_{(2)}) = \oint_{\partial M} \left(\sigma^a_{(1)} D^\perp \sigma^{(2)}_a - \mathcal{K}_{ab} \sigma^a_{(1)} \sigma^b_{(2)} \right) dV^{d-1}(\bar{k}) \tag{29}$$

where $\mathcal{K}$ is the extrinsic curvature of ∂M in M, σ^a is the part of σ^i that is tangential to ∂M, $\bar{k}$ is the induced metric on the boundary and we have defined a normal derivative

$$D^\perp \chi^a \equiv n^i \partial_i \chi^a + \Gamma^a_b \chi^b \quad \text{where} \quad \Gamma^b_a = n^i e^b_j \bar{\nabla}_i e^j_a \ . \tag{30}$$

Note that

- $D^\perp$ is $\bar{k}$-compatible.
- For a basis where $[n, e_a] = 0$ one has $\Gamma^a_b = K^a_b$.

Looking back at the metric Eq. (29) we see that it is completely composed of the boundary data, except the term with the normal derivative. Remember that σ still need to satisfy the constraint equations Eq. (25) and Eq. (26) in the bulk. If we can show given a vector field on the boundary, there exist a solution to these equations with unique normal derivative $D^\perp \sigma$ on the boundary, we can say we have reduced our action to boundary data. Let us examine these equations and their solutions.

We will start with the momentum constraint: Using the theory of differential forms on manifolds with boundary, especially the *Hodge-Morrey-Friedrichs decomposition* following theorem can be proven.[8]

[c] We take this to be true also slightly off the ∂M.

Theorem 2.1. *On a homologically trivial manifold with boundary, given a boundary vector field ζ^a, there exists a vector field σ such that*

$$P(\sigma) = 0, \quad n_i \sigma^i\big|_{\partial M} = 0, \quad \sigma^a = \zeta^a \tag{31}$$

and unique up to the gradients of scalars that vanish on the boundary. More specifically σ can be written as

$$\sigma = (d\alpha + *d * \beta)^\sharp \quad \textit{where} \quad \mathrm{n}\beta = 0 \ . \tag{32}$$

This is true in arbitrary dimensions, and in 3d it takes the form of the Helmholtz theorem. We conjecture that the arbitrariness in α will be fixed by the Hamiltonian constraint, though we were not able to prove this; please see Ref. 8 for more details.

However to show that the metric on the space of vacua is solely determined by boundary data one will not need to show this. This is because for the exact part where arbitrariness lies, one can show

$$D^\perp \partial_a \alpha\big|_{\partial M} = -\mathcal{K}_a^b \partial_b \alpha \, . \tag{33}$$

With this, we have shown that the metric on the space of vacua is solely composed of the data on the spatial boundary.

Because of this conclusion, we can consider this metric as an inner product on the space of boundary vector fields now:

$$\mathrm{g}_h(\sigma_1, \sigma_2) = \langle \zeta_{(1)}, \zeta_{(2)} \rangle_h \tag{34}$$

$$\equiv \oint_{\partial M} \left(\zeta^a_{(1)} D^\perp \zeta^{(2)}_a - \mathcal{K}_{ab} \zeta^a_{(1)} \zeta^b_{(2)} \right) dV^{d-1}(\bar{k}) \ . \tag{35}$$

We conclude this section by noting that the space of vacua now can be described as

$$\mathcal{V} \cong \frac{\mathrm{Diff}(\partial M)}{\mathrm{biso}(\bar{h})}. \tag{36}$$

We quotient by boundary preserving isometries of the reference metric since these will disappear in g_h, see the original expression Eq. (23). This quotient can be performed precisely because of our conjecture that for a given arbitrary boundary diffeomorphism there exists a unique solution to constraint equations implies $\mathrm{Diff}(\partial M) \cong \mathrm{BDiff}_C(M)$, boundary preserving diffeomorphisms of M that satisfies constraint equations.

One can show that $\mathcal{V}$ is a (pseudo-)Riemannian homogeneous space: i.e. the metric $\mathrm{g}_{\bar{h}}$ we have defined is $\mathrm{Diff}(\partial M)$ invariant. This metric will have a mixed signature. Indeed one can see $\langle , \rangle$ is zero for boundary vector fields such that

$$D^\perp \zeta^a - \mathcal{K}^a_b \zeta^b = \mathbb{D}\zeta = 0 \ . \tag{37}$$

i.e. if $\zeta \in \ker \mathbb{D}$. One can show that isometries are necessarily in $\ker \mathbb{D}$. If the reverse is not also true the metric will be degenerate on the space of vacua.

3. Geometric Continuum Mechanics Interpretation

The idea of describing motion as a trajectory on a diffeomorphism group is well-known in studies of "ideal continuum motion",[11] which are generalizations of Arnold's work on putting motion of an incompressible-ideal fluid in the Lagrangian and Hamiltonian framework.[10] In the following we summarize a covariantized generalization of ideal continuum motion of Ref. 11, as presented in Ref. 9. Later on we will see how our formalism of previous section fits within this generalization.

Consider a manifold M with a flow $\phi(x,t)$ on it. Derivative with respect to t, at $t=0$ of this flow is a vector field on M. What about at other times? At other times hardship arises since $\dot{\phi}(x,t) := \partial_t \phi(x,t)$ is the velocity at the point $\phi(x,t)$, not x. However one can define

$$\chi(x;t) := \dot{\phi}(y,t)\Big|_{y=\phi^{-1}(x;t)}, \tag{38}$$

then $\chi(x;t)$ will be a proper vector field. Now assume there exists a metric g on this manifold M, and consider the action

$$S = \frac{1}{2}\int_I \int_M g(\chi, \mathbb{D}\chi) dV_g \, dt \tag{39}$$

for some interval I of t, where dV_g is the Riemannian volume form for the metric g and $\mathbb{D} : \mathfrak{X}(M) \to \mathfrak{X}(M)$ is a self-adjoint, positive definite operator. We want to find the equation of motion for this action. Since the operator $\mathbb{D}$ is self-adjoint

$$\delta S = \int_I \int_M g(\delta\chi, \mathbb{D}\chi) dV_g \, dt. \tag{40}$$

Now let us find $\delta\chi$ in terms of $\delta\phi$. We see

$$\delta\chi^i(x;t) = \delta^i \dot{\phi}(y;t) - \partial_j \dot{\phi}(y;t) \partial_k \left(\phi^{-1}\right)^j \delta\Phi^k(x;t) \tag{41}$$

where we set $y = \phi^{-1}(x;t)$ and defined

$$\delta\Phi^i(z;t) = \delta\phi^j\left(\phi^{-1}(z;t);t\right) . \tag{42}$$

With further modifications we get

$$\delta\chi(x;t) = \partial_t \delta\Phi(x;t) + \mathcal{L}_\chi \delta\Phi , \tag{43}$$

so that

$$\delta S = \int_I \int_M g\left(\partial_t \delta\Phi + \mathcal{L}_\chi \delta\Phi, \mathbb{D}\chi\right) dV_g dt . \tag{44}$$

To get variational principle working we should integrate by parts to collect all the operators to one side. For this we note

$$\int_M g\left(\mathcal{L}_\chi \eta, \alpha\right) dV_g = \int_M \alpha_i \left(\chi^j \nabla_j \eta^i - \eta^j \nabla_j \chi^i\right) dV_g , \tag{45}$$

$$= \int_{\partial M} \alpha_i \eta^i \chi^\perp - \int_M \eta^i \left(\nabla_j \alpha_i \chi^j + \alpha_i \nabla_j \chi^j + \alpha_j \nabla_i \chi^j\right) dV_g , \tag{46}$$

where ∇ is the unique metric compatible and torsion free connection for g. We will assume M to have no boundary so that the first term drops. Defining $\mathcal{L}_\chi^\dagger$ as

$$\int_M g\left(\mathcal{L}_\chi \eta, \alpha\right) dV_g = \int_M g\left(\eta, \mathcal{L}_\chi^\dagger \alpha\right) dV_g \tag{47}$$

we see that

$$\mathcal{L}_\chi^\dagger \alpha = -\left(\nabla \cdot \chi\, \alpha + \mathcal{L}_\chi \alpha + \alpha \lrcorner \mathcal{L}_\chi g\right) \ , \tag{48}$$

where $\mathcal{L}_\chi g_{ij} = 2\nabla_{(i}\chi_{j)}$ and $\left(\alpha \lrcorner \omega\right)_j := \alpha^i \omega_{ij}$. Using this then, we see that the equation of motion becomes

$$\left(\partial_t - \mathcal{L}_\chi^\dagger\right) \mathbb{D}\chi = 0 \ . \tag{49}$$

Writing down explicitly $\mathcal{L}^\dagger$ and expressing in a basis we get

$$(\partial_t + \zeta^b \nabla_b)\mathbb{D}\zeta^a + (\nabla^a \zeta_b + \delta^a_b \nabla_c \zeta^c)\mathbb{D}\zeta^b = 0 \ . \tag{50}$$

One can retrieve some classic examples for certain choices of $\mathbb{D}$:

- $\mathbb{D} = \mathrm{id}$ gives Euler's equation for the free motion of an incompressible fluid.
- $\mathbb{D} = \mathrm{id} - \nabla^2$ gives Camassa-Holm equation for shallow water waves.

As it can be easily identified we get the system of previous subsection for the choice of $\mathbb{D} = D^\perp - \mathcal{K}^a_b$.

4. Some Results in 3+1 and 2+1 Dimensions

Having described our solutions as null geodesics on the space of boundary diffeomorphisms we now proceed to studying some specific examples.

4.1. *On Round Ball*

We start by considering the case where we take Euclidean 3d ball with round boundary as reference. Let us first look at the momentum constraint. Expressed in vector calculus form it turns out to be

$$\vec{\nabla} \times \vec{\nabla} \times \vec{\sigma} = 0 \ . \tag{51}$$

Solution to this in spherical coordinates will be

$$\vec{\sigma} = a_{\ell m} r^\ell \vec{r} \times \vec{\nabla} Y_{\ell m}(\theta, \varphi) + \vec{\nabla}\left(f_{\ell m}(r) Y_{\ell m}(\theta, \varphi)\right) \ . \tag{52}$$

Note that this satisfies our theorem: σ is composed of parts that are exact and coexact with zero normal on the boundary. We conjectured that the exact part should be fixed by the Hamiltonian constraint. However we were not able to solve it even for this simple case.

Plugging in the solution, we get for the metric on the space of vacua

$$\mathrm{g}(\sigma^{(1)}, \sigma^{(2)}) = R^3 \sum_{\ell,m} \ell(\ell+1)\left((\ell-1) a^{(1)}_{\ell m} a^{(2)}_{\ell m} - 2 f^{(1)}_{\ell m}(R) f^{(2)}_{\ell m}(R)\right) \ . \tag{53}$$

Notice that even though we do not know $f_{\ell m}(r)$ in the bulk, indeed its bulk value does not appear in the metric, as we have proposed. Moreover Hamiltonian equations forces $\mathrm{g}(\sigma,\sigma)=0$, thus we see that single towers of $a_{\ell m}$ or $f_{\ell m}$ cannot be solutions, there has to be mixing.

On the boundary our solutions have the form

$$\sigma^a = \epsilon^{ab}\partial_b\tau + \bar{k}^{ab}\partial_b\kappa \ . \tag{54}$$

Note that this is basically the Hodge decomposition of a one form on S^2, thus our solution space is set of all diffeomorphisms on S^2. Except the isotropy group: boundary preserving isometries of $\bar{h}_{ij}=\delta_{ij}$, these will be rotations. For this case the isotropy group will be equal to $\ker\mathbb{D}$ since

$$\ker\mathbb{D} = \{\sigma^a \,|a_{\ell m}=0 \ \ell>1, f_{\ell m}(R)=0 \ \forall \ell,m\} = \{\sigma^a = \sum_m a_{1m}\, R\vec{R}\times\vec{\nabla}Y_{1m}\} \ . \tag{55}$$

Thus our physical vacua space is

$$\mathcal{V} = \mathrm{Diff}(S^2)/\mathrm{SO}(3) \tag{56}$$

and our metric on this is non-degenerate.

4.2. *Case of 2 Dimensions*

Since we were not able to solve the Hamiltonian constraint to find solutions in the bulk, we now check if things simplify in $2+1$ dimensions. We will consider a flat reference metric with an arbitrary boundary, and then focus on some specific choices for the boundary. In two spatial bulk dimensions momentum equation gets solved when

$$\vec{\sigma} = c\frac{\partial}{\partial\theta} + \vec{\nabla}\alpha \tag{57}$$

where c and α is arbitrary. Hamiltonian equation then becomes

$$(\partial_x\partial_y\alpha)^2 - \partial_x^2\alpha\partial_y^2\alpha = 0 \ , \tag{58}$$

the well-known *homogeneous real Monge-Ampere equation (HRMA)*.[17] Most generalized solution to this is known in a parametric form, together with some family of explicit solutions. However we find that these mostly do not survive the boundary preservingness condition we impose for simple choices of the boundary.

Let us first consider some specific examples and start with the case of a round boundary, where $r=R$. The boundary preservingness condition become

$$\partial_r\alpha|_{r=R} = 0 \ . \tag{59}$$

We find no solution that satisfy this condition. Indeed looking at the metric we see

$$\mathrm{g}(\chi,\chi) = -\frac{2}{R^2}\int \partial_\theta\alpha(R,\theta)\partial_\theta\alpha(R,\theta)d\theta \ . \tag{60}$$

Remember that the metric is derived from the Hamiltonian condition, and thus since it cannot be made to be zero for a non trivial α, there exists no non-trivial solution to this problem. (Note that the coexact part is an isometry and will be quotiented out.)

Next simplest example is the case of an elliptic boundary. We consider an ellipse that is written as

$$r = \frac{\rho}{2} \frac{\sinh(2\Upsilon)}{\sqrt{\cosh^2 \Upsilon - \cos^2 \varphi}} \ , \tag{61}$$

where Υ and ρ are parameters of the ellipse. In this case the boundary preservingness condition is

$$\partial_u \alpha|_{\partial M} = -\frac{\rho^2 c}{4} \sin(2v) \tag{62}$$

where u, v are elliptic coordinates such that

$$x = \rho \cosh u \cos v \ , \tag{63}$$

$$y = \rho \sinh u \sin v \ . \tag{64}$$

For this case we find a solution to the HRMA equation

$$\alpha(x, y) = -\frac{\rho^2 c}{2 \cosh \Upsilon} \operatorname{sgn}(x) \ y \ F\left(\frac{y}{x}\right) \ , \tag{65}$$

where F is a hypergeometric function. However this solution has a singularity at the origin. We note here that the HRMA equation is pseudo-elliptic; its elliptic version where the right hand side is positive is more studied and results on existence exists, see e.g. Ref. 18. Because of this we think this type of singularity may not be a surprise in this case. We note that this singularity will be transferred to the resulting metric. We leave further investigation of whether a sensible solution can be obtained from this to the future.

5. Conclusions

In this note we summarized the results of Refs. 8, 9 where using Manton approximation we have proposed some adiabatic solutions of GR produced from diffeomorphisms. We have concluded that an adiabatic solution to GR can be described as a geodesic on the space of vacua

$$\mathcal{V} \sim \mathrm{Diff}(\partial M)/\mathrm{biso}(\bar{h}) \tag{66}$$

that are null with respect to the metric

$$\left\langle \zeta^1, \zeta^2 \right\rangle = \int_{\partial M} \zeta^1_a \mathbb{D} \zeta^a_2 \tag{67}$$

that is solely composed of the data on the boundary of spatial slices. We remind that along the way we have used the conjecture that the Hamiltonian constraint solves for the exact part uniquely. We argued $\mathcal{V}$ is a "pseudo"-Riemannian homogeneous space with respect to this metric. The metric has mixed but constant signature, and is degenerate if $\ker \mathbb{D} \neq \text{biso}(\bar{h})$. We showed our formulation is akin to examples in continuum mechanics in which choice of $\mathbb{D}$ is different.

For the specific example of 3 spatial dimensions with round boundary; we explicitly saw our theorems to be holding, we found our vector field only up to exact parts since Hamiltonian equation seems hard to solve. However we saw any non-trivial solution of it has to have both exact and coexact parts. We also have realized $\ker \mathbb{D} = \text{biso}(\bar{h})$ for this case. In 2 spatial dimensions things got easier in solving the Hamiltonian constraint, since it becomes the Monge-Ampere equation whose solutions are known. For round boundary we found that there exists no non-trivial solution for the vector field in the bulk that is boundary preserving, and for elliptic boundary we were only able to find a solutions that is singular at the origin.

We conclude with a quick overview of the remaining issues. First of all let us list some technical questions still to be worked out:

(1) Does Hamiltonian equation completely fixes the exact part?
(2) Is $\ker \mathbb{D} = \text{biso}(\bar{h})$?
(3) For 2d case can HRMA be solved for some boundary?

Note that only after we complete solve the bulk vector field, we can construct first σ in the bulk of each spatial slice, then we can construct ξ by making the proper transformation for each slice, and only after that one can find $h_{ij}(x,t)$ and the full space-time metric for the adiabatic solutions we propose.

Analysis thus far might be suggesting the set of solutions we propose do not survive for vacuum Einstein equations, so next logical step is to perform the analysis for Einstein equations with matter, for example with a cosmological constant. Similarly one can also consider non-compact spatial slices with some fall-off conditions at infinities and study the infrared effects. This type of study would link our work to the studies in asymptotic symmetries and soft theorems and shed a different light to the subject.

Acknowledgments

This article summarizes and slightly expands the works in Refs. 8, 9, 14 which was produced in collaboration with Dieter Van den Bleeken and Ali Seraj. I am supported by Research Fund of the Middle East Technical University, Project Number DOSAP-B-105-2021-10763.

The point spectrum of the Dirac Hamiltonian on the zero-gravity Kerr-Newman spacetime

M. Kiessling, E. Ling, and A. S. Tahvildar-Zadeh
Math Department, Rutgers University,
New Brunswick, New Jersey 08854, USA

In this short paper, we review the Dirac equation on the zero-gravity Kerr-Newman spacetime. Our main objective is to provide a correspondence between the classification of the bound states for the zGKN spectrum and the usual hydrogenic states $1s_{1/2}$, $2s_{1/2}$, etc. of the Hydrogen atom.

Keywords: Kerr-Newman, Dirac, Hamiltonian, Hydrogen, Point spectrum.

1. The purpose of this paper

The zero-gravity Kerr-Newman (zGKN) spacetime has been studied extensively.[8,9,13] In reference 9 it was shown that the discrete spectrum of the Dirac Hamiltonian on zGKN is nonempty. In an upcoming paper[10] we classify the discrete spectrum and show that the spectrum is indexed by three integers. See Theorem 2.1 below. It was conjectured[8,9] that the discrete spectrum of the Dirac Hamiltonian on zGKN should converge to the Bohr-Sommerfeld spectrum of the usual Hydrogen problem on Minkowski spacetime with a Coulomb potential in the limit as the ring radius of zGKN approaches 0. This problem remains open but a first step in solving this problem is to determine which states in the zGKN spectrum should correspond to which states in the usual hydrogenic spectrum. For example, which states should correspond to $1s_{1/2}$, $2s_{1/2}$, $2p_{1/2}$, etc.? The purpose of this paper is to provide this correspondence.

2. The zGKN spacetime

2.1. *The zGKN spacetime and the Dirac equation*

The zero-gravity Kerr-Newman (zGKN) spacetime[8] is obtained by formally taking Newton's gravitational constant $G \to 0$ in the Kerr-Newman spacetime. In Boyer-Lindquist coordinates, the resulting spacetime has line element

$$ds^2_{\mathbf{g}} = c^2dt^2 - (r^2 + a^2)\sin^2\theta d\varphi^2 - \frac{r^2 + a^2\cos^2\theta}{r^2 + a^2}\big(dr^2 + (r^2 + a^2)d\theta^2\big). \quad (1)$$

The zGKN spacetime is static and its orthogonal slices have the topology of two copies of $\mathbb{R}^3$ glued along a disc in the $z = 0$ plane; this topology is known as the

Zipoy topology.[18] Specifically the spacetime manifold is given by $\mathbb{R} \times \Sigma$ where

$$\Sigma \;=\; \big\{(r,\theta,\varphi) \mid r \in \mathbb{R},\, \theta \in [0,\pi], \varphi \in [0,2\pi)\big\} \setminus R \tag{2}$$

where R denotes the ring $R = \{r = 0, \theta = \pi/2, \varphi \in [0, 2\pi)\}$.

The electromagnetic fields on the Kerr-Newman spacetime $\mathbf{F}_{\mathrm{KN}} = d\mathbf{A}_{\mathrm{KN}}$ do not depend on Newton's gravitational constant and so they survive the $G \to 0$ limit. Hence the zGKN spacetime comes already decorated with the same electromagnetic fields. The four-potential reads

$$\mathbf{A}_{\mathrm{KN}} = -\frac{r}{r^2 + a^2\cos^2\theta}\left(\mathrm{Q}dt - \frac{\mathrm{Q}a}{c}\sin^2\theta\, d\varphi\right). \tag{3}$$

The field $\mathbf{F}$ is thus singular on the same ring $\{r = 0, \theta = \pi/2, \varphi \in [0, 2\pi)\}$ as the metric; for r very large and positive it exhibits an electric monopole of strength Q and a magnetic dipole moment of strength $\mathrm{Q}a$, while for r very negative it exhibits an electric monopole of strength $-\mathrm{Q}$ and a magnetic dipole moment of strength $-\mathrm{Q}a$.

Equipped with the Kerr-Newman electromagnetic fields, one can interpret the ring bounding the disc as an elementary particle. With this interpretation, it is natural to consider the Dirac equation

$$\tilde{\gamma}^{\mu}\left(-i\hbar\nabla_{\mu} + eA_{\mu}\right)\Psi + mc^2\Psi = 0, \tag{4}$$

on the zGKN spacetime and compare its spectral properties to that of the usual Hydrogen problem (i.e. the Dirac equation on Minkowski spacetime with a Coulomb potential centered at the origin in $\mathbb{R}^3$ within the Born-Oppenheimer approximation).

In equation (4), m is the mass of an electron, $-e$ is its fundamental charge, and A_{μ} is the 1-form electromagnetic potential for $\mathbf{F}_{\mathrm{KN}}$ related via $F_{\mu\nu} = \partial_{\mu}A_{\nu} - \partial_{\nu}A_{\mu}$. The Dirac matrices $(\tilde{\gamma}^{\mu})_{\mu=0}^{3}$ satisfy $\tilde{\gamma}^{\mu}\tilde{\gamma}^{\nu} + \tilde{\gamma}^{\nu}\tilde{\gamma}^{\mu} = 2g^{\mu\nu}$, with $g^{\mu\nu}$ the (inverse) metric coefficients of the zGKN metric.

At this point, one should recognize that if one takes the limit $a \to 0$, then (1) becomes the Minkowski metric, (3) becomes the usual Coulomb potential of a charge Q located at the origin, and (4) becomes the usual Dirac equation on Minkowski spacetime. These statements hold only formally as there are issues with the domain of the Dirac Hamiltonian when trying to make these limits precise. In particular, note that the domain of the r coordinate is $\mathbb{R}$ in zGKN while it's just $(0, \infty)$ for Minkowski spacetime. Nevertheless, the $a \to 0$ limit approach of the usual Hydrogen problem suggests a tantalizing mathematical problem.

2.2. *Separation of variables*

Using Cartan's frame method[1] with a frame well-adapted to oblate spheroidal coordinates, Chandrasekhar,[3,4] Page,[12] and Toop[16] transformed the Dirac equation (4) into an equation for a bispinor that allows a clear separation of the t, r, θ, and φ derivatives. The same transformation works for zGKN as well.[9] By introducing an

explicit diagonal matrix $\mathfrak{D} = \mathfrak{D}(r, \theta, \varphi)$ and defining $\hat{\Psi} = \mathfrak{D}^{-1}\Psi$, the Dirac equation becomes

$$(\hat{R} + \hat{A})\hat{\Psi} = 0, \tag{5}$$

where $\hat{R}$ and $\hat{A}$ are given by (with $\hbar = c = 1$ units from now on)

$$\hat{R} := \begin{pmatrix} imr & 0 & D_- - ie\mathrm{Q}\frac{r}{\varpi} & 0 \\ 0 & imr & 0 & D_+ - ie\mathrm{Q}\frac{r}{\varpi} \\ D_+ - ie\mathrm{Q}\frac{r}{\varpi} & 0 & imr & 0 \\ 0 & D_- - ie\mathrm{Q}\frac{r}{\varpi} & 0 & imr \end{pmatrix}, \tag{6}$$

$$\hat{A} := \begin{pmatrix} -ma\cos\theta & 0 & 0 & -L_- \\ 0 & -ma\cos\theta & -L_+ & 0 \\ 0 & L_- & ma\cos\theta & 0 \\ L_+ & 0 & 0 & ma\cos\theta \end{pmatrix}, \tag{7}$$

where

$$D_\pm := \pm\varpi\partial_r + \left(\varpi\partial_t + \frac{a}{\varpi}\partial_\varphi\right), \qquad L_\pm := \partial_\theta \pm i\left(a\sin\theta\partial_t + \csc\theta\partial_\varphi\right), \tag{8}$$

and

$$\varpi := \sqrt{r^2 + a^2}.$$

Once a solution $\hat{\Psi}$ to (5) is found, the bispinor $\Psi := \mathfrak{D}\hat{\Psi}$ solves the original Dirac equation (4). The explicit form of $\mathfrak{D}$ can be found in reference 9, but it's not needed for this paper.

Separation of variables is now achieved with the Ansatz that a solution $\hat{\Psi}$ of (5) is of the form

$$\hat{\Psi} = e^{-i(Et - \kappa\varphi)} \begin{pmatrix} R_1 S_1 \\ R_2 S_2 \\ R_2 S_1 \\ R_1 S_2 \end{pmatrix}, \tag{9}$$

with E a yet to be found energy eigenvalue of the Dirac hamiltonian, $\kappa \in \mathbb{Z} + \frac{1}{2}$, and with R_k being complex-valued functions of r alone, and S_k being real-valued functions of θ alone. Let

$$\vec{R} := \begin{pmatrix} R_1 \\ R_2 \end{pmatrix}, \qquad \vec{S} := \begin{pmatrix} S_1 \\ S_2 \end{pmatrix}. \tag{10}$$

Plugging the Chandrasekhar Ansatz (9) into (5) one easily finds that there must be $\lambda \in \mathbb{C}$ such that

$$T_{rad}\vec{R} = E\vec{R}, \tag{11}$$

$$T_{ang}\vec{S} = \lambda\vec{S}, \tag{12}$$

where

$$T_{rad} := \begin{pmatrix} d_- & m\frac{r}{\varpi} - i\frac{\lambda}{\varpi} \\ m\frac{r}{\varpi} + i\frac{\lambda}{\varpi} & -d_+ \end{pmatrix} \tag{13}$$

$$T_{ang} := \begin{pmatrix} ma\cos\theta & l_- \\ -l_+ & -ma\cos\theta \end{pmatrix} \tag{14}$$

The operators $d_\pm$ and $l_\pm$ are ordinary differential operators in r and θ respectively, with coefficients that depend on the unknown E, and parameters a, κ, and $e\mathrm{Q}$:

$$d_\pm := -i\frac{d}{dr} \pm \frac{-a\kappa + e\mathrm{Q}r}{\varpi^2} \tag{15}$$

$$l_\pm := \frac{d}{d\theta} \pm (aE\sin\theta - \kappa\csc\theta)\,. \tag{16}$$

2.3. *The coupled spectral problems for T_{rad} and T_{ang}*

The angular operator T_{ang} in (12) is easily seen to be essentially self-adjoint on $(C_c^\infty((0,\pi), \sin\theta d\theta))^2 \subset (L^2((0,\pi), \sin\theta d\theta))^2$, and its self-adjoint extension (also denoted T_{ang}) has a purely discrete spectrum $\lambda = \lambda_n(am, aE, \kappa) \in \mathbb{R}$, $n \in \mathbb{Z}\setminus 0$ (see references 2, 14).

With $\lambda \in \mathbb{R}$ it then follows that the radial operator T_{rad} is essentially self-adjoint on $(C_c^\infty(\mathbb{R}, dr))^2 \subset (L^2(\mathbb{R}, dr))^2$; its self-adjoint extension will also be denoted T_{rad}. Moreover, we can take $R_1 = R_2^*$ without loss of generality.[a] Thus, we can set

$$R_1 = \frac{1}{\sqrt{2}}(u - iv), \qquad R_2 = \frac{1}{\sqrt{2}}(u + iv) \tag{17}$$

for real funcions u and v. This brings the radial system (11) into the following standard (Hamiltonian) form

$$(H_{rad} - E)\begin{pmatrix} u \\ v \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \tag{18}$$

where

$$H_{rad} := \begin{pmatrix} m\frac{r}{\varpi} + \frac{\gamma r + a\kappa}{\varpi^2} & -\partial_r + \frac{\lambda}{\varpi} \\ \\ \partial_r + \frac{\lambda}{\varpi} & -m\frac{r}{\varpi} + \frac{\gamma r + a\kappa}{\varpi^2} \end{pmatrix}, \tag{19}$$

and

$$\gamma := -e\mathrm{Q} < 0. \tag{20}$$

Equation (19) should be compared with equation (7.105) in reference 15. Specifically, note that as $a \to 0$, H_{rad} approaches the radial Hamiltonian of the usual Hydrogen problem on Minkowski spacetime with a Coulomb potential.

[a] This follows by multiplying the rows of equation (11) by either R_1^* and R_2^* and adding the equations to conclude that $|R_1| = |R_2|$. Therefore $R_1 = Re^{i\phi_1}$ and $R_2 = Re^{i\phi_2}$. Again, by multiplying by conjugates, one can show that $\frac{d}{dr}(R_1/R_2^*) = 0$ which implies $\frac{d}{dr}(\phi_1 + \phi_2) = 0$.

Using techniques of Weidmann[17] it is straightforward to show that the essential spectrum of H_{rad} consists of values $E \in (-\infty, 1] \cup [1, \infty)$, and its interior is purely absolutely continuous; see reference 9. The remaining task is to characterize the discrete spectrum in the gap, i.e. the eigenvalues $E \in (-1, 1)$. In reference 9 it was shown that the spectrum is symmetric about 0, hence it suffices to consider $E > 0$.

2.4. *The Prüfer transformed system*

Following reference 9, we transform the equations (18) and (12) for the four unknowns (u, v) and (S_1, S_2) by defining four new unknowns (R, Ω) and (S, Θ) via the Prüfer transform

$$u = \sqrt{2}R\cos\frac{\Omega}{2}, \quad v = \sqrt{2}R\sin\frac{\Omega}{2}, \quad S_1 = S\cos\frac{\Theta}{2}, \quad S_2 = S\sin\frac{\Theta}{2}. \tag{21}$$

Thus

$$R = \frac{1}{2}\sqrt{u^2+v^2}, \quad \Omega = 2\tan^{-1}\frac{v}{u}, \quad S = \sqrt{S_1^2+S_2^2}, \quad \Theta = 2\tan^{-1}\frac{S_2}{S_1}. \tag{22}$$

As a result, $R_1 = Re^{-i\Omega/2}$ and $R_2 = Re^{i\Omega/2}$. Hence $\hat{\Psi}$ can be re-expressed in terms of the Prüfer variables as

$$\hat{\Psi}(t, r, \theta, \varphi) = R(r)S(\theta)e^{-i(Et-\kappa\varphi)} \begin{pmatrix} \cos(\Theta(\theta)/2)e^{-i\Omega(r)/2} \\ \sin(\Theta(\theta)/2)e^{i\Omega(r)/2} \\ \cos(\Theta(\theta)/2)e^{i\Omega(r)/2} \\ \sin(\Theta(\theta)/2)e^{-i\Omega(r)/2} \end{pmatrix}, \tag{23}$$

and we obtain the following equations for the new unknowns, first

$$\frac{d}{dr}\Omega = 2\frac{mr}{\varpi}\cos\Omega + 2\frac{\lambda}{\varpi}\sin\Omega + 2\frac{a\kappa+\gamma r}{\varpi^2} - 2E, \tag{24}$$

$$\frac{d}{dr}\ln R = \frac{mr}{\varpi}\sin\Omega - \frac{\lambda}{\varpi}\cos\Omega, \tag{25}$$

and second,

$$\frac{d}{d\theta}\Theta = -2ma\cos\theta\cos\Theta + 2\left(aE\sin\theta - \frac{\kappa}{\sin\theta}\right)\sin\Theta + 2\lambda, \tag{26}$$

$$\frac{d}{d\theta}\ln S = -ma\cos\theta\sin\Theta - \left(aE\sin\theta - \frac{\kappa}{\sin\theta}\right)\cos\Theta. \tag{27}$$

Note that the Ω-equation (24) is decoupled from R, and the Θ-equation (26) is decoupled from S. Thus the pair (24), (26) can be solved together independently of equations (25), (27), which in turn can be integrated subsequently by direct quadrature.

We can further simplify the analysis of these systems and reduce the number of parameters involved by noting that by defining the constants $a' = ma$, $E' = E/m$, and changing to the variable $r' = mr$, we eliminate m from the system. Henceforth we therefore set $m = 1$.

2.5. *Transformation onto a coupled dynamical system on cylinders*

Equations (24) and (26) exhibit the independent and the dependent variables explicitly. It is more convenient to transform them to a parametrically coupled pair of autonomous two-dimensional dynamical systems, by introducing a new independent variable τ, as follows.

Equation (26) can be written as a smooth dynamical system in the (θ, Θ) plane by introducing τ such that $\frac{d\theta}{d\tau} = \sin\theta$. Then, with dot representing differentiation in τ, we have,

$$\begin{cases} \dot{\theta} = \sin\theta \\ \dot{\Theta} = -2a\sin\theta\cos\theta\cos\Theta + 2aE\sin^2\theta\sin\Theta - 2\kappa\sin\Theta + 2\lambda\sin\theta \end{cases} \tag{28}$$

Identifying the line $\Theta = \pi$ with $\Theta = -\pi$, this becomes a dynamical system on a closed finite cylinder $\mathcal{C}_1 := [0, \pi] \times \mathbb{S}^1$. The only equilibrium points of the flow are on the two circular boundaries: Two on the left boundary: $S^- = (0, 0)$, $N^- = (0, \pi)$; two on the right: $S^+ = (\pi, -\pi)$ and $N^+ = (\pi, 0)$.

For $\kappa > 0$, the linearization of the flow at the equilibrium points reveals that S^- and S^+ are hyperbolic saddle points (with eigenvalues $\{1, -2\kappa\}$ and $\{-1, 2\kappa\}$ respectively), while N^- is a source node (with eigenvalues 1 and 2κ) and N^+ is a sink node (with eigenvalues -1 and -2κ). The situation with $\kappa < 0$ is entirely analogous, with the two critical points on each boundary switching their roles.

Similarly, the Ω equation (24) can be rewritten as a smooth dynamical system on a cylinder, in this case by setting $\tau := \frac{r}{a}$ as new independent variable, as well as introducing a new dependent variable

$$\xi := \tan^{-1}\frac{r}{a} = \tan^{-1}\tau \tag{29}$$

Then, with dot again representing differentiation in τ, (24) is equivalent to

$$\begin{cases} \dot{\xi} = \cos^2\xi \\ \dot{\Omega} = 2a\sin\xi\cos\Omega + 2\lambda\cos\xi\sin\Omega + 2\gamma\sin\xi\cos\xi + 2\kappa\cos^2\xi - 2aE \end{cases} \tag{30}$$

Once again, identifying $\Omega = -\pi$ with $\Omega = \pi$ turns this into a smooth flow on the closed finite cylinder $\mathcal{C}_2 := [-\frac{\pi}{2}, \frac{\pi}{2}] \times \mathbb{S}^1$. The only equilibrium points of the flow are on the two circular boundaries. For $E \in (0, 1)$ there are two equilibria on each: $S_E^- = (-\frac{\pi}{2}, -\pi + \cos^{-1}E)$ and $N_E^- = (-\frac{\pi}{2}, \pi - \cos^{-1}E)$ on the left boundary, and $S_E^+ = (\frac{\pi}{2}, -\cos^{-1}E)$ and $N_E^+ = (\frac{\pi}{2}, \cos^{-1}E)$ on the right boundary. $S_E^\pm$ are non-hyperbolic (degenerate) saddle-nodes, with eigenvalues 0 and $\pm 2a\sqrt{1-E^2}$, while N_E^- is a degenerate source-node and N_E^+ a degenerate sink-node (see Theorem 2.19(iii) in reference 6).

In reference 9, it was shown that E is an energy eigenvalue of the Dirac Hamiltonian and the corresponding Ψ is a bound state if and only if there exists a $\lambda \in \mathbb{R}$ such that each of the two dynamical systems above possesses a *saddles connector,* i.e. an orbit on $\mathcal{C}_1$ connecting the two saddle-nodes S^- and S^+ in the Θ-system (28) and an orbit on $\mathcal{C}_2$ connecting the two saddle-nodes S_E^- and S_E^+ in the Ω-system (30).

Given a dynamical system on a cylinder, there corresponds an integer known as the *winding number* which describes how many times an orbit in the dynamical system winds around the cylinder before terminating at an equilibrium point. See reference 9 and the upcoming paper 10. For the Ω system, saddles connectors with different winding numbers correspond to different energy values (with energy increasing as the winding number increases). In reference 9 it was shown that a bound state Ψ exists corresponding to winding number $N_\Theta = 0$ for the Θ system and winding number $N_\Omega = 0$ for the Ω system (and $\kappa = \frac{1}{2}$). In the upcoming paper 10, we improve on this result by fully classifying the spectrum. Specifically, we prove the following theorem.

Theorem 2.1. *Set* $a_{\max} = 1 - \frac{1}{\sqrt{2}}$ *and* $\gamma_{\min} = -\frac{1}{2}$. *Fix* $a \in (0, a_{\max})$, $\gamma \in (\gamma_{\min}, 0)$, *and* $\kappa \in \mathbb{Z} + \frac{1}{2}$. *Assume* Ψ *is of the form* (23) *constructed from solutions of* (24)–(27).

- *Suppose* $N_\Theta \geq 0$ *is an integer. For all integers* $N_\Omega \geq 0$, *there is a bound state* Ψ *such that the* Θ *system and* Ω *system have winding numbers* N_Θ *and* N_Ω, *respectively. There are no bound states with* $N_\Omega \leq -1$.
- *Suppose* $N_\Theta \leq -1$ *is an integer. For all integers* $N_\Omega \geq 1$, *there is a bound state* Ψ *such that the* Θ *system and* Ω *system have winding numbers* N_Θ *and* N_Ω, *respectively. There are no bound states with* $N_\Omega \leq 0$.

Our conditions on a and γ are used to ensure that there are no bound states with $N_\Omega \leq -1$ for $N_\Theta \geq 0$ and no bound states with $N_\Omega \leq 0$ for $N_\Theta \leq -1$, which, as we will see in the next section, occurs in an analogous way for the familiar hydrogenic Dirac operator on a Minkowski background with a Coulomb potential.

When restoring units and mass m, we have $a_{\max} = (1 - \frac{1}{\sqrt{2}})\frac{\hbar}{mc}$ and $\gamma_{\min} = -\frac{1}{2}\hbar c$. If, with the hydrogenic problem in mind, we set $\gamma = -Ze^2$, then $\gamma \in (\gamma_{\min}, 0)$ implies $\frac{Ze^2}{\hbar c} < \frac{1}{2}$, that is, $Z < \frac{137.036}{2}$. Now let's compare these conditions with the conditions on Z for the familiar hydrogenic Dirac operator on a Minkowski background with a Coulomb potential, for which essential self-adjointness breaks down for $Z > 118$. For the Dirac operator on zGKN, there is no condition for essential self-adjointness.[9] So our conditions are probably not optimal.

3. Relating the zGKN bound states to the usual hydrogenic states

In this section we relate the zGKN bound states found in Theorem 2.1 to the usual hydrogenic states of the Dirac problem on Minkowski spacetime with a Coulomb potential. The main objective is to relate the winding numbers which appear in Theorem 2.1 to the usual spectroscopic notation $n\ell_j$ of hydrogenic states.

3.1. *The correspondence between winding numbers and the usual spectroscopic notation of hydrogenic states*

Based on the above results, for fixed a and γ, the discrete spectrum of our Dirac Hamiltonian is indexed by *three* integers: N_Ω, N_Θ, and 2κ. By contrast, the energy spectrum of special relativistic Hydrogen, i.e., the Dirac Hamiltonian for a point-like electron in ordinary Minkowski space interacting with a Coulomb point charge at the origin, is indexed by *two* integers only, namely the main (or Bohr's) quantum number, often denoted by n, and the spin-orbit quantum number[b], i.e., the set of eigenvalues of the spin-orbit operator $K = \beta(2\mathbf{S}\cdot\mathbf{L} + 1)$.

In the limit $a \to 0$, the angular Hamiltonian (14), takes the simple form

$$\mathfrak{a}_\kappa := \lim_{a\to 0} T_{ang} = i\sigma_2\partial_\theta + \frac{\kappa}{\sin\theta}\sigma_1. \tag{31}$$

From reference 2, if λ is an eigenvalue of T_{ang}, then $k := \lim_{a\to 0}\lambda$ is an eigenvalue of $\mathfrak{a}_\kappa$, also the limit defining k exists since λ is analytic in a. Note that $\mathfrak{a}_\kappa$ is independent of E unlike T_{ang}.

In the limit $a \to 0$, the formal limit of the radial Hamiltonian (19) coincides with the radial Hamiltonian arising in the special relativistic Hydrogen problem (e.g. see reference 15, eq. (7.105)):

$$\mathfrak{h}_k := \lim_{a\to 0} H_{rad} = \begin{pmatrix} m + \dfrac{\gamma}{r} & -\partial_r + \dfrac{k}{r} \\ \partial_r + \dfrac{k}{r} & -m + \dfrac{\gamma}{r} \end{pmatrix}. \tag{32}$$

Therefore k can be identified with the *spin-orbit coupling*.

The spectrum of $\mathfrak{a}_\kappa$ is completely understood.[2] In particular, for all half-integers $\kappa \in Z + \frac{1}{2}$, the operator $\mathfrak{a}_\kappa$ is essentially self-adjoint and has a discrete spectrum indexed by a nonzero integer which we call N:

$$k = -\mathrm{sgn}(N)\left(|N| + |\kappa| - \frac{1}{2}\right), \tag{33}$$

as well as a complete set of eigenvectors $\vec{S}_{N,\kappa}$ that are explicitly known and can be expressed in terms of Jacobi polynomials.

$$\vec{S}_{N,\kappa}(\theta) := \sin^{\kappa+\frac{1}{2}}\theta \begin{pmatrix} -\sqrt{\cot\frac{\theta}{2}}\,P^{\kappa-\frac{1}{2},\kappa+\frac{1}{2}}_{|N|-1}(\cos\theta) \\ \mathrm{sgn}(N)\sqrt{\tan\frac{\theta}{2}}\,P^{\kappa+\frac{1}{2},\kappa-\frac{1}{2}}_{|N|-1}(\cos\theta) \end{pmatrix}. \tag{34}$$

Note that the above holds for $\kappa > 0$. To find the eigenvectors for $\kappa < 0$, recognize that if $\vec{S}$ is an eigenvector of $\mathfrak{a}_\kappa$, then $i\sigma_2\vec{S}$ is an eigenvector of $\mathfrak{a}_{-\kappa}$.

[b]The spin-orbit quantum number is called κ_j in reference;[15] it should not be confused with our κ, which is the eigenvalue of the z-component of angular momentum, for which Thaller uses the notation m_j.

From the above and the definition of Θ it follows that the saddles connectors of the Θ-system that correspond to the eigenvectors of the angular Hamiltonian are given explicitly by the formula

$$\Theta_{N,\kappa}(\theta) = -\mathrm{sgn}(N)\left\{2\tan^{-1}\left(\frac{P_{|N|-1}^{|\kappa|+\frac{1}{2},|\kappa|-\frac{1}{2}}(\cos\theta)}{P_{|N|-1}^{|\kappa|-\frac{1}{2},|\kappa|+\frac{1}{2}}(\cos\theta)}\tan\frac{\theta}{2}\right) - \pi\boldsymbol{\chi}_{\kappa<0}\right\}. \tag{35}$$

Here the branch of $\tan^{-1}$ needs to be chosen in such a way that $\Theta_{N,\kappa}$ is continuous on $[0,\pi]$.

The above formula implies that we can fix the initial value of the saddles connectors to be

$$\Theta_{N,\kappa}(0) = \begin{cases} 0 & \kappa > 0 \\ \mathrm{sgn}(N)\pi & \kappa < 0. \end{cases} \tag{36}$$

and that for the final value of those connectors, we need

$$\Theta_{N,\kappa}(\pi) = \begin{cases} -\mathrm{sgn}(N)\pi & \kappa > 0 \\ 0 & \kappa < 0 \end{cases} \qquad [\mathrm{mod} 2\pi] \tag{37}$$

in agreement with what we have already observed about the boundary values of the saddles connectors for the Θ-system (28).

Furthermore, from the properties of Jacobi polynomials, it follows that for $\Theta_{N,\kappa}$ to be a continuous function of θ on $[0,\pi]$, we need

$$\Theta_{N,\kappa}(\pi) = -2\pi\mathrm{sgn}(N)(|N|-1) + \begin{cases} -\mathrm{sgn}(N)\pi & \kappa > 0 \\ 0 & \kappa < 0 \end{cases} \tag{38}$$

Thus we establish a correspondence between the integer N and the winding number N_Θ of the Θ-saddles connectors in the case $a = 0$.

$$N_\Theta \sim \begin{cases} N-1 & N \geq 1 \\ N & N \leq -1, \end{cases} \tag{39}$$

where '$\sim$' simply means a correspondence.

From the relationship (33) between the eigenvalue k and the number N it follows that instead of N we can equally well label the angular eigenstates by the integer k, in which case

$$N \;=\; -\mathrm{sgn}(k)\left(|k| - |\kappa| + \frac{1}{2}\right). \tag{40}$$

We now turn our attention to the radial Hamiltonian $\mathfrak{h}_k = \lim_{a\to 0} H_{rad}$. This operator is closely related to the radial Hamiltonian h_k of the special-relativistic Hydrogen problem, as formulated by Dirac:[5]

$$h_k = -i\sigma_2\partial_r + m\sigma_3 + \frac{k}{r}\sigma_1 + \frac{\gamma}{r}I_{2\times 2}. \tag{41}$$

The only difference between h_k and $\mathfrak{h}_k$ is their domains: Since H_{rad} is defined on the double-sheeted Sommerfeld space, this is inherited by its $a \to 0$ limit $\mathfrak{h}_k$, which

is still defined on two copies of Minkowski space glued together along a timelike line. In particular the r variable in $\mathfrak{h}_k$ has the range $(-\infty, \infty)$. By contrast, the r variable in h_k goes from 0 to ∞. The eigenvalue problem for h_k was shown to be exactly solvable by Gordon,[7] who proved the discrete spectrum to coincide exactly with the Bohr-Sommerfeld spectrum, and found explicit formulas for the eigenfunctions in terms of generalized Laguerre polynomials.

Consider first the restriction of $\mathfrak{h}_k$ to functions supported in the sheet $r > 0$. As described in detail in section 7.4 of Thaller's book,[15] this operator, for all $k \in \mathbb{Z}\backslash\{0\}$, is essentially self-adjoint on $C_c^\infty((0,\infty))$, has a discrete spectrum in $(0,1)$ and a complete set of eigenvectors, if $-\sqrt{3}/2 < \gamma < 0$. The discrete spectrum is indexed by two integers, $n \geq 1$ and $k = -n, \ldots, -1, 1, \ldots, n-1$. Let $M := n - |k|$. Then we have

$$E_{M,k} \;=\; \frac{m}{\sqrt{1 + \left(\frac{\gamma^2}{M + \sqrt{k^2 - \gamma^2}}\right)^2}} \tag{42}$$

Note that the case $k > 0$ and $M = 0$ is excluded.

Gordon[7] computed the corresponding eigenfunctions in terms of generalized Laguerre polynomials: Let (ϕ_1, ϕ_2) be defined by

$$u = \sqrt{1 + E_{M,k}}(\phi_1 + \phi_2), \qquad v = \sqrt{1 - E_{M,k}}(\phi_1 - \phi_2) \tag{43}$$

where (u, v) is an eigenfunction of $\mathfrak{h}_k$ with eigenvalue $E_{M,k}$ (and we have set $m = 1$). Then, using the abbreviations

$$\rho := \sqrt{k^2 - \gamma^2}, \qquad \eta := \sqrt{1 - E_{M,k}^2} \tag{44}$$

we have that for all nonnegative integers M and real constants c_1, c_2 such that

$$\mu := \frac{c_1}{c_2} = \frac{M}{k + \frac{\gamma}{\eta}}. \tag{45}$$

we have

$$\phi_1(r) \;=\; c_1 e^{-\eta r} r^\rho F(-M+1, 2\rho+1, 2\eta r) \tag{46}$$

$$\phi_2(r) \;=\; c_2 e^{-\eta r} r^\rho F(-M, 2\rho+1, 2\eta r) \tag{47}$$

where F denotes Gauss's *confluent hypergeometric function*

$$F(\alpha, \beta, x) \;=\; 1 + \frac{\alpha}{1!\beta}x + \frac{\alpha(\alpha+1)}{2!\beta(\beta+1)}x^2 + \ldots \tag{48}$$

Note that when α is a negative integer, the above series terminates, and F is a polynomial of degree $-\alpha$, which (up to a numerical factor) is the generalized Laguerre polynomial $L_{-\alpha}^{(\beta-1)}(x)$.

Accordingly, since $\Omega = 2\tan^{-1}\frac{v}{u}$, the corresponding solution to the $a \to 0$ limit of the Ω-equation (24) will be

$$\Omega(r) = 2\tan^{-1}\left(\sqrt{\frac{1-E}{1+E}}\;\frac{\mu F(-M+1, 2\rho+1, 2\eta r) - F(-M, 2\rho+1, 2\eta r)}{\mu F(-M+1, 2\rho+1, 2\eta r) + F(-M, 2\rho+1, 2\eta r)}\right) \tag{49}$$

The values of Ω at $r = 0$ and $r = \infty$ can thus be calculated (modulo 2π):

$$\Omega(0) \;=\; 2\tan^{-1}\left(\sqrt{\frac{1-E}{1+E}}\;\frac{\mu-1}{\mu+1}\right) = \sin^{-1}(\frac{-\gamma}{k}) \tag{50}$$

$$\Omega(\infty) \;=\; -2\tan^{-1}\left(\sqrt{\frac{1-E}{1+E}}\right) \;=\; -\cos^{-1}E \tag{51}$$

which is in agreement with the analysis of the equilibrium points of the corresponding dynamical system. We choose our principal branch of $\sin^{-1}$ depending on the sign of k:

$$\Omega(0) \;=\; \begin{cases} \sin^{-1}(\frac{-\gamma}{k}) & \text{if } k < 0. \\ -\pi - \sin^{-1}(\frac{-\gamma}{k}) & \text{if } k > 0 \end{cases} \tag{52}$$

On the other hand, from the properties of Laguerre polynomials, it follows that the denominator of the rational function in (49) has M zeros in $[0, \infty)$ when $k < 0$ and $M - 1$ zeros when $k > 0$ (note that this explains why $k \leq n - 1$). Thus in order for Ω to be a continuous function of r, the branch of $\tan^{-1}$ needs to be chosen such that -2π gets added to the value every time r crosses one of those poles, which implies that

$$\Omega(\infty) \;=\; -2\pi M - \cos^{-1}E \tag{53}$$

which holds for both $k < 0$ and $k > 0$ (this is why we chose $\Omega(0) = -\pi - \sin^{-1}(\frac{-\gamma}{k})$ for $k > 0$). Thus we establish the following correspondence between the integer M and the winding number N_Ω for the Ω-saddles connectors in the case $a = 0$.

$$N_\Omega \;\sim\; M. \tag{54}$$

Now consider the case $a > 0$ (i.e. the Dirac Hamiltonian on zGKN). The bound states are indexed by three integers N_Θ, N_Ω, and 2κ appearing in Theorem 2.1. Using (54) and (39), we can define a correspondence between the integers $N_\Theta, N_\Omega, 2\kappa$ and the usual spectroscopic notation $n\ell_j$ of hydrogenic states. Given N_Θ and N_Ω, define N and M via

$$N \;:=\; \begin{cases} N_\Theta + 1 & N_\Theta \geq 0 \\ N_\Theta & N_\Theta \leq -1, \end{cases} \qquad \text{and} \qquad M \;:=\; N_\Omega. \tag{55}$$

Then n, ℓ, and j appearing in $n\ell_j$ are given by

$$k \;:=\; -N - \operatorname{sgn}(N)\big(|\kappa| - \frac{1}{2}\big) \tag{56}$$

$$n \;:=\; M + |k| \tag{57}$$

$$j \;:=\; |k| - \frac{1}{2} \tag{58}$$

$$\ell \;:=\; j + \operatorname{sgn}(k)\frac{1}{2} \tag{59}$$

$$m_j \;:=\; \kappa. \tag{60}$$

This establishes the desired correspondence between the winding numbers appearing in Theorem 2.1 and the usual spectroscopic notation $n\ell_j$ of hydrogenic states. For example, suppose we ask: which state in zGKN corresponds to $2p_{1/2}$ with $m_{1/2} = -\frac{1}{2}$? Well $\ell = 1$ implies $1 = \frac{1}{2} + \mathrm{sgn}(k)\frac{1}{2}$. Therefore k is positive and so $j = \frac{1}{2}$ implies $k = 1$. Therefore $N = -1$ implies $N_\Theta = -1$. Lastly, $n = 2$ implies $M = 1$ and so $N_\Omega = 1$. Thus the state $2p_{1/2}$ with $m_{1/2} = -\frac{1}{2}$ corresponds to $N_\Theta = -1$, $N_\Omega = 1$, and $\kappa = -\frac{1}{2}$.

3.2. *Breaking degeneracies*

It is well known that the energy levels of the special-relativistic Hydrogen Hamiltonian are independent of m_j, the eigenvalue of the z-component of total angular momentum, while the eigenstates of it do depend on m_j. As a result, all energy levels are degenerate in that case, i.e. have multiplicity at least two. In the case of our Hamiltonian H_{rad}, this degeneracy is broken by the appearance of $a\kappa$ in equation (19). This yields a hyperfine-like splitting of the spectral lines, which in the standard setting is thought of as being a consequence of the nucleus having a magnetic dipole moment. In our setting, it can be thought of as following from the nonzero $d\varphi$ term in equation (3) which produces a magnetic dipole moment.

In addition to the above symmetry-related degeneracy, Dirac's original model for special-relativistic Hydrogen also has *accidental* degeneracies; the energy eigenvalues do not depend on the *sign* of the spin-orbit quantum number k, only on its magnitude, while the eigenstates do depend on the sign of k. The celebrated experiment of Lamb[11] showed that this degeneracy is only in Dirac's model, not in nature, i.e., the measured energy levels of orbitals corresponding to k and $-k$ are slightly different. This difference is known as the *Lamb shift*. In our model, these accidental degeneracies are also broken producing a small but observable Lamb shift-like effect.

Recall that hyperfine splitting and the Lamb shift are calculated using perturbative techniques. It is important to note that our model does not use perturbation theory to calculate energy differences.

In the upcoming paper,[10] we will report on numerical results of the zGKN spectrum showing the breaking of these degeneracies for various values of a.

Causal fermion systems: Classical gravity and beyond

Felix Finster
Fakultät für Mathematik, Universität Regensburg, D-93040 Regensburg, Germany
E-mail: finster@ur.de
www.mathematik.ur.de/Mat1

In this short review, we explain how and in which sense the causal action principle for causal fermion systems gives rise to classical gravity and the Einstein equations. Moreover, methods are presented for going beyond classical gravity, with applications to a positive mass theorem for static causal fermion systems, a connection between area change and matter flux and the construction of a quantum state.

Keywords: Causal fermion system, causal action principle, globally hyperbolic spacetimes, Einstein equations, surface layer integrals.

1. Introduction

The theory of *causal fermion systems* is a recent approach to fundamental physics (see a few basics in Section 2, the reviews,[8,10] the textbooks[7,14] or the website[1]). In this approach, spacetime and all objects therein are described by a measure ρ on a set $\mathcal{F}$ of linear operators on a Hilbert space $(\mathcal{H}, \langle .|. \rangle_{\mathcal{H}})$. The physical equations are formulated via the so-called *causal action principle*, a nonlinear variational principle where an action $\mathcal{S}$ is minimized under variations of the measure ρ.

The purpose of this survey article is to report on the present status of the theory with regards to the gravitational interaction. It has been shown that, in a well-defined limiting case, the so-called *continuum limit*, the causal action principles gives classical gravity and the Einstein equations, with the gravitational coupling constant determined by the regularization scale. Without taking the continuum limit, the causal action principle describes a novel gravitational theory which is presently under investigation. We here give a survey on different approaches towards unraveling the structure and the properties of this gravitational theory.

The paper is structured as follows. After giving the necessary background on causal fermion systems (Section 2), we explain how and in which sense classical gravity and the Einstein equations are obtained in the continuum limit (Section 3). In Section 4 we report on the approaches for going beyond classical gravity. After a few comments on the intrinsic geometric structures of a causal fermion system (Section 4.1), we introduce surface layer integrals as the main object for the subsequent analysis (Section 4.2). We finally report on a positive mass theorem for static causal fermion systems (Section 4.3), a relation between area change and matter flux (Section 4.4) and the construction of a quantum state (Section 4.5).

2. A Brief Introduction to Causal Fermion Systems

This section provides the necessary abstract background on causal fermion systems.

2.1. *Causal Fermion Systems and the Causal Action Principle*

We begin with the general definitions.

Definition 2.1. (causal fermion systems) *Given a separable complex Hilbert space $\mathcal{H}$ with scalar product $\langle .|. \rangle_{\mathcal{H}}$ and a parameter $n \in \mathbb{N}$ (the* spin dimension*), we let $\mathcal{F} \subset L(\mathcal{H})$ be the set of all symmetric operators on $\mathcal{H}$ of finite rank, which (counting multiplicities) have at most n positive and at most n negative eigenvalues. On $\mathcal{F}$ we are given a positive measure ρ (defined on a σ-algebra of subsets of $\mathcal{F}$). We refer to $(\mathcal{H}, \mathcal{F}, \rho)$ as a* causal fermion system*.*

A causal fermion system describes a spacetime together with all structures and objects therein. In order to single out the physically admissible causal fermion systems, one must formulate physical equations. To this end, we impose that the measure ρ should be a minimizer of the causal action principle, which we now introduce. For any $x, y \in \mathcal{F}$, the product xy is an operator of rank at most $2n$. However, in general it is no longer symmetric because $(xy)^* = yx$, and this is different from xy unless x and y commute. As a consequence, the eigenvalues of the operator xy are in general complex. We denote the non-trivial eigenvalues counting algebraic multiplicities by $\lambda_1^{xy}, \ldots, \lambda_{2n}^{xy} \in \mathbb{C}$ (more specifically, denoting the rank of xy by $k \leq 2n$, we choose $\lambda_1^{xy}, \ldots, \lambda_k^{xy}$ as all the non-zero eigenvalues and set $\lambda_{k+1}^{xy}, \ldots, \lambda_{2n}^{xy} = 0$). We introduce the Lagrangian and the causal action by

$$\textit{Lagrangian:} \qquad \mathcal{L}(x,y) = \frac{1}{4n} \sum_{i,j=1}^{2n} \left(\left|\lambda_i^{xy}\right| - \left|\lambda_j^{xy}\right| \right)^2 \tag{1}$$

$$\textit{causal action:} \qquad \mathcal{S}(\rho) = \iint_{\mathcal{F}\times\mathcal{F}} \mathcal{L}(x,y)\, d\rho(x)\, d\rho(y)\,. \tag{2}$$

The *causal action principle* is to minimize $\mathcal{S}$ by varying the measure ρ under the following constraints,

$$\textit{volume constraint:} \qquad \rho(\mathcal{F}) = \text{const} \tag{3}$$

$$\textit{trace constraint:} \qquad \int_{\mathcal{F}} \mathrm{tr}(x)\, d\rho(x) = \text{const} \tag{4}$$

$$\textit{boundedness constraint:} \qquad \iint_{\mathcal{F}\times\mathcal{F}} |xy|^2\, d\rho(x)\, d\rho(y) \leq C\,, \tag{5}$$

where C is a given parameter, tr denotes the trace of a linear operator on $\mathcal{H}$, and the absolute value of xy is the so-called spectral weight,

$$|xy| := \sum_{j=1}^{2n} \left|\lambda_j^{xy}\right|.$$

This variational principle is mathematically well-posed if $\mathcal{H}$ is finite-dimensional. For the existence theory and the analysis of general properties of minimizing measures we refer to[3,5] or [14, Chapter 12]. In the existence theory one varies in the class of regular Borel measures (with respect to the topology on $\mathrm{L}(\mathcal{H})$ induced by the operator norm), and the minimizing measure is again in this class. With this in mind, here we always assume that

$$\rho \text{ is a regular Borel measure}\,.$$

2.2. *Spacetime and Causal Structure*

Let ρ be a *minimizing* measure. *Spacetime* is defined as the support of this measure,

$$M := \operatorname{supp} \rho \;\subset\; \mathcal{F}\,.$$

Thus the spacetime points are symmetric linear operators on $\mathcal{H}$. On M we consider the topology induced by $\mathcal{F}$ (generated by the operator norm on $\mathrm{L}(\mathcal{H})$). Moreover, the measure $\rho|_M$ restricted to M gives a volume measure on spacetime. This gives spacetime the structure of a *topological measure space*.

The operators in M contain a lot of information which, if interpreted correctly, gives rise to spacetime structures like causal and metric structures, spinors and interacting fields (for details see [7, Chapter 1]). All the resulting objects are *inherent* in the sense that we only use information already encoded in the causal fermion system. Here we restrict attention to those structures needed in what follows. We begin with the following notion of causality:

Definition 2.2. (causal structure) *For any $x, y \in \mathcal{F}$, we again denote the non-trivial eigenvalues of the operator product xy (again counting algebraic multiplicities) by $\lambda_1^{xy}, \ldots, \lambda_{2n}^{xy}$. The points x and y are called* spacelike *separated if all the λ_j^{xy} have the same absolute value. They are said to be* timelike *separated if the λ_j^{xy} are all real and do not all have the same absolute value. In all other cases (i.e. if the λ_j^{xy} are not all real and do not all have the same absolute value), the points x and y are said to be* lightlike *separated.*

Restricting the causal structure of $\mathcal{F}$ to M, we get causal relations in spacetime.

The Lagrangian (1) is compatible with the above notion of causality in the following sense. Suppose that two points $x, y \in M$ are spacelike separated. Then the eigenvalues λ_i^{xy} all have the same absolute value. As a consequence, the Lagrangian (1) vanishes. Thus pairs of points with spacelike separation do not enter the action. This can be seen in analogy to the usual notion of causality where points with spacelike separation cannot influence each other. This is the reason for the notion "causal" in *causal* fermion system and *causal* action principle.

Moreover, a causal fermion system distinguishes a *direction of time*. To this end, we let π_x be the orthogonal projection in $\mathcal{H}$ on the subspace $x(\mathcal{H}) \subset \mathcal{H}$ and introduce the functional

$$\mathcal{C} \;:\; M \times M \to \mathbb{R}\,, \qquad \mathcal{C}(x,y) := i \operatorname{tr}\big(y\, x\, \pi_y\, \pi_x - x\, y\, \pi_x\, \pi_y\big)\,.$$

Obviously, this functional is anti-symmetric in its two arguments, making it possible to introduce the notions

$$\begin{cases} y \text{ lies in the } \textit{future} \text{ of } x & \text{if } \mathcal{C}(x,y) > 0 \\ y \text{ lies in the } \textit{past} \text{ of } x & \text{if } \mathcal{C}(x,y) < 0\,. \end{cases}$$

2.3. *The Euler-Lagrange Equations*

A minimizer of a causal variational principle satisfies the following *Euler-Lagrange (EL) equations*. For a suitable value of the parameter $\mathfrak{s} > 0$, the function $\ell : \mathcal{F} \to \mathbb{R}_0^+$ defined by

$$\ell(x) := \int_M \mathcal{L}_\kappa(x,y)\, d\rho(y) - \mathfrak{s} \tag{6}$$

is minimal and vanishes on spacetime $M := \operatorname{supp} \rho$,

$$\ell|_M \equiv \inf_{\mathcal{F}} \ell = 0\,. \tag{7}$$

Here the *κ-Lagrangian* $\mathcal{L}_\kappa$ is defined by

$$\mathcal{L}_\kappa \;:\; \mathcal{F} \times \mathcal{F} \to \mathbb{R}\,, \qquad \mathcal{L}_\kappa(x,y) := \mathcal{L}(x,y) + \kappa\, |xy|^2 \tag{8}$$

with a non-negative parameter κ, which can be thought of as the Lagrange parameter corresponding to the boundedness constraint. Likewise, the parameter $\mathfrak{s} \geq 0$ in (6) is the Lagrange parameter corresponding to the volume constraint. For the derivation and further details we refer to [16, Section 2] or [14, Chapter 7].

2.4. *Spinors and Physical Wave Functions*

A causal fermion system also gives rise to spinorial wave functions in spacetime, as we now explain. For every $x \in \mathcal{F}$ we define the *spin space* S_x by $S_x = x(\mathcal{H})$; it is a subspace of $\mathcal{H}$ of dimension at most $2n$. It is endowed with the *spin inner product* $\prec .|. \succ_x$ defined by

$$\prec u|v\succ_x = -\langle u|xv\rangle_{\mathcal{H}} \qquad (\text{for all } u, v \in S_x)\,. \tag{9}$$

A *wave function* ψ is defined as a function which to every $x \in M$ associates a vector of the corresponding spin space,

$$\psi \;:\; M \to \mathcal{H} \qquad \text{with} \qquad \psi(x) \in S_x M \quad \text{for all } x \in M\,.$$

It is an important observation that every vector $u \in \mathcal{H}$ of the Hilbert space gives rise to a unique wave function denoted by ψ^u. It is obtained by projecting the vector u to the corresponding spin spaces,

$$\psi^u \;:\; M \to \mathcal{H}\,, \qquad \psi^u(x) := \pi_x u \in S_x M\,. \tag{10}$$

We refer to ψ^u as the *physical wave function* of the vector $u \in \mathcal{H}$. Choosing an orthonormal basis (e_i) of $\mathcal{H}$, we obtain a whole family of physical wave functions (ψ^{e_i}).

This ensemble of wave functions is crucial for the understanding of what a causal fermion systems is about. In fact, all spacetime structures (like for example the causal structure in Definition 2.2) can be recovered from this ensemble. Moreover, one can construct concrete examples of causal fermion systems by choosing the physical wave functions more specifically as the quantum mechanical wave functions in a classical Lorentzian spacetime. In the next section we explain this construction in more detail.

3. The Limiting Case of Classical Gravity

In this section we outline how and in which sense the causal action principle gives rise to classical gravity. For more details we refer to[7] and the review article.[8]

3.1. *Describing a Lorentzian Spacetime by a Causal Fermion System*

We now explain how a classical curved spacetime is described by a causal fermion system. Our starting point is Lorentzian spin geometry. Thus we let $(\mathscr{M}, g)$ be a smooth, globally hyperbolic, time-oriented Lorentzian spin manifold of dimension four. For the signature of the metric we use the convention $(+,-,-,-)$. We denote the corresponding spinor bundle by $S\mathscr{M}$. Its fibers $S_x\mathscr{M}$ (with $x \in \mathscr{M}$) are endowed with an inner product $\prec .|. \succ_x$ of signature $(2,2)$. Clifford multiplication is described by a mapping γ which satisfies the anti-commutation relations,

$$\gamma \,:\, T_x\mathscr{M} \to \mathrm{L}(S_x\mathscr{M}) \qquad \text{with} \qquad \gamma(u)\,\gamma(v) + \gamma(v)\,\gamma(u) = 2\,g(u,v)\,\mathbb{1}_{S_x(\mathscr{M})}\,.$$

We also write Clifford multiplication in components with the Dirac matrices γ^j. The metric connections on the tangent bundle and the spinor bundle are denoted by ∇. The sections of the spinor bundle are also referred to as wave functions.

We denote the smooth sections of the spinor bundle by $C^\infty(\mathscr{M}, S\mathscr{M})$. The Dirac operator $\mathcal{D}$ is defined by

$$\mathcal{D} := i\gamma^j \nabla_j \,:\, C^\infty(\mathscr{M}, S\mathscr{M}) \to C^\infty(\mathscr{M}, S\mathscr{M})\,.$$

Given a real parameter $m \in \mathbb{R}$ (the *mass*), the Dirac equation reads

$$(\mathcal{D} - m)\,\psi = 0\,.$$

We mainly consider solutions in the class $C^\infty_{\mathrm{sc}}(\mathscr{M}, S\mathscr{M})$ of smooth sections with spatially compact support (i.e. wave functions whose restriction to any Cauchy surface is compact). On such solutions, one has the scalar product

$$(\psi|\phi)_m = 2\pi \int_{\mathscr{N}} \prec \psi \,|\, \gamma(\nu)\,\phi \succ_x d\mu_{\mathscr{N}}(x)\,,$$

where $\mathscr{N}$ denotes any Cauchy surface and ν its future-directed normal (due to current conservation, the scalar product is in fact independent of the choice

of $\mathcal{N}$; for details see [20, Section 2]). Forming the completion gives the Hilbert space $(\mathcal{H}_m, (.|.)_m)$.

Next, we choose a closed subspace $\mathcal{H} \subset \mathcal{H}_m$ of the solution space of the Dirac equation. The induced scalar product on $\mathcal{H}$ is denoted by $\langle .|. \rangle_{\mathcal{H}}$. There is the technical difficulty that the wave functions in $\mathcal{H}$ are in general not continuous, making it impossible to evaluate them pointwise. For this reason, we need to introduce an *ultraviolet regularization* on the length scale ε, described mathematically by a linear

$$\textit{regularization operator} \qquad \mathfrak{R}_\varepsilon \;:\; \mathcal{H} \to C^0(\mathcal{M}, S\mathcal{M})\,.$$

In the simplest case, the regularization can be realized by a convolution on a Cauchy surface or in spacetime (for details see [20, Section 4] or [7, Section §1.1.2]). For us, the regularization is not merely a technical tool, but it realizes the concept that we want to change the geometric structures on the microscopic scale. With this in mind, we always consider the regularized quantities as those having mathematical and physical significance. Different choices of regularization operators realize different microscopic spacetime structures.

Evaluating the regularization operator at a spacetime point $x \in \mathcal{M}$ gives the *regularized wave evaluation operator* $\Psi^\varepsilon(x)$,

$$\Psi^\varepsilon(x) = \mathfrak{R}_\varepsilon(x) \;:\; \mathcal{H} \to S_x\mathcal{M}\,. \tag{11}$$

We also take its adjoint (with respect to the Hilbert space scalar product $\langle .|. \rangle_{\mathcal{H}}$ and the spin inner product $\prec .|. \succ_x$),

$$\big(\Psi^\varepsilon(x)\big)^* \;:\; S_x\mathcal{M} \to \mathcal{H}\,.$$

Multiplying $\Psi^\varepsilon(x)$ by its adjoint gives the operator

$$F^\varepsilon(x) := -\big(\Psi^\varepsilon(x)\big)^*\, \Psi^\varepsilon(x) \;:\; \mathcal{H} \to \mathcal{H}\,, \tag{12}$$

referred to as the *local correlation operator* at the spacetime point x. The local correlation operator is also characterized by the relation

$$(\psi \,|\, F^\varepsilon(x)\, \phi) = -\prec (\mathfrak{R}_\varepsilon \psi)(x) | (\mathfrak{R}_\varepsilon \phi)(x) \succ_x \qquad \text{for all } \psi, \phi \in \mathcal{H}\,. \tag{13}$$

Taking into account that the inner product on the Dirac spinors at x has signature $(2,2)$, it is a symmetric operator on $\mathcal{H}$ of rank at most four, which (counting multiplicities) has at most two positive and at most two negative eigenvalues. Varying the spacetime point, we obtain a mapping

$$F^\varepsilon \;:\; \mathcal{M} \to \mathcal{F} \subset \mathrm{L}(\mathcal{H})\,,$$

where $\mathcal{F}$ denotes all symmetric operators of rank at most four with at most two positive and at most two negative eigenvalues. Finally, we introduce the measure ρ on $\mathcal{F}$ by taking the push-forward of the volume measure on $\mathcal{M}$ under the mapping F^ε,

$$\rho := (F^\varepsilon)_* \mu_{\mathcal{M}} \tag{14}$$

(thus $\rho(\Omega) := \mu_{\mathcal{M}}((F^\varepsilon)^{-1}(\Omega))$). The resulting structure $(\mathcal{H}, \mathcal{F}, \rho)$ is a causal fermion system of spin dimension two.

We conclude with a few comments on the significance of this construction. We first point out that the construction uses all the structures of Lorentzian spin geometry as well as the properties of the Dirac wave functions in $\mathcal{H}$. We thus obtain a *very specific class of examples* of causal fermion systems describing classical spacetimes. In general, the measure ρ defined by (14) will not be a minimizer of the causal action principle. But it is an approximate minimizer if the Einstein equations are satisfied. Before making this point precise in the next section (Section 3.2), we now explain the physical picture behind the Dirac wave functions in $\mathcal{H}$. These wave functions have the interpretation as being those Dirac wave functions which are realized in the physical system under consideration. If we describe for example a system of one electron, then the wave function of the electron is contained in $\mathcal{H}$. Moreover, $\mathcal{H}$ includes all the wave functions which form the so-called Dirac sea (for an explanation of this point see for example[6]). All the Dirac wave functions in $\mathcal{H}$ can be identified with the ensemble of *physical wave functions* of the causal fermion system as introduced in (10). This "identification" is made mathematically precise by also identifying the objects of Lorentzian spin geometry with corresponding inherent objects of the causal fermion system (for details see [14, Section 1.2]). The name causal *fermion* system is motivated by the fact that Dirac particles are fermions. According to (13), the local correlation operator $F^\varepsilon(p)$ describes densities and correlations of the physical wave functions at the spacetime point p. Working exclusively with the local correlation operators and the corresponding push-forward measure ρ means in particular that the geometric structures are encoded in and must be retrieved from the physical wave functions. Since the physical wave functions describe the distribution of matter in spacetime, one can summarize this concept by saying that *matter encodes geometry*.

3.2. *Classical Gravity in the Continuum Limit*

The construction of the causal fermion system in the previous section involved the Lorentzian metric g. But this Lorentzian metric did not need to satisfy the Einstein equation. Instead of postulating the Einstein equations, our strategy is to *derive* these equations from the causal action principle. To this end, we need to evaluate the EL equations (6) for the causal fermion system $(\mathcal{H}, \mathcal{F}, \rho)$ constructed in the previous section in the limit $\varepsilon \searrow 0$ when the ultraviolet regularization is removed. This analysis, referred to as the *continuum limit*, is carried out in detail in [7, Chapter 4]. Before giving a brief outline of how this analysis works, we state the main result in the context of gravitational fields: The EL equations (6) are satisfied asymptotically for small $\varepsilon > 0$ only if the Lorentzian metric satisfies the Einstein equations, up to possible higher order corrections in curvature (which scale in powers of $(\delta^2 \,\mathrm{Riem})$, where δ is the Planck length and Riem is the curvature tensor), i.e. (see [7, Theorems 4.9.3 and 5.4.4])

$$R_{jk} - \frac{1}{2}\, R\, g_{jk} + \Lambda\, g_{jk} = G\, T_{jk} + \mathcal{O}\big(\delta^4\, \mathrm{Riem}^2\big)\,. \tag{15}$$

Moreover, it is shown that the gravitational coupling constant G is determined by the length scale of the microscopic spacetime structures and has the scaling

$$G \sim \delta^2 .$$

The cosmological constant Λ, however, is not determined by our method. In order to avoid confusion, we finally note that we carefully distinguish the Planck length δ from the regularization length ε. The reason is that, although it seems natural to assume that these length scales coincide, this does not necessarily need to be the case. In fact, the are indications that ε should be chosen even much smaller than δ (for a detailed discussion of the length scales see for example [4, Appendix A]).

We now briefly explain the general procedure in the analysis of the continuum limit. Given a causal fermion system $(\mathcal{H}, \mathcal{F}, \rho)$ describing a globally hyperbolic spacetime $(\mathcal{M}, g)$ (as constructed in Section 3.1), our task is to evaluate the EL equations (7). The first step is to compute the eigenvalues $\lambda_1^{xy}, \ldots, \lambda_{2n}^{xy}$ of the operator product $F^\varepsilon(x)\, F^\varepsilon(y)$ for given $x, y \in \mathcal{M}$. Using (12) together with the fact that the non-zero eigenvalues of a matrix product as well as the corresponding algebraic multiplicities do not change when the matrices are cyclically commuted, one can just as well compute the eigenvalues of the *closed chain* A_{xy} defined by

$$A_{xy} := P^\varepsilon(x,y)\, P^\varepsilon(y,x) \;:\; S_x\mathcal{M} \to S_x\mathcal{M} , \tag{16}$$

where the *regularized kernel of the fermionic projector* $P^\varepsilon(x,y)$ is defined by

$$P^\varepsilon(x,y) = -\Psi^\varepsilon(x)\big(\Psi^\varepsilon(y)\big)^* \;:\; S_y\mathcal{M} \to S_x\mathcal{M} .$$

In this way, it suffices to compute the eigenvalues of a linear endomorphism of S_xM, which can be represented by a 4×4-matrix. Moreover, the regularized kernel of the fermionic projector can be analyzed explicitly using the *regularized Hadamard expansion*. In general terms, $P^\varepsilon(x,y)$ is a smooth function which in the limit $\varepsilon \searrow 0$ converges to a distribution which has singularities on the lightcone (i.e. for lightlike separation of x and y). As a consequence, the pointwise product in (16) is ill-defined in this limit. In the continuum limit analysis, one deals with this issue by studying the Lagrangian and other composite expressions in $P^\varepsilon(x,y)$ asymptotically for small $\varepsilon > 0$. Evaluating the resulting expressions in the EL equations (7), one gets equations involving the gravitational field and the Dirac wave functions. In models containing neutrinos, these equations imply the Einstein equations (15).

The detailed computations can be found in,[7] where the continuum limit analysis is carried out in Minkowski space. In this context, the Hadamard expansion is referred to as the *light cone expansion*. The reader interested in the general construction of the regularized Hadamard expansion in curved spacetime is referred to.[18]

4. Going Beyond Classical Gravity

The above derivation of the Einstein equations in the continuum limit has two disadvantages. First, it is rather technical and thus does not give a good intuitive

understanding of the underlying mechanisms. Second and more importantly, the Einstein equations are obtained only for the special class of examples of causal fermion systems constructed in Section 3.1 and hold only in the continuum limit. But the methods do not give an insight into the geometric meaning of the EL equations (7) for general causal fermion systems describing more general "quantum" spacetimes. This raises the following question:

$$\text{Given a general causal fermion system } (\mathcal{H}, \mathcal{F}, \rho), \text{ how do the EL equations (7) relate matter to the geometry of spacetime?} \tag{17}$$

For a general causal fermion system, we cannot work with tensor fields, making it impossible to formulate the Einstein equations or modifications thereof. Therefore, we need to go beyond the mathematical setting of Lorentzian geometry. In the next sections, we explain step by step how this can be done and mention a few results.

4.1. *A Lorentzian Quantum Geometry*

In[9] it was shown that a causal fermion system gives rise to geometric structures in spacetime. The general strategy for obtaining these geometric structures is as follows. Given two spacetime points $x, y \in M$, the corresponding spin space S_x and S_y (see Section 2.4) are subspaces of the underlying Hilbert space $\mathcal{H}$. Denoting the orthogonal projection to the spin spaces S_x again by

$$\pi_x : \mathcal{H} \to S_x ,$$

the *kernel of the fermionic projector* is introduced by

$$P(x,y) = \pi_x y|_{S_y} \;:\; S_y \to S_x .$$

Being an operator from one spin space to another, it gives relations between the spacetime points. In other words, the kernel of the fermionic projector induces additional structures in spacetime. One important structure is the *spin connection* $D_{x,y}$, being a unitary mapping between the spin spaces,

$$D_{x,y} \;:\; S_y M \to S_x M \qquad \text{unitary} \tag{18}$$

(unitary with respect to the spin inner product (9)). A first idea for construction $D_{x,y}$ is to take a polar decomposition of $P(x,y)$. This idea needs to be refined in order to also obtain a metric connection and to arrange that the different connections are compatible. Here for brevity we omit the details and refer to[9] or the review.[8] In general terms, it turns out that there is a canonical spin connection (18), provided that the operators x and y satisfy certain conditions, which are subsumed in the notion that the spacetime points be *spin-connectable*. *Curvature* $\mathfrak{R}$ can be defined as the holonomy of the spin connection. Thus, in the simplest case, for three points $x, y, z \in M$ which are mutually spin-connectable, one sets

$$\mathfrak{R}(x,y,z) = D_{x,y}\, D_{y,z}\, D_{z,x} \;:\; S_x M \to S_x M .$$

In[9] also the correspondence to Lorentzian spin geometry is established, in the sense that for causal fermion systems describing a globally hyperbolic Lorentzian manifold (as constructed in Section 3.1) and taking a suitable limit $\varepsilon \searrow 0$, the spin connection (18) goes over to the spinorial Levi-Civita connection of the Lorentzian manifold.

While these structures give a good understanding of the geometry of a causal fermion system, so far they have not been fruitful for unraveling the form of the gravitational interaction as described by the causal action principle. The basic problem is that the EL equations (7) cannot be formulated in terms of these geometric structures. In other words, it does not seem possible to rewrite the causal action principle as a geometric variational principle involving $D_{x,y}$ and $\mathfrak{R}$. With this in mind, we now move on to other structures which again have a geometric meaning, but harmonize better with the EL equations (7).

4.2. *Surface Layer Integrals*

Coming back to our question (17), we follow another path for getting a connection between the geometric structures and the EL equations (7). This method is inspired by the fact that the effects of gravity can also be captured by considering the volume and area of surfaces in spacetime, and by analyzing how this area changes under flows of the surfaces. Typical examples for this connection are Huisken's isoperimetric mass (see for example[22]) and Jacobson's connection between area change and matter flux.[4] Thinking along these lines, the first obvious question is how a surface integral can be defined in the setting of causal fermion systems. Once this question has been answered, one can analyze the area of families of surfaces and make the above analogies more precise.

As a typical example, suppose we want to define the analog of an integral over a Cauchy surface $\mathcal{N}$ in a globally hyperbolic spacetime, i.e. symbolically

$$\int_{\mathcal{N}} (\cdots)\, d\mu_{\mathcal{N}}(x)\,, \tag{19}$$

where $d\mu_{\mathcal{N}}$ is the induced volume measure on $\mathcal{N}$. Here one can think of $(\cdots)$ as a density like for example the inner product $\nu_i J^i$ of a current vector field with the future-directed normal ν. In the setting of causal fermion system, surface integrals like (19) are undefined. Instead, one considers so-called *surface layer integrals*. In general terms, a surface layer integral is a double integral of the form

$$\int_{\Omega} \left(\int_{M \setminus \Omega} (\cdots)\, \mathcal{L}_\kappa(x,y)\, d\rho(y) \right) d\rho(x)\,, \tag{20}$$

where one variable is integrated over a subset $\Omega \subset M$, and the other variable is integrated over the complement of Ω. Here $(\cdots)$ is the analog of the corresponding factor in (19), but now having the mathematical structure of being a differential operator acting on the Lagrangian.

In order to explain the basic concept, let us assume for a moment that the Lagrangian is of *short range* in the following sense. We let $d \in C^0(M \times M, \mathbb{R}_0^+)$ be a suitably chosen distance function on M. Then the assumption of short range can be quantified by demanding that $\mathcal{L}_\kappa$ should vanish on distances larger than l, i.e.

$$d(x,y) > l \quad \Longrightarrow \quad \mathcal{L}_\kappa(x,y) = 0\,. \tag{21}$$

Under this assumption, the surface layer integral (20) only involves pairs (x,y) of distance at most l, where x lies in Ω, whereas y lies in the complement $M \setminus \Omega$. As a consequence, the integral only involves points in a layer around the boundary of Ω of width l, i.e.

$$x, y \in B_l\big(\partial\Omega\big)\,.$$

Therefore, a double integral of the form (20) can be regarded as an approximation of a surface integral on the length scale l, as shown in Figure 1. In most applications, the Lagrangian is *not* of short range in the strict sense (21). But it decays on the Compton scale $l \sim 1/m$ (where m denotes again the mass of the Dirac particles), so that the qualitative picture in Figure 1 still applies.

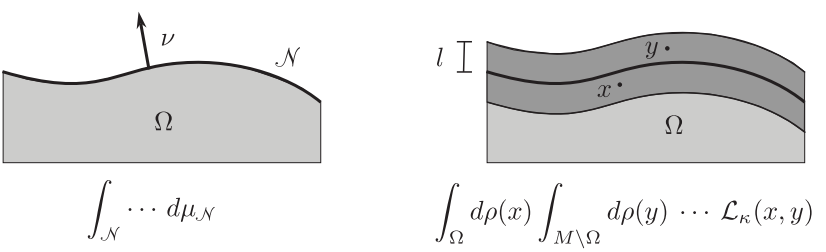

Fig. 1. A surface integral and a corresponding surface layer integral.

Surface layer integrals were first introduce in[15] in the context of Noether-like theorems. The analysis of this paper revealed that, in contrast to the geometric structures in Section 4.1, the structure of a surface layer integral does fit nicely to the EL equations (7), giving rise to very useful conservation laws. This connection was analyzed further and more systematically in.[16,17] Moreover, in[11] another variant of a surface layer integral was introduced, which will be importance for what follows. This new surface layer integral can be regarded as a generalization or "nonlinear version" of (20), as can be understood as follows. The differential operator $(\cdots)$ in the integrand can be regarded as describing first or second variations of the measure ρ. Instead of considering variations of ρ, we now consider an additional measure $\tilde{\rho}$ which can be thought of as a finite perturbation of the measure ρ. Consequently, we also have two spacetimes

$$M := \operatorname{supp} \rho \qquad \text{and} \qquad \tilde{M} := \operatorname{supp} \tilde{\rho}\,.$$

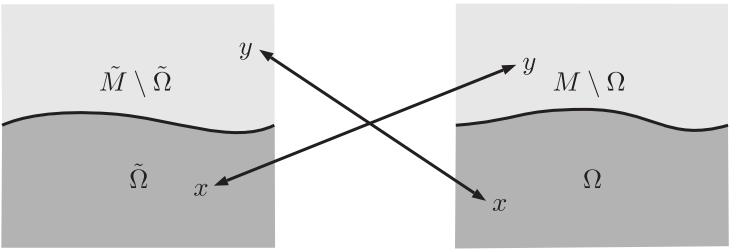

Fig. 2. The nonlinear surface layer integral.

Choosing two compact subsets $\Omega \subset M$ and $\tilde{\Omega} \subset \tilde{M}$ of the corresponding spacetimes, we form the *nonlinear surface layer integral* by

$$\gamma^{\tilde{\Omega},\Omega}(\tilde{\rho}, \rho) := \int_{\tilde{\Omega}} d\tilde{\rho}(x) \int_{M \setminus \Omega} d\rho(y)\, \mathcal{L}_\kappa(x,y) - \int_{\Omega} d\rho(x) \int_{\tilde{M} \setminus \tilde{\Omega}} d\tilde{\rho}(y)\, \mathcal{L}_\kappa(x,y)\,. \quad (22)$$

Note that one argument of the Lagrangian is in M, whereas the other is in $\tilde{M}$. Moreover, one argument lies inside the set Ω respectively $\tilde{\Omega}$, whereas the other argument lies outside this set. In this way, the nonlinear surface layer integral "compares" the two spacetimes near the boundaries of Ω and $\tilde{\Omega}$, as is illustrated in Figure 2.

4.3. *The Total Mass of a Static Causal Fermion System*

Combining the general structure of Huisken's isoperimetric mass with the concept of a surface layer integral, the question arises whether notions like the total mass and total energy can be introduced for a class of causal fermion systems which generalize asymptotically flat Lorentzian manifolds. This question has been answered in the affirmative in[19] in the static setting. We now outline a few constructions and results of this paper.

Static causal fermion systems are introduced as usual by demanding a one-parameter group of symmetries:

Definition 4.1. Let $(\mathcal{U}_t)_{t \in \mathbb{R}}$ be a strongly continuous one-parameter group of unitary transformations on the Hilbert space $\mathcal{H}$ (i.e. $s\text{-}\lim_{t' \to t} \mathcal{U}_{t'} = \mathcal{U}_t$ and $\mathcal{U}_t \mathcal{U}_{t'} = \mathcal{U}_{t+t'}$). The causal fermion system $(\mathcal{H}, \mathcal{F}, \rho)$ is **static with respect to** $(\mathcal{U}_t)_{t \in \mathbb{R}}$ if it has the following properties:

(i) Spacetime $M := \operatorname{supp} \rho \subset \mathcal{F}$ is a topological product,

$$M = \mathbb{R} \times N\,.$$

We write a spacetime point $x \in M$ as $x = (t, \mathbf{x})$ with $t \in \mathbb{R}$ and $\mathbf{x} \in N$.

(ii) The one-parameter group $(\mathcal{U}_t)_{t \in \mathbb{R}}$ leaves the measure ρ invariant, i.e.

$$\rho\big(\mathcal{U}_t\, \Omega\, \mathcal{U}_t^{-1}\big) = \rho(\Omega) \qquad \text{for all } \rho\text{-measurable } \Omega \subset \mathcal{F}\,.$$

Moreover,

$$\mathcal{U}_{t'}\,(t,\mathbf{x})\,\mathcal{U}_{t'}^{-1} = (t+t',\mathbf{x})\,.$$

As a consequence of (ii), the measure ρ has the product form

$$d\rho = dt\, d\mu\,,$$

where μ is a measure on $\mathcal{G} := \mathcal{G} = \mathcal{F}^{\text{reg}}/\mathbb{R}$.

Restricting attention to static causal fermion systems and varying within the class of measures which are invariant under the action of a given one-parameter group $(\mathcal{U}_t)_{t\in\mathbb{R}}$, one obtains a corresponding *static causal action principle*, where one minimizes the static action

$$\mathcal{S}_{\text{static}}(\mu) = \int_{\mathcal{G}} d\mu(\mathbf{x}) \int_{\mathcal{G}} d\mu(\mathbf{y})\, \mathcal{L}_{\text{static}}(\mathbf{x},\mathbf{y})$$

under variations of the measure μ on $\mathcal{G}$, keeping the total volume $\mu(\mathcal{G})$ fixed (*volume constraint*). The static Lagrangian is obtained by integrating one argument of the κ-Lagrangian (8) over time,

$$\mathcal{L}_{\text{static}}(\mathbf{x},\mathbf{y}) := \int_{-\infty}^{\infty} \mathcal{L}_\kappa\big((0,\mathbf{x}),(t,\mathbf{y})\big)\, dt\,.$$

The *total mass* $\mathfrak{M}$ of a static causal fermion system described by the measure $\tilde{\mu}$ is defined by comparing $\tilde{\mu}$ asymptotically near infinity with a measure μ describing the vacuum. To this end, one exhausts the supports N and $\tilde{N}$ of these measures by sequences of compact subsets $(\Omega_n)_{n\in\mathbb{N}}$ and $(\tilde{\Omega}_n)_{n\in\mathbb{N}}$, respectively, and takes the limit of a nonlinear surface layer integral of structure similar to (22),

$$\begin{aligned}\mathfrak{M}(\tilde{\mu},\mu) = &\lim_{\Omega_n \nearrow N,\, \tilde{\Omega}_n \nearrow \tilde{N} \text{ with } \mu(\Omega_n)=\tilde{\mu}(\tilde{\Omega}_n)<\infty} \\ &\times \left(\int_{\tilde{\Omega}_n} d\tilde{\mu}(\mathbf{x}) \int_{N\setminus\Omega_n} d\mu(\mathbf{y})\, \mathcal{L}_{\text{static}}(\mathbf{x},\mathbf{y}) - \int_{\Omega_n} d\mu(\mathbf{x}) \int_{\tilde{N}\setminus\tilde{\Omega}_n} d\tilde{\mu}(\mathbf{y})\, \mathcal{L}_{\text{static}}(\mathbf{x},\mathbf{y}) \right). \quad (23)\end{aligned}$$

In order for this expression to be well-defined, one needs to assume that the spacetimes are *asymptotically flat* (for brevity, we do not give the precise definition, which can be found in [19, Definition 1.5]). As a consequence of the EL equations, the mass does not depend on the choice of the exhaustions, except that the volume condition $\mu(\Omega_n) = \tilde{\mu}(\tilde{\Omega}_n)$ must hold. Moreover, a *positive mass theorem* is proved which states that the total mass $\mathfrak{M}(\tilde{\mu},\mu)$ is non-negative if a suitable *local energy condition* holds (for details see [19, Definition 1.8 and Theorem 1.9]).

The correspondence to the classical positive mass theorem (see for example[23]) is established by showing that for a static causal fermion systems describing the Schwarzschild spacetime (constructed again as explained in Section 3.1), the total mass $\mathfrak{M}(\tilde{\mu},\mu)$ coincides (up to an irrelevant prefactor) with the ADM mass[2] (see [19, Theorem 1.10]). For brevity, we cannot enter the proof and the detailed constructions. But we make one remark which will be important in connection with the construction of the quantum state in Section 4.5: When comparing causal

fermion systems describing the Schwarzschild spacetime and Minkowski space, one needs to take into account that the resulting causal fermion systems are defined on two different Hilbert spaces, namely a Hilbert space $\tilde{\mathcal{H}}$ formed of Dirac solutions in Schwarzschild and a Hilbert space $\mathcal{H}$ formed of Dirac solutions in Minkowski space. Before we can make sense of the nonlinear surface layer integral (23), these Hilbert spaces must be identified by a unitary transformation V,

$$V \,:\, \mathcal{H} \to \tilde{\mathcal{H}}\,. \tag{24}$$

This identification is *not* canonical but leaves us with the freedom of choosing a unitary transformation. Therefore, in order to make sense of (23), one must prove that the total mass is independent of the choice of the unitary transformation V (for details see [19, Section 4.3]).

4.4. *Connection Between Area Change and Matter Flux*

In 1995, Ted Jacobson gave a derivation of the Einstein equations from thermodynamic principles.[21] At the heart of his argument is the formula

$$\frac{d}{d\tau} A(S_\tau) = c\, F(S_\tau) \tag{25}$$

which states that the area change of a family of two-surfaces S_τ propagating along a null Killing direction is proportional to the matter flux $F(S_\tau)$ across these surfaces (with c a universal constant). In,[4] this formula is derived in the setting of causal fermion systems from the EL equations (7) (without referring to thermodynamics). This result gives an alternative derivation of the Einstein equations from the causal action principle (again with an undetermined cosmological constant). Compared to the continuum limit analysis described in Section 3.2, this alternative derivation has the advantage that it is more conceptual and thus gives a more direct understanding of why and how the Einstein equations arise. Moreover, the procedure in[4] has the benefit that it does not rely on tensor calculus. Therefore, it goes beyond Lorentzian geometry and applies to more general "quantum" spacetimes.

We now explain the general procedure and a few constructions from.[4] The first question is how to define the area A of a two-dimensional surface S in the setting of causal fermion systems. It is most convenient to describe $S \subset M$ as

$$S = \partial\Omega \cap \partial V\,,$$

where Ω can be thought of as being the past of a Cauchy surface, and V describing a spacetime cylinder. This description has the advantage that the resulting surface layer integrals are well-defined even in situations when spacetime is singular or discrete, in which case the boundaries $\partial\Omega$ and ∂V are no longer a sensible concept. The most natural way of introducing a surface layer integral localized in a neighborhood of S is a double integral of the form

$$\int_{\Omega\cap V} \left(\int_{M\setminus(\Omega\cup V)} (\cdots)\, \mathcal{L}_\kappa(x,y)\, d\rho(y) \right) d\rho(x) \tag{26}$$

(where $(\cdots)$ stands again for a differential operator acting on the Lagrangian). If the Lagrangian has short range, we only get contributions to this surface layer integral if both x and y are close to the two-dimensional surface S (see the left of Figure 3).

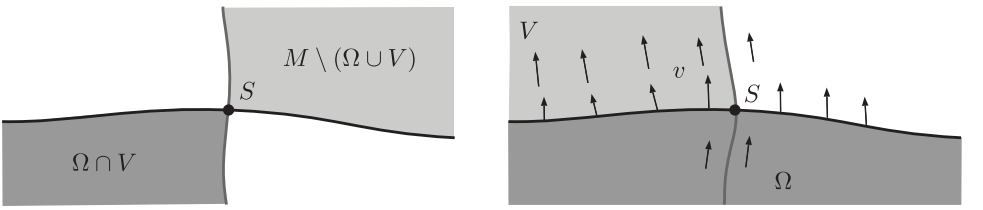

Fig. 3. Two-dimensional surface layer integrals.

The disadvantage of this method is that, similar as explained in Section 4.1 for the structures of the Lorentzian quantum geometry and the EL equations, the surface layer integral (26) does not fit together with the notion of matter flux. Therefore, it is preferable to define the two-dimensional area as follows. We need to assume that M has a smooth manifold structure, and that the measure ρ is absolutely continuous and smooth with respect to the Lebesgue measure in every chart (x, U) of M, i.e.

$$d\rho = h(x)\, d^4x \qquad \text{with } h \in C^\infty(U, \mathbb{R}^+)\,. \tag{27}$$

Also assuming that the boundaries of Ω and V are smooth, we can choose a smooth vector field v which is transverse to the hypersurface $\partial\Omega$ and tangential to ∂V (see the right of Figure 3). Under these additional assumptions, one can introduce an integration measure $d\mu$ on the hypersurface $\partial\Omega$ by

$$d\mu(v, x) = h\, \epsilon_{ijkl}\, v^i\, dx^j dx^k dx^l\,,$$

where ϵ_{ijkl} is the totally anti-symmetric Levi-Civita symbol (normalized by $\epsilon_{0123} = 1$). Now we can define the two-dimensional area by

$$A := \int_{\partial\Omega \cap V} d\mu(v, x) \int_{M \setminus V} d\rho(y)\, \mathcal{L}_\kappa(x, y)\,. \tag{28}$$

We next describe a symmetry by a notion of a Killing field. This notion will also give rise to a notion of matter flux.

Definition 4.2. A vector field u on M is called **Killing field** of the causal fermion system if the following conditions hold:

(i) The divergence of u vanishes, i.e.

$$\frac{1}{h}\, \partial_j \big(h\, u^j\big) = 0$$

(where h is again the weight function in (27)).

(ii) The directional derivative of the Lagrangian is small in the sense that

$$\big(D_{1,u} + D_{2,u}\big)\mathcal{L}_\kappa(x,y) \lesssim \frac{m^4}{\varepsilon^4\, \delta^4} \tag{29}$$

(where again ε is the regularization length, and δ is the Planck length).

The reason why the right side in (29) is non-zero is that the derivative of the Lagrangian involves contributions from both the geometry and the matter fields. The condition (29) means that the geometric contributions vanish (which are typically much larger). The fact that the matter contribution remains makes it possible to define the matter flux by

$$F(S) := \int_{\partial\Omega\cap V} d\mu(v,x) \int_{M\setminus V} d\rho(y)\, \big(D_{1,u} + D_{2,u}\big)\mathcal{L}_\kappa(x,y)\,, \tag{30}$$

where we assume that the Killing field u is tangential to Ω (see Figure 4). In the limiting case of lightlike propagation, the vector fields u and v coincide, making it possible to recover the matter flux (30) as the derivative of the area (28) in the direction of the Killing field u. This gives the desired relation (25).

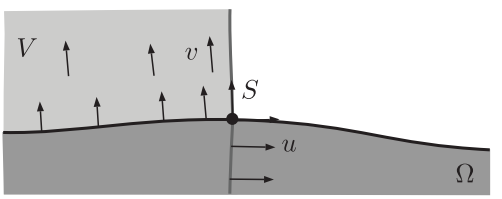

Fig. 4. Matter flux through S.

4.5. *The Quantum State of a Causal Fermion System*

We finally give an outlook on quantum field theory and quantum gravity. So far, the connection to quantum field theory has been established only for causal fermion systems describing Minkowski space.[11,12] But most of the methods apply just as well to more general causal fermion systems describing curved spacetimes. Moreover, one should keep in mind that in a causal fermion system, all the bosonic interactions are described in a unified way with the same mathematical structures, giving hope that methods developed for the electromagnetic interaction in Minkowski space can be adapted to the gravitational field. But, as is usually the case in mathematics, the connections and analogies are rather subtle and need to be explored carefully and in depth. We plan to do so in the near future.

Coming back to causal fermion systems describing Minkowski space, in[12] a *quantum state* ω^t of a causal fermion system $(\tilde{\mathcal{H}}, \tilde{\mathcal{F}}, \tilde{\rho})$, which describes an interacting

spacetime, is constructed. Here by a "quantum state" we mean a positive linear functional on the $*$-algebra of observables $\mathscr{A}$, i.e.

$$\omega^t : \mathscr{A} \to \mathbb{C} \quad \text{complex linear} \qquad \text{and} \qquad \omega^t\big(A^* A\big) \geq 0 \quad \text{for all } A \in \mathscr{A} .$$

The observables are formed of linearized solutions of the EL equations. The general idea for constructing the quantum state is to compare $(\tilde{\mathcal{H}}, \tilde{\mathcal{F}}, \rho)$ at time t with a causal fermion system $(\mathcal{H}, \mathcal{F}, \rho)$ describing the vacuum. Similar to the procedure for the total mass (23), the "comparison" is again performed with a nonlinear surface layer integral (22), but now with $\tilde{\Omega}$ and Ω chosen as the past of the respective Cauchy surfaces (similar as shown in Figure 2). The unitary freedom in identifying the Hilbert spaces already mentioned in the connection of the positive mass theorem in (24) is now taken care of by integrating over a group $\mathcal{G}$ of unitary operators. This leads to a formula for the quantum state of the symbolic form

$$\omega^t(A) := \frac{1}{Z^t\big(\beta, \tilde{\rho}\big)} \int_{\mathcal{G}} (\cdots)\, e^{\beta\, \gamma^t(\tilde{\rho}, \mathcal{U}\rho)}\, d\mu_{\mathcal{G}}(\mathcal{U}) , \tag{31}$$

where $Z^t\big(\beta, \tilde{\rho}\big)$ is the partition function defined by

$$Z^t\big(\beta, \tilde{\rho}\big) := \int_{\mathcal{G}} e^{\beta\, \gamma^t(\tilde{\rho}, \mathcal{U}\rho)}\, d\mu_{\mathcal{G}}(\mathcal{U}) ,$$

and β is a real parameter. The factor $(\cdots)$ in (31) consists of a product of surface layer integrals formed of the linearized solutions contained in the observable A (for details see [12, Section 4]).

The significance of this construction is that it becomes possible to describe the interacting causal fermion system in the familiar language of quantum field theory. Consequently, also the dynamics as described by the EL equations (7) can be rewritten as a time evolution of the state ω^t. The detailed form of the resulting quantum dynamics is presently under investigation.[13]

Acknowledgments

I would like to thank Michael Kiessling and Shadi Tahvildar-Zadeh for the kind invitation to the Marcel Grossmann Meeting. I am grateful to Christoph Krpoun for helpful comments on the manuscript.

Using Newman-Penrose formalism in tetrad and spinor forms, we perform separation of variables in the wave equations for massless fields of various spins s=1/2, 1, 3/2, 2 on the background of exact plane-fronted gravitational wave metrics. Then, applying Wald's method of conjugate operators, we derive equations for Debye potentials and we find the back-projection operators expressing multicomponent fields in terms of these potentials. For shock wave backgrounds, as a special case of the non-vacuum pp-waves, the exact solutions for Debye potentials are constructed explicitly. The possibilities of generalization to the case of massive fields are discussed, in particular, construction of exact solutions of the Dirac and Proca equations. These results can be used in various supergravity problems on the pp-wave backgrounds, including holographic applications.

Keywords: PP-waves, Newman-Penrose formalism, Debye potentials, shock waves

1. Introduction

Wave equations for fields of different spins in curved space have been extensively studied since the early 1970s. Solutions describing propagation of fields on curved backgrounds are in demand in various contexts including the problem of radiation, supergravity and superstrings theories. Generically, considering fields of higher spins in curved space-time, difficulties arise with splitting the systems of coupled equations into separate ones for certain combinations of the field components. Two efficient methods to do this are known. The first is the application of the Newman-Penrose (NP) formalism,[1] in which the intrinsic symmetries of the masseless field equations with respect to the Lorentz group are conveniently incorporated. The second efficient tool is the method of Debye potentials,[2] which allows to reconstruct the multicomponent fields in terms of solutions of some scalar equations. Debye potentials are complex functions which incorporate two degree of freedom of the massless field of any spin.

Formalism of Debye potentials was suggested in gravity theory in the works by Cohen[3] and Kegeles[4] and then effectively used by Chrzanowksi[5] in Kerr spacetime of type D, according to the Petrov classification,[6] in combination with the Teukolsky

equation.[7] In the Kerr metric Debye representations were found for electromagnetic field and gravitational perturbations. Later, formalism of Debye potentials was discussed in detail for Rarita-Schwinger spin 3/2 field by Torres del Castilho.[8]

In this work we apply the Newman-Penrose-Debye formalism to the case of metrics of type N. More specifically, we consider the case of pp-wave metrics, which have numerous applications both in astrophysics and in various theoretical aspects, including supergravity and holography.

2. PP-waves

These metrics were introduced by Brinkmann[9] in 1925 and later interpreted as representing the plane-fronted gravitational waves (pp-waves). They are exact solutions of Einstein's equations of the following form

$$ds^2 = dudv - H(u,\zeta,\bar{\zeta})dudu - d\zeta d\bar{\zeta}, \tag{1}$$

where $\zeta = x + iy$ is a complex transverse coordinate, H is arbitrary nonlinear real profile function of ζ, $\bar{\zeta}$, which specifies the nature of the wave. The determinant $g = 1/16$ is coordinate-independent. The scalar curvature turns out to be zero. For $H = 0$ the metric is Minkowski. These metrics describe plane waves with parallel rays belonging to the class of solutions that admits isotropic nonexpanding congruences without shear and twist, as well as the existence of an isotropic Killing vector.

A natural choice of the null tetrad basis for them is

$$\mathbf{l} = \sqrt{2}\partial_v, \qquad \mathbf{n} = \sqrt{2}(\partial_u + H\partial_v), \qquad \mathbf{m} = \sqrt{2}\partial_\zeta, \qquad \bar{\mathbf{m}} = \sqrt{2}\partial_{\bar{\zeta}}. \tag{2}$$

We will also use the NP covariant derivatives along the null tetrad vectors:

$$D = l^\mu\nabla_\mu, \qquad \Delta = n^\mu\nabla_\mu, \qquad \delta = m^\mu\nabla_\mu, \qquad \bar{\delta} = \bar{m}^\mu\nabla_\mu \tag{3}$$

and satisfying, in the case of a plane wave metrics, the following commutation relations

$$[\Delta, D] = 0, \qquad [\delta, D] = 0, \qquad [\delta, \Delta] = -\bar{\nu}D, \qquad [\bar{\delta}, \delta] = 0. \tag{4}$$

The nonzero tetrad projections of the traceless part of the Ricci tensor, the Weyl scalar, and the only nonzero spin coefficient ν are

$$\begin{aligned} &\Phi_{22} = \frac{1}{2}n^\alpha n^\beta R_{\alpha\beta} = -H_{,\zeta\bar{\zeta}}, && \nu = -\bar{m}^\mu\delta n_\mu = -H_{,\bar{\zeta}}, \\ &\Psi_4 = -n^\alpha\bar{m}^\beta n^\sigma\bar{m}^\tau C_{\alpha\beta\sigma\tau} = -H_{,\bar{\zeta}\bar{\zeta}}, && \Lambda = \frac{1}{24}R = 0, \end{aligned} \tag{5}$$

where $C_{\alpha\beta\sigma\tau}$ is the Weyl tensor. In the vacuum case, the gravitational field equations $\Phi_{22} = 0$ reduce to the two-dimensional Laplace equation

$$H_{,\zeta\bar{\zeta}} = 0.$$

The d'Alembert operator for the massless scalar field $\Box = \nabla_\mu\nabla^\mu$ reads:

$$\Box \equiv \frac{1}{\sqrt{|g|}}\partial_\mu\left(\sqrt{|g|}g^{\mu\nu}\partial_\nu\right) = 2(D\Delta - \delta\bar{\delta}). \tag{6}$$

3. Debye potentials

Here we briefly recall the Wald's procedure[10] for constructing a solution of the field equations of higher spins, which we then apply to the metrics of plane waves. Consider some multicomponent field f (tensor or spinor) satisfying the field equation $\mathcal{E}(f) = 0$, where $\mathcal{E}$ is an appropriate matrix linear differential operator. This is generically a non-quadratic matrix $n \times m$ taking the m-component field into the column of n differential equation. To solve this system of equations one has to disentangle it, which in general is not possible in the closed form. However, it can be possible to decouple a separate equation (or several equations) for some combination φ of the components of the initial field f by the action of another linear partial differential operator $\mathcal{T}$, defining a scalar $\varphi = \mathcal{T}(f)$. Then one can define a pair of linear operators $\mathcal{S}$ and $\mathcal{O}$ such, that

$$\mathcal{S}\mathcal{E}(f) = \mathcal{O}\mathcal{T}(f) = \mathcal{O}(\varphi).$$

The problem of finding such operators is facilitated if one knows the source terms in the inhomogeneous equations both for an initial multicomponent field $\mathcal{E}(f) = J$, and in the decoupled scalar equation $O(\varphi) = \mathcal{S}(J)$. The number of decoupled equations depends on the number of principal null direction of the metric.

The final step is the construction of the adjoint operator $S^\dagger$ with respect to a suitably defined functional scalar product such that, in the matrix form,

$$\int \phi^{A_n} M_{A_n B_m} \psi^{B_m} = \int \psi^{B_n} M^\dagger_{B_n A_m} \phi^{A_m} \ ,$$

where the indices A_n, B_m take n and m values respectively and the integration measure is supressed. Note that complex conjugation is not used.

Now it can be verified that the solution of the homogeneous field equation $\mathcal{E}(f) = 0$ will be guaranteed if

$$f = \mathcal{S}^\dagger \psi, \qquad\qquad \mathcal{O}^\dagger \psi = 0. \tag{7}$$

The last equation is the Debye potential equation, the relevant operator is therefore the adjoint to one used in the equation for a decoupled scalar. It there are several such decoupled equations (e.g. two in type D metrics), one will have two different representations for the initial multicomponent field which are usually related by some tetrad transformation. In type N case the Debye potential is unique.

The complex Debye representation for for real-valued massless fields reflects the existence of two independent polarizations, which can be obtained as the real and imaginary parts of the complex f in the Debye form.

In what follows we apply this procedure to the pp-wave background with the only one nonzero spin coefficient ν. Clearly, the adjoint to the product of two operators will be the product of the adjoints to each of them in reverse order. So to construct an adjoint of some polynomial product it will suffice to know the adjoint to basic operators. The adjoint NP differential operators will read

$$D^\dagger = -D, \qquad \Delta^\dagger = -\Delta, \qquad \delta^\dagger = -\delta, \qquad \bar{\delta}^\dagger = -\bar{\delta}. \tag{8}$$

4. Maxwell field

Maxwell's equations in the Newman-Penrose formalism are written in terms of the projections of the electromagnetic field tensor onto the bivector constructed of null tetrad as follows:

$$\Phi_0 = F_{lm}, \qquad 2\Phi_1 = (F_{ln} + F_{m\bar{m}}), \qquad \Phi_2 = F_{\bar{m}n}. \tag{9}$$

A sourceless decoupled equation for the scalar Φ_0 in the case of vacuum pp-waves was obtained in the Refs.[11] and.[12] According to above procedure, we have to construct the source term to this equation. For this, one should act with an appropriate NP differential operators on the first pair of the system of equations and exclude the variable Φ_1 from them using the commutation relations. This gives

$$\Box\Phi_0 = 2\pi J_0, \qquad J_0 = 2\left[\delta J_l - D J_m\right]. \tag{10}$$

Since metrics of type N have only one principal null direction (contrary to the type D, where there are two), the NP component Φ_0 will be the only one for which the decoupling can be made. Further, having written down both adjoint operators, one can easily construct a solution for vector A^μ, satisfying the Lorentz gauge condition, in terms of the Debye potential:

$$A^\mu = \left[\bar{m}^\mu D - l^\mu \bar{\delta}\right]\psi, \qquad \Box\psi = 0. \tag{11}$$

It is easy to see that the contraction of the Ricci tensor with the expression for the vector potential gives zero; therefore, the solution is valid also for the non-vacuum pp-waves.

5. Weyl field

For the Weyl equations of spin 1/2, one uses the two-component spinor version of the NP formalism. In this case, we will no longer deal with a tetrad, but with a spinor dyad. The massless spin 1/2 equation has the following form:

$$\nabla^A{}_{B'}\chi_A = 0. \tag{12}$$

Writing this in components and carrying out transformations similar those for the vector field, we obtain the decoupled equation with the source term:

$$\Box\chi_0 = N_0, \qquad N_0 = 2\left[D j_{1'} - \delta j_{0'}\right], \tag{13}$$

where the spinor source is denoted as $j_{A'}$. Then performing the conjugation, we construct a solution in terms of the Debye potential, which, in turn, satisfies the d'Alembert equation:

$$\chi_0 = -D\psi, \qquad \chi_1 = -\bar{\delta}\psi, \qquad \Box\psi = 0. \tag{14}$$

6. Rarita-Schwinger field

The spin 3/2 field is described by the Rarita-Schwinger equation for the spinor-vector ψ_μ, which satisfies the equations

$$\gamma^\mu(\nabla_\mu\psi_\nu - \nabla_\nu\psi_\mu) = 0, \qquad \gamma^\rho\psi_\rho = 0. \tag{15}$$

This system is consistent only in the case of the vacuum metrics, the non-vacuum case refers to the supergravity context.

The field of an arbitrary spin s in the two-component spinor formalism is described by a totally symmetric spinor of valence 2s satisfying the equation of motion

$$\nabla^{AB'}\phi_{AB\ldots C} = 0.$$

If $s \geqslant 3/2$ the Buchdahl consistency constraint[13]

$$\Psi^{ABC}{}_{(D}\phi_{EF\ldots)ABC} = 0$$

must be satisfyed, where Ψ_{SABC} denotes the Weyl spinor. But there exists also an alternative approach, developed in the work,[8] where the consistency constraint is satisfied automatically. This method can be easily adapted to the case of the pp-wave backgrounds.

In the spinor equivalent of the Eq. (15)

$$\nabla_{AB'}\psi^A{}_{CD'} - \nabla_{CD'}\psi^A{}_{AB'} = 0, \tag{16}$$

one has to pass from field $\psi^A{}_{CD'}$ to the symmetric rank three spinor arriving at the modified equations of motion

$$\nabla^{AB'}\phi_{ABC} = \Psi^S{}_{ABC}\psi^A{}_S{}^{B'}, \quad \phi^A{}_{BC} \equiv \nabla_{(B|R'|}\psi^A{}_{C)}{}^{R'}.$$

We write down the complete system of equations with the sources for the symmetric spinor field ϕ_{ABC} in the component form, applicable to the type N metrics:

$$\begin{aligned}
&\bar\delta\phi_{000} - D\phi_{100} = \delta J_{0'0'0} - DJ_{1'0'0}; \qquad \Delta\phi_{000} - \delta\phi_{100} = \delta J_{0'1'0} - DJ_{1'1'0};\\
&\bar\delta\phi_{100} - D\phi_{110} = \frac{1}{2}\big[\Delta J_{0'0'0} + \delta J_{0'0'1} - \bar\delta J_{0'1'0} - DJ_{1'0'1}\big];\\
&\Delta\phi_{100} - \delta\phi_{110} - \nu\phi_{000} = \frac{1}{2}\big[\Delta J_{1'0'0} + \delta J_{0'1'1} - \bar\delta J_{1'1'0} - DJ_{1'1'1} - \bar\nu J_{0'0'0}\big];\\
&\bar\delta\phi_{110} - D\phi_{111} = \Psi_4\psi_{000'} + \Delta J_{0'0'1} - \frac{1}{2}\bar\delta(J_{1'0'1} + J_{0'1'1}) - \nu J_{0'0'0};\\
&\Delta\phi_{110} - \delta\phi_{111} - 2\nu\phi_{100} = \Psi_4\psi_{001'} - \bar\delta J_{1'1'1} + \frac{1}{2}\Delta(J_{0'1'1} + J_{1'0'1}) - \bar\nu J_{0'0'1} - \nu J_{1'0'0}.
\end{aligned} \tag{17}$$

One can exclude the component ϕ_{100} from the first pair of equations, obtaining the decoupled equation for ϕ_{000} with the source term:

$$\Box\phi_{000} = K_0, \qquad K_0 = 2\big[D\delta(J_{0'1'0} + J_{1'0'0}) - D^2J_{1'1'0} - \delta^2J_{0'0'0}\big]. \tag{18}$$

Using this, one can further represent a spin-vector in terms of the Debye potential as follows:

$$\psi_\mu = \begin{pmatrix} \bar{m}_\mu D\bar{\delta} - l_\mu \bar{\delta}^2 \\ l_\mu D\bar{\delta} - \bar{m}_\mu D^2 \end{pmatrix} \psi, \qquad \Box\psi = 0. \tag{19}$$

The resulting expression satisfies the system (15). Note that the equation for the Debye potential is the same for the vector field, the Weyl field and, as we will see in the next section, also for the tensor field.

7. Gravitational perturbations

Starting with the Einstein's equations and expanding the metric on the background

$$g_{\mu\nu} = g^{(0)}_{\mu\nu} + h_{\mu\nu},$$

one derives the Lichnerowitz equation for the spin 2 field in curved space-time:[14]

$$\nabla^\alpha \nabla_\alpha \psi_{\mu\nu} + 2R^\sigma{}_\mu{}^\tau{}_\nu{}^{(0)} \psi_{\sigma\tau} - 2R^\sigma{}_{(\nu}{}^{(0)} \psi_{\mu)\sigma} = 0, \qquad \nabla_\mu \psi^{\mu\nu} = 0, \tag{20}$$

where

$$\psi_{\mu\nu} = h_{\mu\nu} - \frac{1}{2} g_{\mu\nu} h, \quad h = g^{\mu\nu} h_{\mu\nu}, \quad \psi = g^{\mu\nu} \psi_{\mu\nu}.$$

In the case of non-vacuum background, the additional gauge fixing condition $\psi = 0$ should be imposed.

To apply the NP formalism, similar splitting has to be performed in the null tetrad vectors, spin coefficients, Weyl scalars and Ricci tensor deviators, equipping the first order perturbations with an index one. The complete set of gravitational perturbation equations in the Newman-Penrose formalism is obtained by linearizing the Bianchi identities. We present here two equations from the resulting system, which are relevant for pp-waves:

$$\bar{\delta}\Psi_0^{(1)} - D\Psi_1^{(1)} = 4\pi\left[\delta T_{ll}^{(1)} - DT_{lm}^{(1)}\right], \qquad \Delta\Psi_0^{(1)} - \delta\,\Psi_1^{(1)} = 4\pi\left[\delta T_{lm}^{(1)} - DT_{mm}^{(1)}\right]. \tag{21}$$

After some manipulations using the perturbed Ricci identities in the NP formalism, we obtain the decoupled equation for the perturbation of Ψ_0 with the corresponding source term:

$$\Box\Psi_0^{(1)} = 4\pi T_0^{(1)}, \qquad T_0^{(1)} = 2\left[2D\delta T_{lm}^{(1)} - D^2 T_{mm}^{(1)} - \delta^2 T_{ll}^{(1)}\right]. \tag{22}$$

Then using the conjugate operator we can write down the solution in terms of the Debye potential:

$$\psi^{\mu\nu} = \left[2l^{(\mu}\bar{m}^{\nu)}\bar{\delta}D - \bar{m}^\mu \bar{m}^\nu D^2 - l^\mu l^\nu \bar{\delta}^2\right]\psi, \qquad \Box\psi = 0. \tag{23}$$

This expression satisfies the Lichnerowitz equation with the gauge condition (20).

As in the case of the vector field, this construction will be also valid for the non-vacuum pp-waves. This can be easily verified by the direct substitution.

8. Shock wave backgrounds

An important subclass of pp-waves is generated via boosting the black hole metrics to an infinite-momentum frame. The line element of the resulting metrics (parametrized by the real transverse coordinates x_i $i = 1, 2$) reads

$$ds^2 = \delta(u) f(\mathrm{x}) du^2 + du dv - dx_i^2. \tag{24}$$

This is an exact solution of the Einstein equations representing the gravitational shock wave. When $u \neq 0$, the space-time is flat, but for $u = 0$ it has a delta-like singularity. But the field equations on such a background are still meaningful due to lack of singularities in the metric determinant. The function $f(\mathrm{x})$ describes the gravitational wave profile. In particular, for the case of the boosted Schwarzschild solution (the Aichelburg-Sexl metric[15])

$$f(\mathrm{x}) = -8p_m \ln \rho, \quad \rho = \sqrt{x_1^2 + x_2^2},$$

where p_m denotes the energy of shock wave. For the case of a boosted Einstein-Maxwell-dilaton solution[16]

$$f(\mathrm{x}) = -8p_m \ln \rho + \frac{(3 - 4a^2)}{(1 - a^2)} \frac{\pi p_e}{\rho},$$

whetre a - the dilaton coupling constant, p_e - the electric charge. For boosted Taub-NUT[17]

$$f(\mathrm{x}) = -8p_n \tan^{-1} \frac{x_1}{x_2},$$

where p_n is the NUT charge. Also known in the literature are the boosted Kerr- Newman solution,[18] the boosted Schwarzschild-anti-de Sitter[19] space and some other metrics.

Here we present the solution of the massive Klein-Gordon equation on the background of the singular shock-wave metrics:

$$(\Box + m^2)\phi = 2(D\Delta - \delta\bar{\delta})\psi + m\psi = \left(4\partial_u \partial_v + 4\,\kappa\,\delta(u) f(\mathrm{x}) \partial_v^2 - \partial_i^2 + m^2\right) \phi = 0. \tag{25}$$

In spite of presence of the singularity, there exists an exact solution of this equation containing the Heaviside function discontinuity only:

$$\phi = \int \exp[i\,\mathcal{W}]\, d\mathcal{G}, \qquad d\mathcal{G} = \frac{d\boldsymbol{q}}{(2\pi)^2}\, d\boldsymbol{x},$$

$$\mathcal{W} = -\frac{k_v}{2}\big[v - \kappa\,\theta(u) f(\mathrm{x}')\big] - \frac{(\boldsymbol{k} - \boldsymbol{q})^2 + m^2}{2k_v} u + \boldsymbol{k}\boldsymbol{x} + \boldsymbol{q}(\boldsymbol{x}' - \boldsymbol{x}), \tag{26}$$

where we have introduced the notation $\boldsymbol{k} = (k_{x_1}, k_{x_2})$, $\boldsymbol{q} = (q_{x_1}, q_{x_2})$, $\boldsymbol{x} = (x_1, x_2)$ for the two-dimensional transverse vectors. If we put the mass equal to zero, then we obtain the solution of the equation for the Debye potential.

9. Massive field with spin $\frac{1}{2}$

Now consider other massive fields, starting from the spin 1/2. In the two-component notation, the Dirac bispinor equation $i\gamma^\mu\nabla_\mu\psi - \mu\,\psi = 0$ with $\psi = \left(\xi^A, \eta_{A'}\right)$, splits into two equations

$$\nabla_{AB'}\xi^A - i\mu\,\eta_{B'} = 0, \qquad\qquad \nabla^{AB'}\eta_{B'} - i\mu\,\xi^A = 0. \tag{27}$$

Their solution in the case of shock-wave backgrounds is a generalization of the previously obtained expression (14) for the massless field and can be written in the following form

$$\eta_{1'} = 2\int([k_{x_1} - q_{x_1}] + i[k_{x_2} - q_{x_2}] - \mu)\exp[i\,\mathcal{W}]\;d\mathcal{G}, \quad \eta_{0'} = -\int k_v \exp[i\,\mathcal{W}]\;d\mathcal{G},$$
$$\xi^0 = 2\int\Big([k_{x_1} - q_{x_1}] - i[k_{x_2} - q_{x_2}] + \mu\Big)\exp[i\,\mathcal{W}]\;d\mathcal{G}, \quad \xi^1 = \int k_v \exp[i\,\mathcal{W}]\;d\mathcal{G}, \tag{28}$$

where $\mathcal{W}$ defined in (26).

10. Proca equation

For the massive spin-1 field the gauge invariance of Maxwell's field is broken by the mass term. Instead of the gauge fixing condition, we deal with the Lorentz-like dynamical constraint, so we have two equations:

$$\nabla_\mu F^{\mu\nu} + m^2 A^\nu = 0, \qquad\qquad \nabla_\mu A^\mu = 0. \tag{29}$$

The massive vector field is no longer transverse, possessing three physical degrees of freedom. The first two polarizations in the case of shock wave background are realized by modified expressions with Debye potentials (the real and imaginary parts of the solution):

$$A^\mu_{(1,2)} = \int \mathcal{K}^\mu_{(1,2)} \exp[i\,\mathcal{W}]\;d\mathcal{G}, \quad \mathcal{K}^\mu_{(1,2)} = \Big\{0, 2[k_{x_1} - q_{x_1}] - 2i[k_{x_2} - q_{x_2}], k_v, -ik_v\Big\}. \tag{30}$$

For the third polarization we solve the dynamical constraint acting by the covariant derivative on the massive scalar field, obtaining

$$A^\mu_{(3)} = \int \mathcal{K}^\mu_{(3)} \exp[i\,\mathcal{W}]\;d\mathcal{G} + c.c,$$

$$\mathcal{K}^\mu_{(3)} = \Big\{k_v,\ \frac{(-\boldsymbol{q})^2 - m^2}{k_v} + k_v\delta(u)f(\mathrm{x}),\ \ k_{x_1} - q_{x_1},\ k_{x_1} - q_{x_1}\Big\}. \tag{31}$$

It can be seen that this expression satisfies the constraint indeed. But this expression gives us only one additional polarization, because of real multipliers in front of the exponent. Therefore the complete solution of the Proca equation in AS metric is a sum $A^\mu = A^\mu_{(1,2)} + A^\mu_{(3)}$. To write down the solution for massless electromagnetic field, it is sufficient to set the mass to zero.

11. Conclusions

This work is devoted to some novel applications of the Newman-Penrose formalism and the method of Debye potentials. Previously this technique was successfully used to construct solutions of equations for massless fields of different spins on the background of vacuum black hole solutions of Petrov type D. Here it was applied to solutions of type N. Unlike the case D, where the metric has two principal null directions and, accordingly, two decoupled equations for NP projections can be derived, in the metrics of type N only one decoupled equation exists. Namely, one can decouple the χ_0-equation for the Weyl field, the ϕ_{000}-equation for the Rarita-Schwinger field, and the equations for perturbations of Φ_0 and Ψ_0 of the vector and tensor fields respectively. It is still enough to construct the Debye representation for the solutions obtaining the universal equation for the Debye potential for all spins. We also managed to generalize our construction to the case of massive fields on the background of shock-wave metrics. Our formulas can be used for quantization in shock wave backgrounds and in some holographic applications.

We show that spinors propagating in curved gravitational background acquire an interaction with spacetime curvature, which leads to a quantum mechanical geometric effect. This is similar to what happens in the case of magnetic fields, known as Pancharatnam-Berry phase. As the magnetic and gravitational fields have certain similar properties, e.g. both contribute to curvature, this result is not difficult to understand. Interestingly, while spacetime around a rotating black hole offers Aharonov-Bohm and Pancharatnam-Berry both kinds of geometric effect, a static spacetime offers only the latter. In the bath of primordial black holes, such gravity induced effects could easily be measured due to their smaller radius.

Keywords: Geometric phase; Dirac equation; semi-classical theory; classical black holes; field theory; curved spacetime.

1. Introduction

In recent works,[1,2] we showed that spinors propagating in a curved background acquire a geometric phase (GP) similar to the case of GP in electromagnetic field. The study of GP in electromagnetic field has been widely explored. Two most important notions of GPs are: Aharonov-Bohm (AB) effect[3] and Pancharatnam-Berry (PB)[4,5] phase. AB effect and PB phase occur in two different physical scenarios. In presence of a varying magnetic field, PB phase is acquired by a spinor, whereas AB effect can be acquired even without a varying field. In fact, AB effect is one of the signature properties of magnetic potential influencing a particle's quantum state. These effects/phases in case of electromagnetic fields originate from the effective curvature of magnetic potential and field in the (flat) Minkowski spacetime. We showed[2] that in a curved spacetime, a spinor in the vicinity of a gravitating body can acquire similar geometric phases which originate from the effective curvature of the spacetime itself.

Analogous effects for gravitational and magnetic fields are well known. Some of the examples are: curvature generated in both scenarios; electromagnetic radiation from accelerated charge and gravitational radiation from accelerated mass (only quadrupolar in nature), both propagating with the speed of light; energy splitting of spin-half particles in presence of both fields.[6,7] With the continuation of these analogous results, it is expected that the quantum effects, which generate the GPs in case of magnetic field, similarly should be present in case of gravitational field. Some studies have already explored these effects in local coordinates.[1,7,8] There are many astrophysical and cosmological phenomena like baryogenesis, neutrino emissions from supernovae and active galactic nuclei (AGNs), neutrino oscillation, neutrino dominated accretion disks, Fermi degenerate gas in compact objects, etc., where study of spinor propagation and evolution is crucial to understand the physical nature of these phenomena.[9–16]

When it comes to the study of gravity with quantum mechanics and understand various effects of quantum systems in curved spacetime, semi-classical formalism is a very effective tool to perform such study. In fact, there are plenty of available works in the literatures which have explored the dynamics of spinors in curved spacetime. These have been done with the Lagrangian[9,17] and Hamiltonian[6,18] formalisms. It is also well known fact that in the Hamiltonian formalism, the Dirac Hamiltonian of a spinor in curved spacetime has a non-hermiticity and uniqueness problem. Different authors tried to implement different approaches to address these issues.[6,18–22] Non-hermitian biorthogonal quantum mechanics[23] provides tool for solving the non-hermiticity issue of Dirac Hamiltonian. One approach is to define a relativistically invariant scalar product (Parker scalar product)[6,18] and use that scalar product to define the expectation values of all operators. In case of curved spacetime, this scalar product is different from the standard flat spacetime scalar product because of the presence of curved spacetime metric and vierbeins. The other approach is known as $\eta-$ representation or pseudo-Hermitian approach,[21,22] where the Hamiltonian and eigenstates of the particle are modified by the metric and vierbeins in such a way that effectively one can use the standard flat scalar product to define all the operators in the Hilbert space. In fact, these two approaches are shown to be equivalent.[21,22]

In this work, we explore the Dirac Hamiltonian in curved spacetime background, especially in Kerr and Schwarzschild geometries, using the pseudo-Hermitian approach or the η-representation and explore the possibilities of appearance of GPs in spinors traversing in curved spacetime. In section 2, we recapitulate the quantum mechanics in η-representation. Then in section 3, we derive the Dirac Hamiltonian in the Kerr geometry and further derive its non-relativistic counterpart for slowly moving particles around a weakly rotating black hole and its analogy with that in electromagnetic fields in section 4. In section 5, we find GPs in curved spacetime. Finally, in section 6, we summarize our findings.

2. Quantum Mechanics in the η-Representation

We briefly discuss the quantum mechanics in η-representation.[21,22,24,25] If an operator η satisfies the relation

$$\rho = \eta^\dagger \eta, \tag{1}$$

where ρ is an invertible operator which assures the relation to be satisfied as

$$\rho H \rho^{-1} = H^\dagger, \tag{2}$$

then the Hamiltonian in η-representation turns out to be

$$H_\eta = \eta H \eta^{-1} = H_\eta^\dagger. \tag{3}$$

The relation between the wave functions in the η–representation and in the standard representation is given by

$$\Psi = \eta\psi, \tag{4}$$

where these two wave functions satisfy the following wave equations:

$$i\frac{\partial\psi}{\partial t} = H\psi, \tag{5}$$

$$i\frac{\partial\Psi}{\partial t} = H_\eta\Psi. \tag{6}$$

As we mentioned above, the Parker scalar product,[6,18] which is a modification of standard scalar product, in Hilbert space is defined as

$$(\phi,\psi)_\rho = \int d^3x(\phi^\dagger\rho\psi), \tag{7}$$

whereas in the pseudo-Hermitian approach, the scalar product takes the standard form of flat space scalar product since the Hamiltonian and the wave functions are already modified there, which is

$$(\Phi,\Psi) = \int (\Phi^\dagger\Psi)d^3x. \tag{8}$$

We can easily verify that

$$(\phi,\psi)_\rho = (\Phi,\Psi). \tag{9}$$

3. Dirac Hamiltonian in the Kerr and Schwarzschild Metrices

We use the convention of natural unit system with $\hbar = G = c = 1$ and metric signature of $(+,-,-,-)$.

We can start from the Dirac equation in curved spacetime which is,

$$(i\gamma^\mu D_\mu - m)\psi(x) = 0. \tag{10}$$

where the covariant derivative $D_\mu = \partial_\mu + \Gamma_\mu$. Here Γ_μ is the spinorial affine connection.[6,18] m is the mass of the Dirac particle, ψ is the four-component column bispinor. γ^μ are the Dirac matrices in curved spacetime which satisfies the relation

$$\gamma^\alpha \gamma^\beta + \gamma^\beta \gamma^\alpha = 2g^{\alpha\beta} I_4, \tag{11}$$

where I_4 is the 4×4 identity matrix and $g^{\alpha\beta}$ is the contravariant metric tensor of curved spacetime. The adjoint spinor is defined as $\bar{\psi} = \psi^\dagger \gamma^0$.

The gamma matrices in curved spacetime, also known as global gamma matrices (γ^α), are related to the local flat spacetime gamma matrices (γ^a) by the relation

$$\gamma^\alpha = e^\alpha_a \gamma^a, \tag{12}$$

where e^α_a-s are the tetrads defined by

$$g_{\mu\nu} = e^a_\mu e^b_\nu \eta_{ab}. \tag{13}$$

We then derive the global Dirac Hamiltonian operator from equation (10), which is

$$\begin{aligned} H = &-i\Gamma_t - i(g^{tt})^{-1}\gamma^t \left[\gamma^r(\partial_r + \Gamma_r)\right. \\ &\left. + \gamma^\theta(\partial_\theta + \Gamma_\theta) + \gamma^\phi(\partial_\phi + \Gamma_\phi)\right] + (g^{tt})^{-1}\gamma^t m. \end{aligned} \tag{14}$$

This Hamiltonian is self-adjoint under the Parker scalar product given in equation (7). Nevertheless, our purpose is to find the Dirac Hamiltonian in η-representation which will be useful for working in standard flat Hilbert space. We choose astrophysically important metrices to work with and hence we shall find the Dirac Hamiltonian in η-representation for the Kerr metric, which reduces to the Schwarzschild metric when the Kerr parameter $a = 0$.

3.1. *Kerr metric*

The Kerr metric in the Boyer-Lindquist coordinates is

$$\begin{aligned} ds^2 = &\left(1 - \frac{2Mr}{\rho^2}\right) dt^2 + \frac{4Mra\sin^2\theta}{\rho^2} dt d\phi - \frac{\rho^2}{\Delta} dr^2 \\ &- \rho^2 d\theta^2 - \left[(r^2 + a^2)\sin^2\theta + \frac{2Mra^2\sin^4\theta}{\rho^2}\right] d\phi^2, \end{aligned} \tag{15}$$

where $\rho^2 = r^2 + a^2\cos^2\theta$, $\Delta = r^2 - 2Mr + a^2$, M is the mass of black hole and a is the Kerr parameter (angular momentum per unit mass of the black hole). We choose the Schwinger gauge of tetrad,[26–28] given by

$$\begin{aligned} e^t_0 = \sqrt{g^{tt}}, e^r_1 = \frac{\sqrt{\Delta}}{\rho}, e^\theta_2 = \frac{1}{\rho}, \\ e^\phi_3 = \frac{1}{\sin\theta\sqrt{\Delta}\sqrt{g^{tt}}}, e^\phi_0 = \frac{2Mar}{\rho^2\Delta\sqrt{g^{tt}}}. \end{aligned} \tag{16}$$

The Dirac Hamiltonian in the η-formalism in Kerr metric then turns out to be[29]

$$\begin{aligned}H_\eta = &\frac{m}{\sqrt{g^{tt}}}\gamma^0 - i\frac{\sqrt{\Delta}}{\rho\sqrt{g^{tt}}}\left(\frac{\partial}{\partial r}+\frac{1}{r}\right)\gamma^0\gamma^1\\ &- i\frac{1}{\rho\sqrt{g^{tt}}}\left(\frac{\partial}{\partial\theta}+\frac{1}{2}\cot\theta\right)\gamma^0\gamma^2 - i\frac{1}{g^{tt}\sqrt{\Delta}\sin\theta}\frac{\partial}{\partial\phi}\gamma^0\gamma^3\\ &- i\frac{2Mar}{g^{tt}\rho^2\Delta}\frac{\partial}{\partial\phi} - i\frac{1}{2}\frac{\partial}{\partial r}\left(\frac{\sqrt{\Delta}}{\rho\sqrt{g^{tt}}}\right)\gamma^0\gamma^1 - i\frac{1}{2}\frac{\partial}{\partial\theta}\left(\frac{1}{\rho\sqrt{g^{tt}}}\right)\gamma^0\gamma^2\\ &+ i\frac{\sqrt{g^{tt}}\Delta Ma\sin\theta}{2\rho}\left(\frac{\partial}{\partial r}\left(\frac{r}{g^{tt}\rho^2\Delta}\right)\gamma^3\gamma^1\right.\\ &\left.+\frac{1}{\sqrt{\Delta}}\frac{\partial}{\partial\theta}\left(\frac{r}{g^{tt}\rho^2\Delta}\right)\gamma^3\gamma^2\right).\end{aligned} \tag{17}$$

We can write this Hamiltonian as

$$H_\eta = (\sqrt{g^{tt}})^{-1}\left[\gamma^0 m + \gamma^0\gamma^j(p_j - iA_j) + i\gamma^0\gamma^j\gamma^5 k_j + e_0^\phi p_\phi\right], \tag{18}$$

where $A_1 = \frac{\sqrt{\Delta}}{\rho r} + \frac{\sqrt{g^{tt}}}{2}\frac{\partial}{\partial r}\left(\frac{\sqrt{\Delta}}{\rho\sqrt{g^{tt}}}\right)$, $A_2 = \frac{\cot\theta}{2\rho} + \frac{\sqrt{g^{tt}}}{2}\frac{\partial}{\partial\theta}\left(\frac{1}{\rho\sqrt{g^{tt}}}\right)$ and $A_3 = 0$; $k_1 = \frac{ig^{tt}Ma\sqrt{\Delta}\sin\theta}{2\rho}\frac{\partial}{\partial\theta}\left(\frac{r}{g^{tt}\rho^2\Delta}\right)$, $k_2 = -\frac{ig^{tt}Ma\Delta\sin\theta}{2\rho}\frac{\partial}{\partial r}\left(\frac{r}{g^{tt}\rho^2\Delta}\right)$ and $k_3 = 0$. Here we use the fact that $\gamma^3\gamma^2$ and $\gamma^3\gamma^1$ can be respectively written as $i\gamma^0\gamma^1\gamma^5$ and $-i\gamma^0\gamma^2\gamma^5$.

Now using the relations $H_\eta = i\frac{\partial}{\partial t} = p_t$ and $\partial_0 = e_0^t\partial_t + e_0^\phi\partial_\phi$, we rearrange the equation (18) to

$$\left[p_0 - \gamma^0\{m + \gamma^j(p_j - iA_j) + i\gamma^j\gamma^5 k_j\}\right]\Psi = 0, \tag{19}$$

where we use the tetrad transformation relation between global and local 4-momenta as

$$p_j = e_j^\mu p_\mu, \tag{20}$$

where Greek indices represent global coordinates (t, r, θ, ϕ) and roman indices represent flat coordinates $(0, 1, 2, 3)$.

Now we need to identify the terms in these equations with the analogy of magnetic field scenario which we discussed in section 1. A_js are analogous to the magnetic vector potential and k_js are "pseudo-vector" potential, which in this case of Kerr metric appears due to the chirality in the system owing to the rotation of spacetime.

If we put $a = 0$, the equations in the Kerr metric reduce to those in the Schwarzschild metric. The Hamiltonian then turns out to be

$$H_\eta = (\sqrt{g^{tt}})^{-1}\left[\gamma^0 m + \gamma^0\gamma^j(p_j - iA_j^s)\right], \tag{21}$$

where $A_1^s = \frac{1}{r}\sqrt{1-\frac{2M}{r}} + \frac{\sqrt{g^{tt}}}{2}\frac{\partial}{\partial r}\left(\frac{\sqrt{1-\frac{2M}{r}}}{\sqrt{g^{tt}}}\right)$, $A_2^s = \frac{\cot\theta}{2r}$ and $A_3^s = 0$.

We can also rearrange the Hamiltonian for $a = 0$ to write the Dirac equation in a compact form as

$$\left[p_0 - \gamma^0\{m + \gamma^j(p_j - iA_j^s)\}\right]\Psi = 0. \tag{22}$$

Here A_j^ss are the "gravito-magnetic potential" in the Schwarzschild geometry similar to the A_js in Kerr metric.

4. Nonrelativistic Approximation of Dirac Hamiltonian

In the standard Dirac representation, we write the Dirac equation in Kerr metric from equation (19) as

$$\begin{pmatrix} -p_0 + i\vec{\sigma}\cdot\vec{k} + m & \vec{\sigma}\cdot\vec{\Pi}_A \\ \vec{\sigma}\cdot\vec{\Pi}_A & -p_0 + i\vec{\sigma}\cdot\vec{k} - m \end{pmatrix}\Psi = 0, \tag{23}$$

where

$$\begin{aligned} \vec{k} &= (k_1, k_2, 0), \\ \vec{\Pi}_A &= \vec{p} - i\vec{A}. \end{aligned} \tag{24}$$

Following the standard process of deriving the non-relativistic limit of the Hamiltonian (see reference 30) we can write the coupled equations as

$$(\vec{\sigma}\cdot\vec{\Pi}_A)\Psi_B = (E - i\vec{\sigma}\cdot\vec{k} - m)\Psi_A, \tag{25a}$$

$$(\vec{\sigma}\cdot\vec{\Pi}_A)\Psi_A = (E - i\vec{\sigma}\cdot\vec{k} + m)\Psi_B. \tag{25b}$$

where E is the energy eigenvalue, Ψ_A and Ψ_B are the two components of wavefunction Ψ and we take into account the fact that $\vec{A}$ and $\vec{k}$ are time-independent.

We now assume slowly rotating spacetime and non-relativistic particles such that the particle velocity $v << c$, hence

$$E \sim m, \qquad |\vec{k}| << m \tag{26}$$

and define the non-relativistic particle energy,

$$E^{NR} = E - m. \tag{27}$$

It can easily be derived that by keeping only leading order terms by combining equations (25a) and (25b), we obtain

$$\frac{1}{2m}(\vec{\sigma}\cdot\vec{\Pi}_A)(\vec{\sigma}\cdot\vec{\Pi}_A)\Psi_A = (E^{NR} - i\vec{\sigma}\cdot\vec{k})\Psi_A, \tag{28}$$

which can be further written as

$$\left[\frac{\Pi^2}{2m} + \sigma\cdot(i\vec{k} - \frac{i}{2m}\vec{B}_g)\right]\Psi_A = E^{NR}\Psi_A, \tag{29}$$

where $\vec{B}_g = \vec{\nabla}\times\vec{A}$ is the effective "gravito-magnetic field" and $\vec{A}$ is "gravito-magnetic potential". This implies that

$$H^{NR}\Psi_A = \left[\frac{\Pi^2}{2m} + \vec{\sigma}\cdot\vec{B}_g^{kerr}\right]\Psi_A, \tag{30}$$

where $\vec{B}_g^{kerr} = (i\vec{k} - \frac{i}{2m}\vec{B}_g)$ which involves both field analogue term and potential analogue term.

Similarly for $a = 0$ (Schwarzschild) case, we can find that

$$H^{sNR}\Psi_A = \left[\frac{\Pi^{s\,2}}{2m} + \vec{\sigma}\cdot\vec{B}_g^{sch}\right]\Psi_A, \tag{31}$$

where $\vec{B}_g^{sch} = -\frac{i}{2m}\vec{B}_g^s$ where $\vec{B}_g^s = \vec{\nabla}\times\vec{A}^s$.

Note importantly that $\vec{B}_g^{kerr}$ involves the field $(\vec{B}_g)$ and potential $(\vec{k})$ both, whereas $\vec{B}_g^{sch}$ involves only field.

4.1. *Analogy with electromagnetism*

In the presence of electromagnetic field, the Dirac equation is given by

$$\left[i\gamma^\mu\left(\partial_\mu - ieA_\mu\right) - m\right]\psi = 0, \tag{32}$$

where e is the electric charge and A_μ is the electromagnetic covariant 4-vector potential. For the non-trivial solution for ψ, the energies/Hamiltonians of the spin-up and spin-down particles are given by

$$(H + eA_0)^2 = (\hat{p} - e\vec{A})^2 + m^2 + e\vec{\sigma}\cdot\vec{B}, \tag{33}$$

where A_0 is the temporal component of A_μ which is basically the Coulomb potential and $\hat{p}$ is the quantum mechanical momentum operator $-i\nabla$. In the non-relativistic limit, equation (33) reduces to[1]

$$H = -eA_0 \pm \left[\frac{(\hat{p} - e\vec{A})^2}{2m} + m + \frac{e\vec{\sigma}\cdot\vec{B}}{2m}\right]. \tag{34}$$

Clearly equation (34) is very similar to equation (31) and, hence, whatever effects have been proposed for electromagnetism, the same are expected to suffice for gravitation.

Apart from the split due to the positive and negative energy solutions, clearly there is an additional split in the respective energy levels in equations (31) and (34). This is basically the Zeeman-splitting (or Zeeman-like for gravitation) governed by the term with Pauli's spin matrix, in the up- and down-spinors for the positive and negative energy spinors induced by magnetic/gravitational fields, whether we choose relativistic or non-relativistic regimes.

5. Geometric Phase

To find the geometric effects, we construct Poincaré sphere by $\vec{B}_g^{kerr}$. Essentially, the interaction between the spinor and the gravitational background comes from the interaction Hamiltonian of

$$H_{int} = \vec{\sigma}\cdot\vec{B}, \tag{35}$$

where $\vec{B} = \vec{B}_g^{kerr}$. We can write this Hamiltonian as

$$H_{int} = |\vec{B}| \begin{pmatrix} \cos\zeta & \sin\zeta \exp(-i\xi) \\ \sin\zeta \exp(+i\xi) & -\cos\zeta \end{pmatrix}, \tag{36}$$

where ζ and ξ are the latitude and azimuthal angles of spherical polar coordinates respectively of the parameter space constructed by the vector $\vec{B}$. Here ρ is the radial coordinate in this system.

Now, using the standard definition of phase (Φ_B) and connection ($\vec{A}_B$) (see reference 2 for details) we find that the connection is

$$\vec{A}_B = \frac{(1-\cos\zeta)}{2\rho\sin\zeta}\hat{\xi}, \tag{37}$$

and the phase is

$$\Phi_B = \frac{\tilde{\xi}}{2}(1-\cos\zeta) = \frac{\Omega}{2}, \tag{38}$$

where $\tilde{\xi}$ is the total integrated azimuthal coordinate and Ω is the integrated solid angle.

Thus the GP in curved spacetime around Kerr (and Schwarzschild) geometry takes the similar form as revealed in the case of magnetic field but the angle coordinates and phases are fixed by the spacetime geometry. It is important to note that in the Kerr metric case, the GP is a combination of AB effect which appears due to the potential like term $\vec{k}$ and PB phase which appears due to the field like term $\vec{\nabla} \times \vec{A}$. In case of Schwarzschild metric however only PB contributes to the GP.

5.1. *Possible measurement*

Previous studies[31,32] have proven the relevance of semi-classical effects in gravitational background for massive particles. In this paper, we have shown that origin of GPs in spinors traversing in curved spacetime is theoretically possible. However, the question remains that how effectively these effects can be measured. For that, we need to estimate some of the length scales of the systems. Usually, quantum effects become prominent when length scale (l) of the system becomes comparable to or less than the de-Broglie wavelength of the particle $\lambda = \hbar/p$, where p is the momentum. In the case of gravity, this l is typically the radius of the gravitational body. We find that although the appearance of GPs is theoretically possible in all conditions, it may be detected only in selective cases like, e.g. primordial black holes (see reference 2 for details). The qualitative reason is simple. Larger the size of the gravitating body, smaller the field $\vec{B}$ (or $\vec{A}$ or $\vec{k} \sim 1/r$) is and thus smaller the geometric effects are. Hence, for smaller black holes these effects are prominent, but not for astrophysical black holes.

6. Summary

It is found that the Dirac particles interacting with spacetime curvature give rise to effective spin-orbit coupling which eventually manifests geometric phases/effects: Aharonov-Bohm (AB) effect and Pancharatnam-Berry (PB) phase. AB term originates from the spin of the background geometry which is responsible for the chirality in the system and this effect goes off when black hole spin becomes zero. PB phase appears in the Kerr metric as well as in spherically symmetric static spacetime like Schwarzschild geometry. Although theoretically these effects can appear in all cases, detection of such semi-classical effects is observationally possible, at least for non-relativistic particles, in a scenario where a nonrelativistic massive particle moves around a primordial black hole. Future mission by *Fermi* satellite can prove the existence of primordial black holes by detecting small interference pattern within gamma-ray bursts. Although the results of this work are outcome for a special case of nonrelativistic particles and weakly rotating black holes, it is expected that a covariant formalism will provide similar results in a general gravitational background from the analogy of covariant formalism of study of GPs in magnetic fields.[33]

Free massless fields of any spin in flat D-dimensional spacetime propagate at the speed of light. But the retarded fields produced by the corresponding point-like moving sources share this property only for even D. Since the Green's functions of the d'Alembert equation are localized on the light cone in even-dimensional spacetime, but not in odd dimensions, extraction of the emitted part of the retarded field in odd D requires some care. We consider the wave equations for spins 0, 1, and 2 in five-dimensional spacetime and analyze the fall-off conditions for the retarded fields at large distances. It is shown that the farthest part of the field contains a component propagating at the speed of light, while the non-derivative terms propagate with all velocities up to that of light. The generated radiation will contain a radiation tail corresponding to the complete prehistory of the source's motion preceding the retarded moment of time. We also demonstrate that dividing the Green's function into a part localized on the light cone and another part that is not zero inside the light cone gives separately the divergent terms in the Coulomb field of a point source. Their sum, however, is finite and corresponds to the usual power-law behaviour.

Keywords: Extra dimensions, radiation, scalar field, electromagnetic field, gravitational waves

1. Introduction

The recent interest in the theory of radiation in spacetime dimensions other than four is mostly related to the development of the theories with extra dimensions of spacetime. While the superstring theory, pretending to the status of fundamental theory, predicts the existence of extra dimensions, there is a number of phenomenological multi-dimensional gravity theories[1–4] solving some problems of elementary particles physics and cosmology. However, the characteristics of extra dimensions, such as their number, geometry and size, vary widely from one theory to another.

The actively developing gravitational-wave astronomy is the one of the most promising tools to probe the extra dimensions. So, the first constraints on the characteristics of extra dimensions have already been obtained by use of the GW170817/GRB170817A event data.[5–7] The possibility of using the future gravitational-wave observatories, such as LISA, to constrain the extra dimensions on cosmological scales has also been discussed.[8,9] Also, it is worth to note the recent advances in the constraining extra dimensions by the photograph of the supermassive black hole M87* shadow.[10,11]

However, in most of the literature, only the radiation in even-dimensional spacetimes is considered,[12–16] while the odd dimensions have been mainly discussed in the context of radiation reaction force.[17–20] It is mostly due to the Huygens principle violation in odd dimensions known since the classical works of Hadamard, Courant and Hilbert, Ivanenko and Sokolov.[21–23] In any dimensions, the signal from the instant flash of the source reaches an observer in the interval of time required for it to propagate at the speed of light. However, in odd dimensions, the endless tail signal decaying with time is observed after that, which is not the case in even dimensions. Mathematically, the Huygens principle violation consists in odd-dimensional retarded Green's functions being localised not only on the light cone, as they are in even dimensions, but also inside it. As a result, the retarded fields in odd dimensions propagate in space with all velocities up to that of light. However, free massless fields propagate exactly at the speed of light in any dimensions. Therefore, there is the apparent mismatch as the radiation being the free field far from the source is determined by its retarded field.

In this paper, we demonstrate that despite the Huygens principle violation in odd dimensions the radiation can be computed by the integration of the energy-momentum flux in the wave zone. We use the Rohrlich-Teitelboim radiation definition[24–26] (see, also,[27–29]) based on the Lorentz-invariant decomposition of the on-shell energy-momentum tensor. Considering the radiation of spin-0, spin-1 and spin-2 fields in five spacetime dimensions we show that the emitted part of the field energy-momentum propagates in space exactly at the speed of light, while it depends on the entire history of the source motion preceding the retarded time, in contrast with the four-dimensional theory.

The paper is organised as follows. In second section we consider the scalar radiation from the point charge in five spacetime dimensions. We briefly recall the recurrent relation for the odd-dimensional retarded Green's functions and the Rohrlich-Teitelboim approach to radiation. Based on the latter, we compute the emitted part of the on-shell energy-momentum tensor. In Sec. 3, we consider the analogous problem for the five-dimensional electromagnetic field. Section 4 is devoted to the calculation of the gravitational radiation from the point particle moving along an arbitrary world line in five dimensions. In the last section we briefly discuss our results.

2. Scalar radiation in five dimensions

Action of the massless scalar field $\varphi(x)$ interacting with the massive point particle moving along an arbitrary world line $z^\mu(\tau)$ in the five-dimensional Minkowski spacetime is written as

$$S = \frac{1}{4\pi^2}\int d^{4+1}x\,\partial^\mu\varphi(x)\partial_\mu\varphi(x) - \int d\tau\sqrt{\dot z^\alpha \dot z_\alpha}(m + g\varphi(z)), \quad \dot z^\mu = \frac{dz^\mu}{d\tau}, \qquad (1)$$

where m is the particle's mass, g its scalar charge, and Minkowski metric is $\eta_{\mu\nu} = \mathrm{diag}(1,-1,-1,-1,-1)$. We assume that particle's motion is governed by

the external forces and is not affected by the radiation of scalar field, so here the world line variables are non-dynamical.

The action (1) leads to the scalar field equation of motion in form

$$\Box\varphi(x) = -2\pi^2 j(x), \tag{2}$$

$$j(x) = g\int d\tau\sqrt{\dot{z}^\alpha \dot{z}_\alpha}\,\delta^{(4+1)}(x-z), \tag{3}$$

where $j(x)$ is the scalar current, and $\Box = \partial^\mu\partial_\mu$ is the d'Alembert operator on the five-dimensional Minkowski space. To determine the radiation energy-momentum flux carried by the scalar field, we use its canonical energy-momentum tensor

$$T_{\mu\nu}(x) = \frac{1}{2\pi^2}\left(\partial_\mu\varphi\partial_\nu\varphi - \frac{1}{2}\eta_{\mu\nu}\partial^\alpha\varphi\partial_\alpha\varphi\right). \tag{4}$$

The retarded solution of the Eq. (2) is given as

$$\varphi(x) = -2\pi^2\int d^{4+1}x'\, j(x')G^{4+1}_{\rm ret}(x-x'), \tag{5}$$

where $G^{4+1}_{\rm ret}(x)$ is the retarded Green's function of the five-dimensional d'Alembert equation. It is defined by the equation

$$\Box G^{4+1}_{\rm ret}(x) = \delta^{(4+1)}(x), \tag{6}$$

$$G^{4+1}_{\rm ret}(x) = 0,\ x^0 < 0. \tag{7}$$

In the odd-dimensional Minkowski spacetimes, retarded Green's functions are determined by the following recurrent relation[23] (see, also,[30])

$$G^{2\nu+1}_{\rm ret}(x) = \frac{(-1)^{\nu-1}}{(2\pi)^\nu}\frac{d^{\nu-1}}{(rdr)^{\nu-1}}\frac{\theta(t)\,\theta(t^2-r^2)}{\sqrt{t^2-r^2}},\ \nu\in\mathbb{N}, \tag{8}$$

where $t = x^0$ and $r = |\mathbf{x}|$. Considering the expression under derivatives in Eq. (8) as a product of separate distributions and taking into that $d\theta(x)/dx = \delta(x)$, we find the five-dimensional retarded Green's function as

$$G^{4+1}_{\rm ret}(x) = \frac{\theta(t)}{2\pi^2}\left[\frac{\delta(t^2-r^2)}{(t^2-r^2)^{1/2}} - \frac{1}{2}\frac{\theta(t^2-r^2)}{(t^2-r^2)^{3/2}}\right]. \tag{9}$$

As discussed above, it is localised not only on the light cone, but also inside it, leading to the propagation of the retarded field in space with all velocities up to that of light. Also, retarded field depends on the entire history of the source's motion preceding the retarded time and is given by the sum of separately divergent on the light cone $t^2 - r^2 = 0$ terms. However, one can show that the divergences contained in each of the terms in Eq. (9) mutually cancel out and the resulting field is finite.

2.1. *Field of a static charge*

Let us consider the case of static particle, to demonstrate the absence of divergences in the retarded field. In our calculations, we will use the "finite lifetime" trick to show the cancellation of divergences between the two terms.

We assume that the particle is at the origin and it is "switched on" for a finite interval of the proper time $a < \tau < b$, where $a < 0$ and $b > 0$ for concreteness. For this interval its world line has the form $z^\mu = [\tau, 0, 0, 0, 0]$. Then, by use of Eqs. (5), (3) and (9) the scalar field is written as

$$\varphi(x) = \frac{g}{2}\int_a^b d\tau \left[\frac{\theta(t-\tau-r-\epsilon)}{[(t-\tau)^2-r^2]^{3/2}} - \frac{\delta(t-\tau-r-\epsilon)}{r[(t-\tau)^2-r^2]^{1/2}}\right], \tag{10}$$

where we introduced the regularising parameter $\epsilon \to +0$ into the delta and Heaviside functions to shift the divergences from the light cone. Preforming the integration we obtain

$$\varphi(x) = \frac{g}{2}\begin{cases} 0, \ t < a + r, \\ -\dfrac{t-a}{r^2[(t-a)^2-r^2]^{1/2}}, \ a + r \le t < b + r, \\ \dfrac{t-b}{r^2[(t-b)^2-r^2]^{1/2}} - \dfrac{t-a}{r^2[(t-a)^2-r^2]^{1/2}}, \ t \ge b + r. \end{cases} \tag{11}$$

In the limit of eternal particle, we arrive at the finite Coulomb-like field

$$\lim_{a,b\to\pm\infty} \varphi(x) = -\frac{g}{2r^2}, \tag{12}$$

with the power-law behaviour corresponding to the increased dimensionality of space. Similar cancellation of divergences has been shown to take place, also, for the moving particle.[30]

2.2. *The Rohrlich-Teitelboim radiation definition*

The structure of the odd-dimensional Green's functions (8) makes the extraction of the emitted part of the retarded field in a standard manner non-trivial and requires a more sophisticated approach.

Such an approach was suggested by Rohrlich[24,25] and Teitelboim[26] (see, also,[27–29]). It is based on the use of certain covariantly defined quantities, so we briefly recall their definitions. Let us consider the point particle moving along the world line $z^\mu(\tau)$ with velocity $v^\mu = dz^\mu/d\tau$ in the D-dimensional spacetime. The observation point coordinates are denoted as x^μ. Assume the observation point to be a top of the light cone in the past and denote the intersection point of this light cone with the particle's world line as $z^\mu(\hat{\tau}) \equiv \hat{z}^\mu$. The corresponding moment of proper time $\hat{\tau}$ is called the retarded proper time and is defined by equation

$$(x^\mu - \hat{z}^\mu)^2 = 0, \ x^0 \ge \hat{z}^0. \tag{13}$$

Further, all the hatted quantities correspond to that moment. Then, we introduce three spacetime vectors: a lightlike vector $\hat{X}^\mu = x^\mu - \hat{z}^\mu$ directed from the retarded

point of the world line to the observation point, a spacelike vector $\hat{u}^\mu$ orthogonal to the particle's velocity at the retarded moment of proper time, and a lightlike vector $\hat{c}^\mu = \hat{u}^\mu + \hat{v}^\mu$ aligned with the vector $\hat{X}^\mu$. Introduced vectors have the following properties

$$\hat{X}^2 = 0, \quad (\hat{u}\hat{v}) = 0, \quad \hat{u}^2 = -\hat{v}^2 = -1, \quad \hat{c}^2 = 0, \tag{14}$$

where $(\hat{u}\hat{v}) \equiv \hat{u}^\alpha \hat{v}_\alpha$. Using these vectors we, also, introduce the Lorentz-invariant distance $\hat{\rho}$ being the scalar product of two spacetime vectors

$$\hat{\rho} \equiv (\hat{v}\hat{X}), \quad \hat{X}^\mu = \hat{\rho}\hat{c}^\mu. \tag{15}$$

It is equal to the spatial distance in the Lorentz frame comoving with the particle at the retarded proper time. If the particle moves inside the compact region of space, then the Lorentz-invariant distance $\hat{\rho}$ is equivalent to the spatial distance

$$\hat{\rho} \xrightarrow{r \gg |\mathbf{\hat{z}}|} r. \tag{16}$$

In accordance with the Rohrlich-Teitelboim approach, it is the Lorentz-invariant distance $\hat{\rho}$ that is used in the long-range expansion of tensors and definition of the wave zone.

In the Rohrlich-Teitelboim approach, the radiation is determined by the most long-range part of the on-shell energy-momentum tensor expansion in the inverse powers of the Lorentz-invariant distance $\hat{\rho}$. In D dimensions, the retarded field's on-shell energy-momentum tensor is expanded as[12, 16, 26–29]

$$T^{\mu\nu} = T^{\mu\nu}_{\text{Coul}} + T^{\mu\nu}_{\text{mix}} + T^{\mu\nu}_{\text{rad}} \tag{17}$$

$$T^{\mu\nu}_{\text{Coul}} \sim \frac{A^{\mu\nu}}{\hat{\rho}^{2D-4}}, \quad T^{\mu\nu}_{\text{mix}} \sim \frac{B^{\mu\nu}}{\hat{\rho}^{2D-5}} + \ldots + \frac{C^{\mu\nu}}{\hat{\rho}^{D-1}}, \quad T^{\mu\nu}_{\text{rad}} \sim \frac{D^{\mu\nu}}{\hat{\rho}^{D-2}}. \tag{18}$$

Here, the first term $T^{\mu\nu}_{\text{Coul}}$ is the energy-momentum tensor of the deformed Coulomb-like part of the retarded field. The second one is the mixed part, which consists of more than one term for $D > 4$ and is absent in $D = 3$. The most long-range part $T^{\mu\nu}_{\text{rad}}$ of the on-shell energy-momentum tensor expansion has the properties allowing to associate it with the radiation energy-momentum:

- It is separately conserved $\partial_\mu T^{\mu\nu}_{\text{rad}} = 0$, corresponding to its dynamical independence from the other parts;
- It is proportional to the direct product of two null vectors $T^{\mu\nu}_{\text{rad}} \sim \hat{c}^\mu \hat{c}^\nu$, corresponding to its propagation exactly with the speed of light $\hat{c}_\mu T^{\mu\nu}_{\text{rad}} = 0$;
- It falls down as $T^{\mu\nu}_{\text{rad}} \sim 1/r^{D-2}$ and gives positive definite energy-momentum flux through the distant $(D-2)$-dimensional sphere of area $\sim r^{D-2}$.

Therefore, the radiation power in D-dimensions can be computed as the energy flux associated with $T^{\mu\nu}_{\text{rad}}$ through the distant $(D-2)$-dimensional sphere of radius r

$$W_D = \int T^{0i}_{\text{rad}}\, n^i\, r^{D-2}\, d\Omega_{D-2}; \quad i = \overline{1, D-1}, \tag{19}$$

where $n^i = x^i/r$ is the unit spacelike vector in the direction of observation, and $d\Omega_{D-2}$ is the angular element on the $(D-2)$-dimensional sphere. This structure holds in both even and odd dimensions with the only difference that in odd dimensions the emitted part of the energy-momentum tensor depends on the entire history of the particle's motion preceding the retarded proper time $\hat{\tau}$.

Note that, usually, the energy-momentum tensor is just the bilinear form of the field derivatives, as, e.g., in Eq. (4). Then, one can define the emitted part of the retarded field derivative, by analogy with that of the energy-momentum tensor,

$$(\partial_\mu \Phi)^{\rm rad} \sim 1/\hat{\rho}^{D/2-1}. \tag{20}$$

This definition is valid in the cases of scalar and electromagnetic fields and linearised gravity considered below.

2.3. *Emitted part of the scalar field*

Now we turn to the calculation of the emitted part of the retarded scalar field derivative. The computations below are similar to that in,[30] where we have considered the scalar synchrotron radiation in three and five spacetime dimensions.

Using the Eq. (5) together with Eqs. (9) and (3) we obtain the retarded scalar field of the moving particle as

$$\varphi(x) = -g \int d\tau\, \theta(X^0(\tau)) \left[\frac{\delta(X^2(\tau))}{(X^2(\tau))^{1/2}} - \frac{1}{2} \frac{\theta(X^2(\tau))}{(X^2(\tau))^{3/2}} \right], \tag{21}$$

where we introduced the vector $X^\mu(\tau) = x^\mu - z^\mu(\tau)$. In what follows, we omit its dependence on the proper time for brevity.

Its derivative is found to have the form

$$\partial_\mu \varphi(x) = -2g \int d\tau\, \theta(X^0) \left[\frac{3}{4} \frac{\theta(X^2)}{(X^2)^{5/2}} + \frac{\delta'(X^2)}{(X^2)^{1/2}} - \frac{\delta(X^2)}{(X^2)^{3/2}} \right] X_\mu, \tag{22}$$

where $\delta'(x) = d\delta(x)/dx$. Integrating by parts the term containing derivative of delta function by use of the relation

$$\frac{dX^2}{d\tau} = -2(vX), \tag{23}$$

we obtain the scalar field derivative in form

$$\begin{aligned} \partial_\mu \varphi(x) = -g \int d\tau\, \theta(X^0) \Bigg[& \frac{3}{2} \frac{\theta(X^2)}{(X^2)^{5/2}} X_\mu - \frac{\delta(X^2)}{(X^2)^{3/2}} X_\mu - \\ & - \frac{\delta(X^2)}{(vX)^2 (X^2)^{1/2}} \left[(aX) - 1 \right] X_\mu - \frac{\delta(X^2)}{(vX)(X^2)^{1/2}} v_\mu \Bigg], \end{aligned} \tag{24}$$

where we introduced the acceleration vector $a^\mu = d^2 z^\mu / d\tau^2$.

To obtain its emitted part, we extract the leading $\hat{\rho}$-asymptotic of the Eq. (24). We transform the products of delta and Heaviside functions by use of the relation for the delta function of complex argument

$$\theta(X^0)\delta(X^2) = \frac{\delta(\tau - \hat{\tau})}{2\hat{\rho}}. \tag{25}$$

We, also, rewrite the vector X^μ in terms of the Lorentz-invariant distance

$$X^\mu = Z^\mu + \hat{\rho}\hat{c}^\mu, \quad Z^\mu = \hat{z}^\mu - z^\mu. \tag{26}$$

Then, by use of Eqs. (25) and (26) we arrive at the emitted part of the scalar field derivative in form

$$(\partial_\mu \varphi(x))^{\rm rad} = -\frac{g\hat{c}_\mu}{2^{5/2}\hat{\rho}^{3/2}} \int_{-\infty}^{\hat{\tau}} d\tau \left[\frac{3}{2}\frac{1}{(Z\hat{c})^{5/2}} - \frac{\delta(\tau-\hat{\tau})}{(Z\hat{c})^{3/2}} - \frac{2(a\hat{c})\delta(\tau-\hat{\tau})}{(v\hat{c})^2(Z\hat{c})^{1/2}}\right], \tag{27}$$

where we have taken into account that up to the leading order $X^2 \sim 2\hat{\rho}(Z\hat{c})$ and $(vX) \sim \hat{\rho}(v\hat{c})$. Note that each integral in the Eq. (27) diverges on the upper integration limit $\tau \to \hat{\tau}$, as $(Z\hat{c}) \to (\hat{v}\hat{c})(\hat{\tau}-\tau) = (\hat{\tau}-\tau)$. However, one can show that the last two terms of the integrand do not carry physical information concerning the field in the wave zone and just eliminate the divergences contained in the first one. To do this, we introduce the regularising parameter $\epsilon \to +0$ into the argument of delta function and perform integration by use of it, obtaining the divergent result

$$\int_{-\infty}^{\hat{\tau}} d\tau \, \frac{\delta(\tau-\hat{\tau}+\epsilon)}{(Z\hat{c})^{3/2}} = \frac{1}{\epsilon^{3/2}}, \tag{28}$$

which can be rewritten as

$$\frac{1}{\epsilon^{3/2}} = \frac{3}{2}\int_{-\infty}^{\hat{\tau}-\epsilon} \frac{d\tau}{(\hat{\tau}-\tau)^{3/2}}. \tag{29}$$

By analogy, the second term with the delta function transforms to

$$\int_{-\infty}^{\hat{\tau}} d\tau \, \frac{(a\hat{c})\delta(\tau-\hat{\tau})}{(v\hat{c})^2(Z\hat{c})^{1/2}} = \frac{1}{2}\int_{-\infty}^{\hat{\tau}-\epsilon} d\tau \frac{(\hat{a}\hat{c})}{(\hat{\tau}-\tau)^{3/2}}. \tag{30}$$

Then, omitting the regularising parameter in the upper integration limit we find the emitted part of the scalar field derivative as

$$(\partial_\mu \varphi(x))^{\rm rad} = -\frac{g\hat{c}_\mu}{2^{5/2}\hat{\rho}^{3/2}} \int_{-\infty}^{\hat{\tau}} d\tau \left[\frac{3}{2}\frac{1}{(Z\hat{c})^{5/2}} - \frac{3}{2}\frac{1}{(\hat{\tau}-\tau)^{5/2}} - \frac{(\hat{a}\hat{c})}{(\hat{\tau}-\tau)^{3/2}}\right]. \tag{31}$$

In practice, calculating the radiation from the particle moving along some trajectory one needs to make the convergence of the integral in Eq. (31) explicit. To achieve it, one has to reintroduce the regularising parameter $\epsilon \to +0$ into the upper integration limit and perform some transformation of the first term in the integrand: usually, it is the integrations by parts, which extract the divergences from it and cancel them out by use of the remaining two integrals. The above structure of the emitted part of the field holds in any odd spacetime dimensions.[30]

Substituting the emitted part of the scalar field derivative into the Eq. (4) we find the radiated part of the energy-momentum tensor

$$T^{\rm rad}_{\mu\nu}(x) = \frac{g^2\hat{c}_\mu\hat{c}_\nu}{64\pi^2\hat{\rho}^3}\mathcal{A}^2(x), \tag{32}$$

$$\mathcal{A}(x) = \int_{-\infty}^{\hat{\tau}} d\tau \left[\frac{3}{2}\frac{1}{(Z\hat{c})^{5/2}} - \frac{3}{2}\frac{1}{(\hat{\tau}-\tau)^{5/2}} - \frac{(\hat{a}\hat{c})}{(\hat{\tau}-\tau)^{3/2}}\right]. \tag{33}$$

In accordance with the Rohrlich-Teitelboim approach, it is proportional to the direct product of two null vectors $\hat{c}_\mu \hat{c}_\nu$ corresponding to the propagation of this part of field's energy-momentum exactly with the speed of light. Also, as was discussed above, the emitted part of the energy-momentum tensor depends on the entire history of the source's motion preceding the retarded proper time $\hat{\tau}$, as well as the radiation power determined by it.

3. Electromagnetic radiation in five dimensions

Having found the emitted part of the five-dimensional scalar field and the corresponding radiation energy-momentum tensor, let us now briefly discuss the electromagnetic and gravitational radiation in five dimensions. We start with the former.

3.1. *The setup*

Action of the electromagnetic field $A_\mu(x)$ interacting with the massive point particle moving along an arbitrary world line $z^\mu(\tau)$ in five dimensions is analogous to that of the scalar field (1) and has the form

$$S = -\frac{1}{8\pi^2}\int d^{4+1}x\, F^{\mu\nu}F_{\mu\nu} - e\int d\tau\, \dot{z}^\mu A_\mu(z), \quad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu, \tag{34}$$

where e is particle's electric charge. Here, we omit the particle's kinetic term in the action, given that its motion is completely governed by the external forces and, thus, the world line variables are non-dynamical.

The action (34) yields the standard equation of motion of the electromagnetic field

$$\Box A^\mu(x) = 2\pi^2 j^\mu(x), \tag{35}$$

$$j^\mu(x) = e\int d\tau\, \dot{z}^\mu\, \delta^{(4+1)}(x - z). \tag{36}$$

where we imposed on the field the Lorentz gauge condition to fix its gauge symmetry

$$\partial_\mu A^\mu = 0. \tag{37}$$

Note that this condition requires the current to be conserved

$$\partial_\mu j^\mu = 0, \tag{38}$$

and it is, when the observation point is off the world line, as can be easily seen from the Eq. (36).

To determine the energy flux carried by the electromagnetic radiation we use symmetric energy-momentum tensor of the electromagnetic field

$$\Theta_{\mu\nu} = \frac{1}{2\pi^2}\left[F_{\mu\cdot}^{\ \alpha}F_{\alpha\nu} + \frac{1}{4}\eta_{\mu\nu}F_{\alpha\beta}F^{\alpha\beta}\right]. \tag{39}$$

By analogy with that of the scalar field, it is the bilinear functional of the field derivatives $\Theta \sim \partial A \partial A$ and, thus, admits defining the emitted part of the electromagnetic field derivative.

3.2. *Emitted part of the electromagnetic field*

By use of the Eqs. (36) and (9) we obtain the retarded electromagnetic field of the point charge in form

$$A_\mu(x) = e\int d\tau\, \dot{z}_\mu\, \theta(X^0)\left[\frac{\delta(X^2)}{(X^2)^{1/2}} - \frac{1}{2}\frac{\theta(X^2)}{(X^2)^{3/2}}\right]. \tag{40}$$

We calculate its derivative using the relation (23)

$$\partial_\nu A_\mu(x) = e\int d\tau\, \theta(X^0)\left[\frac{3}{2}\frac{\theta(X^2)}{(X^2)^{5/2}}v_\mu X_\nu - \frac{\delta(X^2)}{(X^2)^{3/2}}v_\mu X_\nu - \right.$$
$$\left. - \frac{\delta(X^2)}{(vX)^2(X^2)^{1/2}}[(aX)-1]v_\mu X_\nu + \frac{\delta(X^2)}{(vX)(X^2)^{1/2}}[a_\mu X_\nu - v_\mu v_\nu]\right]. \tag{41}$$

Using the relations (25) and (26), and transforming the terms with delta functions by analogy with the Eqs. (28–30) we obtain the emitted part of the retarded electromagnetic field as the long-range part of its derivative with respect to the Lorentz-invariant distance

$$(\partial_\nu A_\mu)^{\rm rad} \;=\; \frac{e\hat{c}_\nu}{2^{5/2}\hat{\rho}^{3/2}}\int_{-\infty}^{\hat{\tau}} d\tau\left[\frac{3}{2}\frac{v_\mu}{(Z\hat{c})^{5/2}} - \frac{3}{2}\frac{\hat{v}_\mu}{(\hat{\tau}-\tau)^{5/2}} - \frac{(\hat{a}\hat{c})\hat{v}_\mu - \hat{a}_\mu}{(\hat{\tau}-\tau)^{3/2}}\right]. \tag{42}$$

By analogy with the scalar field, in Eq. (42) all the physical information concerning the electromagnetic field in the wave zone is contained in the first term of the integrand, while the remaining ones just subtract the divergences contained in it at the upper integration limit.

Substituting the Eq. (42) into the symmetric energy-momentum tensor (39) we arrive at the five-dimensional electromagnetic radiation energy-momentum tensor

$$\Theta^{\rm rad}_{\mu\nu} = -\frac{e^2\hat{c}_\mu\hat{c}_\nu}{64\pi^2\hat{\rho}^3}\mathcal{A}^2_\alpha(x), \tag{43}$$

$$\mathcal{A}_\alpha(x) = \int_{-\infty}^{\hat{\tau}} d\tau\left[\frac{3}{2}\frac{v_\alpha}{(Z\hat{c})^{5/2}} - \frac{3}{2}\frac{\hat{v}_\alpha}{(\hat{\tau}-\tau)^{5/2}} - \frac{(\hat{a}\hat{c})\hat{v}_\alpha - \hat{a}_\alpha}{(\hat{\tau}-\tau)^{3/2}}\right]. \tag{44}$$

The obtained tensor structure of the radiated part of the energy-momentum tensor corresponds to the propagation of the associated energy flux exactly with the speed of light. Also, by analogy with the scalar field (32), it depends on the history of charge's motion preceding the retarded proper time.

4. Five-dimensional gravitational radiation

Now we turn to the calculation of the gravitational radiation produced by the point particles. If interaction between them is also gravitational, the problem is not described by the linearized approximation, and the quadratic terms in expansion of the Einstein tensor are required to take into account the contribution of field stresses to radiation.[32] If the dominant forces are non-gravitational, the corresponding field stresses are also required, making the calculation rather difficult. Here we calculate

only the local contribution of particles themselves, so the result is incomplete. We give it just to reveal difference with the scalar and electromagnetic cases and to show how to deal with polarisations.

4.1. *The setup*

We start with the generally covariant Einstein-Hilbert action for the five-dimensional gravity interacting with massive point particle and some external field governing its motion

$$S = \frac{1}{2\kappa_5}\int d^{4+1}x\sqrt{-g}R - m\int d\tau\sqrt{g_{\alpha\beta}(z)\dot{z}^\alpha\dot{z}^\beta} + S_{\rm F}, \tag{45}$$

where κ_5 is the five-dimensional gravitational constant, g is the determinant of metric tensor, and $S_{\rm F}$ is the action for the external field moving point particle.

We linearise the Einstein's equation over the background Minkowski metric

$$g_{\mu\nu}(x) = \eta_{\mu\nu} + h_{\mu\nu}(x), \quad |h_{\mu\nu}| \ll 1. \tag{46}$$

Introducing the reduced metric perturbations

$$\bar{h}_{\mu\nu} = h_{\mu\nu} - \frac{1}{2}\eta_{\mu\nu}h, \quad h = \eta^{\alpha\beta}h_{\alpha\beta}, \tag{47}$$

we arrive at the linearised Einstein equation

$$\Box\bar{h}_{\mu\nu}(x) = 2\kappa_5\left(T^{\rm P}_{\mu\nu}(x) + T^{\rm F}_{\mu\nu}(x)\right), \tag{48}$$

$$T^{\rm P}_{\mu\nu}(x) = m\int d\tau\,\dot{z}_\mu\dot{z}_\nu\,\delta^{(5)}(x-z), \quad T^{\rm F}_{\mu\nu}(x) = -\frac{2}{\sqrt{-g}}\frac{\delta S_{\rm F}}{\delta g^{\mu\nu}}\bigg|_{g=\eta} \tag{49}$$

where $T^{\rm P}_{\mu\nu}(x)$ is the energy-momentum of point particle moving on the flat Minkowski background and interacting with some external field, which energy-momentum tensor is given by $T^{\rm F}_{\mu\nu}(x)$. To obtain the Eq. (48) we, also, imposed the Lorentz gauge condition on the metric perturbations

$$\partial^\mu\bar{h}_{\mu\nu} = 0, \tag{50}$$

to fix the gauge symmetry of the system. Such a condition requires the particle's and external field's energy momentum-tensors to be jointly conserved

$$\partial^\mu\left(T^{\rm P}_{\mu\nu} + T^{\rm F}_{\mu\nu}\right) = 0, \tag{51}$$

which is assumed to be valid on-shell.

To determine the energy-momentum flux carried by the gravitational radiation we use the effective energy-momentum tensor of metric perturbations, by analogy with,[31]

$$t_{\mu\nu} = \frac{1}{4\kappa_5}\left\langle\partial_\mu\bar{h}^{\rm TT}_{ij}\,\partial_\nu\bar{h}^{\rm TT}_{ij}\right\rangle, \quad \bar{h}^{\rm TT}_{ij}(x) = \Lambda_{ij,kl}(\mathbf{n})\bar{h}_{kl}(x), \tag{52}$$

$$\Lambda_{ij,kl}(\mathbf{n}) = P_{ik}P_{jl} - \frac{1}{3}P_{ij}P_{kl}, \quad P_{ij} = \delta_{ij} - n_in_j, \quad n^i = \frac{x^i}{r}, \tag{53}$$

where we assume the particle's motion to be periodic, and $\langle \dots \rangle$ is the averaging over the period. Here, we turned into the transverse-traceless gauge by the contraction of metric perturbations (52) with the projector (53) defined by analogy with.[31] Note that differentiation of the projector would increase the fall-off asymptotic of the field, so its derivative can be neglected when one computes the emitted part of the gravitational field in the transverse-traceless gauge.

4.2. *Emitted part of the gravitational field (incomplete)*

Using the Eqs. (9) and (49) we find the retarded gravitational field of the point particle as

$$\bar{h}^{\rm P}_{\mu\nu}(x) = \frac{m\kappa_5}{\pi^2}\int d\tau\, \dot{z}_\mu \dot{z}_\nu\, \theta(X^0)\left[\frac{\delta(X^2)}{(X^2)^{1/2}} - \frac{1}{2}\frac{\theta(X^2)}{(X^2)^{3/2}}\right]. \tag{54}$$

We compute its derivative integrating by parts by use of the relation (23) arriving at

$$\partial_\alpha \bar{h}^{\rm P}_{\mu\nu} = \frac{m\kappa_5}{\pi^2}\int d\tau\, \theta(X^0)\left[\frac{3}{2}\frac{\theta(X^2)}{(X^2)^{5/2}} v_\mu v_\nu X_\alpha - \frac{\delta(X^2)}{(X^2)^{3/2}} v_\mu v_\nu X_\alpha - \right.$$
$$\left. - \frac{\delta(X^2)}{(vX)^2(X^2)^{1/2}}[(aX)-1] v_\mu v_\nu X_\alpha + \frac{\delta(X^2)}{(vX)(X^2)^{1/2}}[2a_{(\mu}v_{\nu)}X_\alpha - v_\mu v_\nu v_\alpha]\right], \tag{55}$$

where $a^\mu = d^2 z^\mu/d\tau^2$ is the acceleration vector, and we define the symmetrisation over two indices as $A_{(\mu}B_{\nu)} = (A_\mu B_\nu + A_\nu B_\mu)/2$.

Extracting the long-range part of the gravitational field derivative by use of the relations (25) and (26) and transforming the terms with delta functions by analogy with Eqs. (28–30) we obtain the emitted part of the gravitational field as

$$\left(\partial_\alpha \bar{h}^{\rm P}_{\mu\nu}\right)^{\rm rad} = \frac{m\kappa_5 \hat{c}_\alpha}{2^{5/2}\pi^2\hat{\rho}^{3/2}}\int_{-\infty}^{\hat{\tau}} d\tau \left[\frac{3}{2}\frac{v_\mu v_\nu}{(Z\hat{c})^{5/2}} - \frac{3}{2}\frac{\hat{v}_\mu\hat{v}_\nu}{(\hat{\tau}-\tau)^{5/2}} - \frac{(\hat{a}\hat{c})\hat{v}_\mu\hat{v}_\nu - 2\hat{a}_{(\mu}\hat{v}_{\nu)}}{(\hat{\tau}-\tau)^{3/2}}\right]. \tag{56}$$

By analogy with the scalar (31) and electromagnetic (42) fields, it consists of one integral determining the properties of the gravitational field in the wave zone and two integral being counter-terms eliminating the divergences from the first one.

Substituting the obtained expression for the emitted part of the retarded gravitational field (56) into the Eq. (52) we find the energy-momentum tensor of gravitational radiation generated by the point particle

$$\left(t^{\rm P}_{\mu\nu}\right)^{\rm rad} = \frac{m^2\kappa_5 \hat{c}_\mu \hat{c}_\nu}{128\pi^4\hat{\rho}^3}\mathcal{A}^{\rm TT}_{ij}(x)\mathcal{A}^{\rm TT}_{ij}(x), \quad \mathcal{A}^{\rm TT}_{ij}(x) \equiv \Lambda_{ij,kl}(\mathbf{n})\mathcal{A}_{kl}(x), \tag{57}$$

$$\mathcal{A}_{ij}(x) = \int_{-\infty}^{\hat{\tau}} d\tau \left[\frac{3}{2}\frac{v_i v_j}{(Z\hat{c})^{5/2}} - \frac{3}{2}\frac{\hat{v}_i\hat{v}_j}{(\hat{\tau}-\tau)^{5/2}} - \frac{(\hat{a}\hat{c})\hat{v}_i\hat{v}_j - 2\hat{a}_{(i}\hat{v}_{j)}}{(\hat{\tau}-\tau)^{3/2}}\right]. \tag{58}$$

As in the cases of scalar (32) and electromagnetic (43) radiation, the emitted part of the gravitational field energy-momentum tensor has the tensor structure corresponding to the propagation of the associated energy-momentum flux exactly at the

speed of light and depends on the entire history of the particle's motion preceding the retarded proper time $\hat{\tau}$.

5. Conclusions

In this short article, we have demonstrated that despite the Huygens principle violation in odd spacetime dimensions, radiation can be computed by the integration of the energy-momentum flux in the wave zone. However, it requires the Lorentz-invariant modification of the radiation and wave zone definitions, in accordance with the Rohrlich-Teitelboim approach. Also, due to the Huygens principle violation, the emitted part of the field depends on the history of the source's motion preceding the retarded proper time, in contrast with even dimensions, where properties of radiation at given moment of time are determined only by the state of the source at the retarded time. Another feature of the odd dimensions is that the retarded field is given by the sum of separately divergent integrals. Nevertheless, these divergence mutually cancel out and the resulting field is finite.

Based on the Rohrlich-Teitelboim approach, we have considered the radiation of the scalar, electromagnetic and gravitational fields by point particle in five dimensions. We computed the emitted parts of the fields' energy-momentum tensors. The obtained expressions have the tensor structures corresponding to the propagation of the radiated energy-momentum in space exactly with the speed of light. Also, they are given by the sum of separately divergent integrals over the history of particle's motion, one of which carries all the physical information concerning the field in the wave zone, while the remaining ones are just the counter-terms subtracting the divergences from the former. To make the convergence of the resulting tensor explicit, one has to integrate the first term by parts.

In our previous work,[30] we have considered the scalar synchrotron radiation in three and five dimensions. The results were checked by the calculation of the spectral decompositions of the radiation power, which are indifferent to the dimensionality of the spacetime. Based on this, we assume that the obtained similar expressions for the emitted parts of the electromagnetic and gravitational fields should, also, be valid.

In this work, we use the fact that kinematics of light propagation in a *non-dispersive medium* associated with a bi-metric spacetime is expressed by means of a 1-parameter family of contact transformations. We present a general technique to find such transformations and explore some explicit examples for Minkowski and anti-deSitter spacetimes geometries.

Keywords: Contact geometry; Wave propagation; Anti-deSitter.

1. Introduction

Soon after the advent of general relativity, it was observed that the gravitational field *bends* the path followed by a light ray. This was confirmed by Eddington after noticing that the apparent position of the stars are shifted from their expected position in the sky when observed during a solar eclipse. This *bending* phenomenon is analogous to the deviation of light rays while traveling in a medium whose refractive index changes from one place to the other. In this sense, it was shown that a class of optical media can be modeled by means of a metric tensor encoding its electromagnetic properties (Refs. 1–3). Furthermore, this analogy has evolved into the very active field of transformation optics, where the techniques and tools of differential geometry – that have been insightful in gravitational physics – have found its way into the more applied area of material science (Refs. 4–7). In addition, this has also been used in modeling analogue gravitational spacetimes such as black holes and cosmological solutions (Refs. 8–11).

Fermat's principle poses a well known problem in the calculus of variations. In the non-relativistic setting – where the notion of time is *absolute* and *universal* – it states that light travels between two given *spatial* locations following a path

minimizing a time functional. Such a perspective is clearly untenable in the context of General Relativity, where it is commonly replaced by the assumption that the path taken by light in traveling from one location to another corresponds to a null geodesic. However, albeit it remains a variational problem, its precise formulation is far more elaborate (see Theorem 7.3.1 in Ref. 12).

Similarly (cf. Theorem 7.1.2 in Ref.12), Huygens' principle is centered in the idea of light emissions being instantaneous for different observers at each instant in time (Ref. 13). In this way, light emission is described by well localized wavefronts, as they travel through three dimensional space. In the relativistic setting, the electromagnetic field on a precise event on spacetime should depend only on initial conditions originated its past null cone (Ref. 14). This has led to explore different wave phenomena where Huygens' principle is not fulfilled, most of which are due to dissipation processes where the wave distribution has not converging tails. As a consequence, the wavefronts cannot be located in exactly at a point of spacetime. With the Hadamard conjecture, this phenomenon has been related to the dimensions and curvature of spacetime (Refs. 15, 16).

One of the simplest and of most interesting curved spacetimes for theoretical physicists, is the anti-deSitter spacetime (AdS). This spacetime model has a very deep relationship with hyperbolic geometry, where its boundary at spacelike infinity leads to have strange peculiar like closed timelike curves and achornal surfaces (Refs. 17,18). Nevertheless, AdS has gained more interest in recent years, as it has showed its value in topics like the *holographic principle*, the ground state of gauged supergravity theories and its central role in high energy physics in the correspondence with the Conformal Field Theory (AdS/CFT).

In this work, we use the fact that an optical medium can be represented by a Riemannian manifold $(\mathcal{B}, g)$ where $\mathcal{B}$ is considered to be the physical space and g the optical spatial metric. The geodesic flow in its unitary tangent bundle can be represented by a contact transformation acting on its space of contact elements. This fact, allows us to describe the wavefront evolution in an optical medium solely in terms of the contact transformation and to reconstruct the geodesic flow from the Reeb vector field. This provides us with a way to construct wavefronts in optical media without directly solving the wave equation. Particularly, we use this powerful tool to reconstruct wave propagation, along with with its corresponding light rays in a $(2+1)$-dimensional AdS spacetime.

This manuscript is structured as follows. In section 2 we give the mathematical formalism to construct the technique. In section 3 we use this technique to reconstruct wavefronts and ray lights in a $(2+1)$-dimensional anti-deSitter spacetime. We find explicitly the 1-parameter family of contact transformations and solve numerically to reconstruct the wave propagation in optical media with interfaces of different refractive index.

2. Mathematical background

In this work, an optical medium will be a Riemannian manifold $(\mathcal{B}, g)$ submersed in a bi-metric Lorentzian spacetime $(M, g_0, \tilde{g})$. Where g_0 is the spacetime metric, used to low and rise index, the metric $\tilde{g}$ is the optical metric introduced by Gordon (Ref. 1), from which the effective speed of light in a medium can be read off.The manifold $\mathcal{B}$ along with his metric g, is called *the material manifold*, The metric g can be decomposed in terms of the material manifold Riemannian metric and an observer's four velocity.

The cotangent bundle of the material manifold carries a natural symplectic structure, endowed by a non-degenerated closed 2-form ω. In this sense, the Liouville's vector filed, which preserves the symplectic 2-form in terms of its Lie derivative, defines a 1-form $\lambda \in T^*(T^*\mathcal{B})$ which generates the symplectic structure. As defined by Perlick (see Definition 5.1.1 and Proposition 5.1.1 in Ref. 12) the punctured cotangent bundle $PT^*\mathcal{B}$, corresponds to a *ray-optical structure* $\mathcal{N}$. Using the inclusion map from this ray-optical structure to the cotangent bundle, the 1-form λ induces a contact 1-form η, where the pair $(\mathcal{N}, \mathcal{D})$ is a contact manifold, known as the *space of contact elements* or the *contact bundle* of $\mathcal{B}$.

Let us use the defintion of a *wave front* centered at the point $b \in \mathcal{B}$ as the hypersurface (Ref. 19)

$$F_b(t) = \{b_i \in \mathcal{B} \,|\gamma(0) = b, \gamma(t) = b_i\} \tag{1}$$

where γ is a geodesic on $(\mathcal{B}, g)$. For every point in the wave front, the contact element of $\mathcal{B}$ associated to that point is tangent to the wave front. If we consider a geodesic flow on the unitary tangent bundle of $\mathcal{B}$, there exists a unique contact element, which is perpendicular to. So the Reeb vector filed, associated to the contact 1-form of the ray-optical structure is dual to the geodesic flow in the unitary tangent bundle of $\mathcal{B}$. The Reeb vector field is also, the infinitesimal generator of a family of 1-parameter strict contact transformations $\phi_t : \mathcal{N} \to \mathcal{N}$, which preserves the contact form and thus the contact elements on $\mathcal{B}$, which are tangent to the wave fronts. In this sense, the family of transformations ϕ_t can evolve the geodesic flow preserving the wave fronts in each point.

The method is to solve the Reeb's vector field flow, associated to contact 1-form in the ray-optical structure to reconstruct numerically from it, the wave fronts and the ray lights propagating in an optical medium. When interfaces are present between media with different refractive index, no further adaptions are needed for the technique to reconstruct wave fronts and light rays while refracted. If this technique is used in a Minkowski spacetime geometry, Snell's law can be deduced and total inner reflection is obtained when the source of light is settle to refract to another medium with smaller refractive index.

3. Wave propagation in (2 + 1)-dimensional anti-deSitter spacetime

If we consider now a (2+1)-dimensional anti-deSitter spacetime with spatial optical metric given by (Ref. 7)

$$g = \left(\frac{n}{y}\right)^2 \sum_{i=1}^{2} \mathrm{d}x^i \otimes \mathrm{d}x^i. \tag{2}$$

we find the associated 1-parameter family of strict contact transformations, generated by the Reeb's flow, for which we obtained

$$\phi_t = \Bigg[x = \frac{(x\sin\varphi + y\cos\varphi - x)e^{\frac{2t}{n}} - x\sin\varphi - y\cos\varphi - x}{(\sin\varphi - 1)e^{\frac{2t}{n}} - \sin\varphi - 1}, \tag{3}$$

$$y = -\frac{2ye^{\frac{t}{n}}}{(\sin\varphi - 1)e^{\frac{2t}{n}} - \sin\varphi - 1}\ ,$$

$$\varphi = \arctan\left(-\frac{(-\sin\varphi + 1)e^{\frac{2t}{n}} - \sin\varphi - 1}{2e^{\frac{t}{n}}\cos\varphi}\right).\Bigg]$$

With this transformation, it is possible to observe that the projection of the flows corresponds to semi-circles centered in the x-axis, as expected by the hyperbolic geometry associated to the anti-deSitter spacetime. For interfaces between media with different refractive index, refraction can be observed and no total inner reflection is observed when projected to the Poincaré disc. As it is known, the AdS spacetime is nos globally hyperbolic, so it admits closed timelike curves and achronal surfaces can be observed where light rays are closer to the infinity circle boundary of the disc. It is also observed that light rays can intersect more than one time the same wave front (figure 1 Ref. 20).

4. Final remarks

The fact that geodesic flows can be written in terms of a 1-parameter family of contact transformations, allows us to reconstruct trajectories and wavefronts of light while propagating through an optical medium, just from the Reeb flow. With this technique, we recreate the wave fronts as they propagate in an optical medium with interfaces of different refractive index in a (2 + 1)-dimensional Minkowski spacetime and (2 + 1)-dimensional anti-deSitter spacetime. In the first example, we could reproduce Snell's law of refraction and the total inner reflexion phenomenon. In the second example, we observe refraction when mapped to the Poincaré disc. No inner total reflection was observed when the light source is in a medium with larger refractive index. Achronal surfaces can be observed in this configuration, as light rays closer to the circle boundary intersects more than once the same wavefront.

The formalism, is robust enough to deal with interfaces without further adaptations. This technique can be used to recreate wave propagation in analogue gravitational spacetimes, such as Schwarzschild's blackholes, or to study interface between

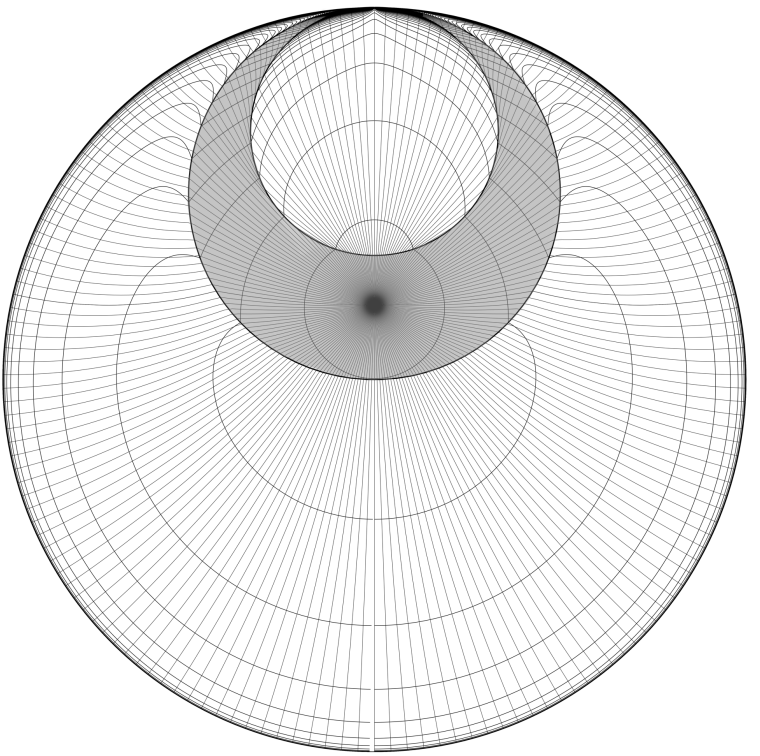

Fig. 1. Light rays and wavefronts emitted by a source of light refracting through a horizontal interface mapped to the Poincaré disc. The refractive index in the darker layer (where the light source is settled) is larger than the one in the whiter space.

vacuum and plasma. In recent years, this type of techniques can be important in the development of metamaterials, which can mimic some spacetime properties impossible to find in nature.

Élie Cartan's invariant integral formalism is extended to gauge field theory, including general relativity. This constitutes an alternative procedure that is equivalent to the Rosenfeld, Bergmann, Dirac algorithm. Also a new derivation of the generator of diffeomorphism-induced canonical transformations is given that proceed's from the Poincaré-Cartan form. In addition, a Hamilton-Jacobi formalism is developed for constructing explicit phase space functions in general relativity that are invariant under the full four-dimensional diffeomorphism group. These identify equivalence classes of classical solutions of Einstein's equations. Each member is dependent on intrinsic spatial coordinates and also undergoes non-trivial evolution in intrinsic time. The intrinsic coordinates are determined by the spacetime geometry in terms of Weyl scalars. The implications of this analysis for an eventual quantum theory of gravity are profound.

Keywords: General relativity; Hamilton-Jacobi formalism.

1. Introduction

We have found some new profound implications of Élie Cartan's theory, as presented in his 1922 work, Ref. 1. We show how his invariant integral program can be extended to gauge field theories, including general relativity. Our procedure in fact constitutes a new approach to constrained Hamiltonian dynamics that is equivalent to the Rosenfeld-Bergmann-Dirac procedure. Secondly, we show that the Poincaré-Cartan form that arises in this context can be utilized to deduce the generator of diffeomorphism-induced canonical transformations that have previously been derived using group theoretical arguments. We show how the required metric field dependence of the diffeomorphism-induced transformation group comes into play. Finally, employing the related symplectic form, we undertake canonical transformations to intrinsic spacetime coordinates, thus isolating the true gravitational degrees of freedom in a formalism in which all objects are invariant under the action of the full four-dimensional diffeomorphism group. The following is a summary of some results. Full details will appear in Ref. 2.

2. Cartan invariant integral — extension to gauge field theory

In 1922 Élie Cartan, Ref. 1, introduced an alternative approach to the classical dynamics of a configuration variable $q^i(t)$ in which he demanded that a certain closed integral evaluated at a fixed time t be independent of the chosen time.[a] He proposed that one consider a tube of trajectories parameterized by s with the property that as s ranges varies over its full range one returns to the original trajectory. Thus he demanded that the integral I over s, employing the parameterized set $q^i(t(s);s)$, $v^j(t(s);s)$, $t(s)$, be independent of t where

$$\begin{aligned} I &= \oint ds \left(\frac{\partial L}{\partial v^i} \left. \frac{\partial q^i}{\partial s} \right|_{t(s)} - \left(\frac{\partial L}{\partial v^i} v^i - L \right) \frac{dt}{ds} \right) \\ &=: \oint \left(\frac{\partial L}{\partial v^i} dq^i - \left(\frac{\partial L}{\partial v^i} v^i - L \right) dt \right) \end{aligned} \tag{1}$$

We consider the free relativistic particle as a first example of an extension of this procedure to a gauge model. In this case the required invariant integral is

$$I_p = \oint \left(N^{-1} v_\mu dq^\mu - \frac{1}{2} \left(N^{-1} v^2 + N m^2 \right) dt \right). \tag{2}$$

We require that its variation vanish under independent δ variations. Integrating by parts over the closed interval we get

$$\begin{aligned} \delta I_p = \oint \Bigg[&\left(-N^{-2} \delta N v_\mu + N^{-1} \delta v_\mu \right) dq^\mu + \left(\frac{1}{2} N^{-2} \delta N v^2 - N^{-1} v_\mu \delta v^\mu \right. \\ &\left. \frac{1}{2} \delta N m^2 \right) dt - \left(\frac{1}{2} N^{-2} dN v^2 - N^{-1} v_\mu dv^\mu - \frac{1}{2} dN m^2 \right) \delta t \Bigg] = 0. \end{aligned} \tag{3}$$

The required vanishing coefficient of δv^μ yields $v^\mu = \frac{dq^\mu}{dt} := \dot{q}^\mu$. Similarly, the vanishing coefficient for δN, gives $N = m^{-1} \left(-\dot{q}^2 \right)^{1/2}$. The result for δt is redundant, yielding $-m^2 \dot{N} = N^{-1} \dot{q} \cdot \ddot{q}$. Finally, the coefficient of δq^μ yields the reparameterization covariant equation of motion $\frac{d}{dt} \left(N^{-1} \dot{q}^\mu \right) = 0$.

It is especially instructive to undertake a Legendre transformation, but with the understanding that the analogues of the velocities that we represent as v^μ and N_v represent independent functions. Thus $\pi = \frac{\partial L_p}{\partial N_v} = 0$ is a primary constraint. The required invariant integral becomes

$$I_p = \oint \left[p_\mu dq^\mu + \pi dN - \left(\frac{N}{2} \left(p^2 + m^2 \right) + \pi N_v \right) dt \right], \tag{4}$$

[a] A translation into English by D. H. Delphenich, Ref. 3, is available.

resulting in

$$dI_p = \oint \Big[\delta p_\mu \left(dq^\mu - Np^\mu dt\right) - \delta q^\mu dp_\mu + \delta N \left(-d\pi - \frac{1}{2}(p^2+m^2)dt\right) + \delta\pi\left(dN - \dot{N}dt\right) + \delta t\left(\left(\frac{1}{2}(p^2+m^2)\right)dN + Np^\mu\delta p_\mu + \delta\pi\dot{N} + \pi\delta\dot{N}\right) + \delta\dot{N}\pi dt\Big] = 0. \tag{5}$$

The required vanishing of the first and second coefficients result in $\frac{dq^\mu}{dt} = Np^\mu$ and $\frac{dp^\mu}{dt} = 0$. The third term yields the secondary constraint $p^2 + m^2 = 0$, and the forth $N_v = \frac{dN}{dt}$. The remaining terms are redundant.

One can in fact carry out a similar variation with an analogous general relativistic invariant integral, namely

$$I_{ADM} = \oint d^3x \left[p^{ab}dg_{ab} + P_\mu dN^\mu - \mathcal{H}_{ADM}dt - P_\mu N_v^\mu dt\right], \tag{6}$$

where the Arnowittt-Deser-Misner (ADM) Hamiltonian

$$\mathcal{H}_{ADM} = \frac{N}{\sqrt{{}^3g}}\left(p_{ab}p^{ab} - \left(p^a{}_a\right)^2 - N\sqrt{{}^3g}{}^3R - 2N^a p^b{}_{a|b}\right), \tag{7}$$

is derived from the ADM Lagrangian

$$\mathcal{L}_{ADM} = \left({}^3g\right)^{1/2} N\left({}^3R + K_{ab}K^{ab} - K^2\right), \tag{8}$$

with $K_{ab} = \frac{1}{2N}\left(v_{ab} - N_{a|b} - N_{b|a}\right)$. Note that the v_{ab} are assumed to be independent spacetime functions. This Lagrangian is independent of the analogue velocity N_v^μ and there is therefore a primary constraint $P_\mu = 0$. The independent variations of g_{ab}, K_{ab}, N^μ, and N_v^μ. yields the correct secondary constraints and the correct Einstein Hamiltonian equations. Details are given in Ref. 2. These two systems are examples of a general new invariant integral approach to constrained Hamiltonian dynamics, equivalent to the Rosenfeld-Bergmann-Dirac prodedure.

3. Derivation of diffeomorphism generator

In the free relattivistic particle model take ds in the Poincaré-Cartan increment to correspond to the change in solutions that results from an infinitesimal reparameterization $t' = t - ds\epsilon(t)$. Represent the change in the variables as $\bar{d}q^\mu = ds\dot{q}^\mu\epsilon$ and $\bar{d}N = ds(\dot{\epsilon}N + \epsilon\dot{N})$, recognizing that N transforms as a scalar density under the reparamterization. (These are actually the Lie derivatives with respect to ϵ.)

Now use the identity which is the statement that the particle Lagrangian transforms as a scalar density under reparameterizations to deduce the existence of a vanishing Noether charge C_p:

$$\frac{dC_p}{dt} = \frac{d}{dt}\left[\frac{N\epsilon}{2}\left(p^2+m^2\right) + \pi\left(\dot{N}\epsilon + N\dot{\epsilon}\right)\right] = 0. \tag{9}$$

But since this depends on $\dot{N}$ this is clearly not projectable under the Legendre transformation to the particle co-tangent space. We must assume a variable-dependent reparameterizations $\epsilon(t) = N^{-1}\xi(t)$ to get Legendre-projectable reparameterizations. The general proof for the required dependence is given in.[4] In this case we have

$$\begin{aligned} C_p &= \frac{\xi}{2}\left(p^2 + m^2\right) + \pi\left(\dot{N}\epsilon + N\dot{\epsilon}\right) \\ &= \frac{\xi}{2}\left(p^2 + m^2\right) + \pi\left(\dot{N}N^{-1}\xi - NN^{-2}\dot{N}\xi + \dot{\xi}\right) \\ &= \frac{\xi}{2}\left(p^2 + m^2\right) + \pi\dot{\xi}. \end{aligned} \tag{10}$$

This is the phase space generator of the N-dependent reparameterizations.

It is shown in Ref. 2 that the analogous substitution into the ADM vanishing Noether charge yields the Pons-Salisbury-Shepley generator $\mathcal{C}_{PSS}$, Ref. 4, of diffeomorphism-induced general coordinate transformations $\epsilon^\mu(x) = \left(N^{-1}\xi^0(x), -N^{-1}N^a\xi^0(x) + \xi^a(x)\right)$,

$$\begin{aligned} \mathcal{C}_{PSS} &= P_\mu\dot{\xi}^\mu + \mathcal{H}_\mu\xi^\mu + P_0(\xi^0 - N^a\xi^0_{,a} + N_{,a}\xi^a) \\ &\quad + P_a(N_{,b}e^{ab}\xi^0_{,b} - N\xi^0_{,b}e^{ab} + N_{,a}\xi^a + N^a_{,b}\xi^b - N^b\xi^a_{,b}). \end{aligned} \tag{11}$$

4. Intrinsic coordinates and diffeomophism invariants

The non-vanishing contributions to the integrand in Cartan's invariant integral are of course now recognized as the symplectic potential one-form. Perhaps less fully appreciated is the fact that Cartan justified canonical transformations to new phase space coordinates through the recognition that exact differential generator did not contribute to the invariant integral. We examine first what we believe is novel new approach to the introduction of a proper time parameterization of the relativistic free particle. This is an example of a choice of intrinsic time. As proved in general in Ref. 5 the chosen intrinsic canonical coordinate must transform as a scalar under general coordinate transformations - in this case, reparamterizations.

Thus we now choose as the intrinsic particle time evolution variable the scalar $T = -mq^0/p_0$. This is the proper time. Then we perform a canonical transformation in the Poincaré-Cartan increment such that

$$p_0 dq^0 = PdT + \frac{\partial G}{\partial q^0}dq^0 + \frac{\partial G}{\partial T}dT. \tag{12}$$

The required non-trivial generator is

$$G = -\frac{m}{2T}\left(q^0\right)^2 - mT + mT\ln(T), \tag{13}$$

with the resulting canonical conjugate

$$P = -m\ln\left(-\frac{mq^0}{p_0}\right) - \frac{p_0^2}{2m}. \tag{14}$$

It is important to recognize that the system is still reparameterization covariant – and now with a new generator

$$C_p = \xi \left[-P - m \ln(T) + \frac{1}{2} \left(p^a p_a + m^2 \right) \right] + \pi \dot{\xi} \tag{15}$$

But we can now make a proper time gauge choice by setting the evolution parameter equal to the intrinsic variable T, i.e., set $t = T$. And given particle solutions in any parameterization the gauge generator can be employed to transform to solutions satisfying the gauge condition. The remaining canonical variables are invariants under reparameterizations. The general procedure is described in Ref. 5.

We can indeed, in principle, carry out a similar procedure in general relativity. Choose appropriate spacetime scalars $X^\mu \left(g_{ab}, p^{cd} \right)$, constructed with the use of Weyl scalars, as intrinsic spacetime coordinates. An initial effort in this direction is described in Refs. 6 and 7. Fuller details with corrections and revisions will appear in Ref. 2. Perform canonical transformations in the non-vanishing portion of the Poincaré-Cartan increment so that the non-vanishing contribution becomes

$$\begin{aligned} dI_{ADM} &= \int d^3x \, p^{ab} dg_{ab} \\ &= \int d^3x \left(\pi_\mu dX^\mu + p^A dg_A + \frac{\delta G}{\delta g_{ab}} dg_{ab} + \frac{\delta G}{\delta \alpha_A} d\alpha_A + \frac{\delta G}{\delta X^\mu} dX^\mu \right). \end{aligned} \tag{16}$$

Now make the gauge choices $x^\mu = X^\mu \left(g_{ab}, p^{cd} \right)$. The diffeomorphism generator C_{PSS} can be employed to explicitly display the corresponding diffeomorphism invariants, as shown in Ref. 5.

5. Quantum outlook

The results that we describe here were largely inspired by the work of Peter G. Bergmann and his associates. An extensive analysis of the work of his school and the conflicts that arose with the geometrical dynamical approach advocated by the John A. Wheeler can be found in Ref. 8. Of particular relevance is work performed by Bergmann in collaboration with Arthur Komar, analyzed in detail in Ref. 9. A revision and further elaboration is in preparation. The fundamental disagreement with the conventional geometrodynamical approach is in the treatment of the full four-dimensional diffeomorphism invariance. The classical approach we describe here works exclusively with the $2 \times \infty^3$ invariant fundamental gravitational degrees of freedom. It remains to be seen how these invariants may be employed in an eventual quantum theory of gravity. Work is now underway. A central challenge is to find a scheme that takes into account the abundance of physically distinct gauge choices, each of which leads to a distinct classical intrinsic time evolution.

Whether the 3−space where we live is a globally orientable manifold M_3, and whether the local laws of physics require that M_3 be equipped with a canonical orientation, are among the important unsettled questions in cosmology and quantum field theory. It is often assumed that a test for spatial orientability requires a global journey across the whole 3−space to check for orientation-reversing closed paths. Since such a global expedition is not feasible, physically motivated theoretical arguments are usually offered to support the choice of canonical time orientation for the 4−dimensional spacetime manifold, and space orientation for 3−space. One can certainly take advantage of such theoretical arguments to support these assumptions on orientability, but the ultimate answer should rely on cosmological observations or local experiments, or can come from a topological fundamental theory of physics. In a recent paper we have argued that it is potentially possible to locally access the the 3−space orientability of Minkowski empty spacetime through physical effects involving point-like 'charged' objects under vacuum quantum electromagnetic fluctuations. More specifically, we have studied the stochastic motions of a charged particle and an electric dipole subjected to these fluctuations in Minkowski spacetime, with either an orientable or a non-orientable 3−space topology, and derived analytical expressions for a statistical orientability indicator in these two flat topologically inequivalent manifolds. For the charged particle, we have shown that it is possible to distinguish the two topologies by contrasting the evolution of their respective indicators. For the point electric dipole we have found that a characteristic inversion pattern exhibited by the curves of the orientability indicator is a signature of non-orientability, making it possible to locally probe the orientability of Minkowski 3−space in itself. Here to shed some additional light on the spatial orientability, we briefly review these results, and also discuss some of its features and consequences. The reviewed results might be seen as opening the way to a conceivable experiment involving quantum vacuum electromagnetic fluctuations to look into the spatial orientability of Minkowski empty spacetime.

1. Introduction

In the framework of general relativity the Universe is described as a four-dimensional differentiable manifold locally endowed with a spatially homogeneous and isotropic

Friedmann–Lemaître–Robertson–Walker (FLRW) metric. Geometry is a local attribute that brings about intrinsic curvature, whereas topology is a global feature of a manifold related, for example, to compactness and orientability. The FLRW spatial geometry constrains but does not specify the topology of the spatial sections, M_3, of the space-time manifold, which we assume to be of the form $\mathscr{M}_4 = \mathbb{R} \times M_3$. In the FLRW description of the Universe, two diverse sets of fundamental questions are related to, first, the 3−geometry; second, to the topology of spatial sections M_3. Regarding the latter, at the cosmological level it is expected that one should be able to detect the spatial topology through cosmic microwave background radiation (CMB) or (and) stochastic primordial gravitational waves.[1,2] However, so far, direct searches for a nontrivial topology of M_3, using CMB data from Wilkinson Microwave Anisotropy Probe (WMAP) and Planck collaborations, have found no convincing evidence of nontrivial topology below the radius of the last scattering surface.[3–9] This absence of evidences does not exclude the possibility of a FLRW universe with a detectable nontrivial spatial topology.[10–12]

It is well-known that the topological properties of a manifold antecede its geometrical features and the differential tensor structure with which the physical theories are formulated. Thus, it is relevant to determine whether, how and to what extent physical results depend upon or are somehow affected by a nontrivial topology. Since the net role played by the spatial topology is more properly examined in static space-times, the dynamical degrees of freedom of which are frozen, here we focus on the static Minkowski space-time, whose spatial geometry is Euclidean. However, rather than the general topology of the spatial sections M_3 of Minkowski space-time, in this work we investigate its topological property called *orientability*, which is related to the existence of orientation-reversing closed paths on the spatial section M_3. Questions as to whether the 3−space of Minkowski space-time, which is the standard arena of quantum field theory, is necessarily an orientable manifold, or to what extent the known *laws of physics require a canonical spatial orientation* are among the underlying primary concerns of this work.

To be more precise regarding the setting of the present work, let us first briefly provide some mathematical results. The spatial section M_3 of the Minkowski space-time manifold $\mathscr{M}_4 = \mathbb{R} \times M_3$ is usually taken to be the simply-connected Euclidean space $\mathbb{E}^3$, but it is known mathematical result that it can also be any one of the possible 17 topologically distinct quotient manifolds $M_3 = \mathbb{E}^3/\Gamma$, where Γ is a discrete group of isometries or holonomies acting freely on the covering space $\mathbb{E}^3$.[a] The action of Γ tiles the covering manifold $\mathbb{E}^3$ into identical cells which are copies of what is known as fundamental domain (FD) fundamental cell or polyhedron (FC or FP). So, the multiple-connectedness gives rise to periodic conditions (repeated cells) in the simply-connected covering manifold $\mathbb{E}^3$ that are defined by the action

[a]For recent accounts on the classification of three-dimensional Euclidean spaces the reader is referred to Refs. 13 –18.

of the group Γ on $\mathbb{E}^3$. Different groups Γ give rise to different periodicities on the covering manifold $\mathbb{E}^3$, which in turn define different Euclidean spatial topologies M_3 for Minkowski spacetime. These mathematical results make it explicit that besides the simply-connected $\mathbb{E}^3$ there is a variety of topological possibilities (17 classes) for the spatial section of Minkowski spacetime. The potential consequences of multiple-connectedness for physics come about when, for example, one takes into account that in a manifold with periodic boundary conditions only certain modes of fields can exist. In this way, a nontrivial topology may leave its signature on the expectation values of local physical quantities.[19] So, for example, the energy density for a scalar field in Minkowski space-time with nontrivial spatial section is shifted from the corresponding result for the Minkowski space-time with trivial spatial topology. This is the Casimir effect of topological origin.[20–25]

Regarding orientability, the central issue of this work, three important points should be emphasized. First, we mention that it is widely assumed, implicitly or explicitly, that a four-dimensional manifold $\mathscr{M}_4 = \mathbb{R} \times M_3$ that models the physical world is spacetime orientable and, additionally, that it is separately time and space orientable. Second, eight out of the above-mentioned 17 quotient flat 3−manifolds are non-orientable.[13–18] A non-orientable 3−space is then a concrete mathematical possibility among the quotient manifolds $M_3 = \mathbb{E}^3/\Gamma$, and it comes about when the holonomy group Γ contains at least a flip or reflexion as one of its elements. Finally, it is generally assumed that, being a global property, the 3−space orientability cannot be tested locally. In this way, to disclose the spatial orientability of our physical world one would have to make trips along some specific closed paths around 3−space to check, for example, whether one returns with left- and right-hand sides exchanged.

Since such a global journey across the whole 3−space is not feasible one might think that spatial orientability cannot be probed. In this way, one would have either to answer the orientability question through cosmological observations or local experiments. Hence, assuming that spatial orientability is a falsifiable property of 3−space, a question that arises is whether spatial orientability can be subjected to local tests. Our main goal in this work is to present a way to tackle this question. To this end, we have investigated[26] stochastic motions of a charge particle and an electric dipole under vacuum quantum fluctuations of the electromagnetic field in Minkowski spacetime with two inequivalent spatial topologies, namely the non-orientable *slab with flip* and the orientable *slab*, which are often denoted by the symbols E_{17} and E_{16}, respectively.[17,18] Manifolds endowed with these topologies turned out to be appropriate to identify orientability or non-orientability signatures through the stochastic motions of point-like particles in Minkowski spacetime. In the next section, to shed some additional light on spatial orientability, we briefly review the most significant results of our article, Ref. 26, and discuss some of their consequences.

2. Main results and their interpretation

The general idea underlying our work is to perform a comparative study of the time evolution of physical systems in Minkowski spacetime with orientable and non-orientable spatial sections. To this end, the physical systems chosen are a point charged particle and a point electric dipole under vacuum quantum electromagnetic fluctuations. We shall describe the results for the dipole only because they are more significant — see Ref. 26 for the point charge case.

2.1. *The setting and the physical system*

We begin by recalling that simply-connected spacetime manifolds are necessarily orientable. On the other hand, the product of two manifolds is simply-connected if and only if the factors are. Thus, the space-orientability of Minkowski spacetime manifold $\mathscr{M}_4 = \mathbb{R} \times M_3$ reduces to orientability of the 3−space M_3. In this paper, we shall consider the topologically nontrivial spaces E_{16} and E_{17}. The slab space E_{16} is constructed by tessellating $\mathbb{E}^3$ by equidistant parallel planes, so it has only one compact dimension associated with a direction perpendicular to those planes. Taking the x-direction as compact, one has that, with $n_x \in \mathbb{Z}$ and $a > 0$, points (x, y, z) and $(x + n_x a, y, z)$ are identified in the case of the slab space E_{16}. The slab space with flip E_{17} involves an additional inversion of a direction orthogonal to the compact direction, that is, one direction in the tessellating planes is flipped as one moves from one plane to the next. Letting the flip be in the y-direction, the identification of points (x, y, z) and $(x + n_x a, (-1)^{n_x} y, z)$ defines the E_{17} topology. The slab space E_{16} is orientable whereas the slab space with flip E_{17} is non-orientable.

We consider a nonrelativistic point electric dipole with mass m and electric dipole moment $\mathbf{p}$ which is locally subject to vacuum fluctuations of the electric field $\mathbf{E}(\mathbf{x}, t)$ in a topologically nontrivial spacetime manifold equipped with the Minkowski metric $\eta_{\mu\nu} = \mathrm{diag}(+1, -1, -1, -1)$. The spatial section is usually taken to be $\mathbb{E}^3$, but here we take for M_3 either E_{16} or E_{17}.

Locally, the nonrelativistic motion of the dipole is determined by the equation of motion

$$m\frac{d\mathbf{v}}{dt} = \mathbf{p} \cdot \boldsymbol{\nabla}\mathbf{E}(\mathbf{x}, t)\,, \tag{1}$$

where $\mathbf{v}$ is the dipole's velocity and $\mathbf{x}$ its position at time t. We assume that on the time scales of interest the dipole practically does not move, that is, it has a negligible displacement, so we can ignore the time dependence of $\mathbf{x}$. Thus, the dipole's position $\mathbf{x}$ is taken as constant in what follows.[27, 28] Assuming the dipole is initially at rest, integration of Eq. (1) yields

$$\mathbf{v}(\mathbf{x}, t) = \frac{1}{m} p_j \int_0^t \partial_j \mathbf{E}(\mathbf{x}, t')\, dt' \tag{2}$$

with $\partial_j = \partial/\partial x_j$ and summation over repeated indices implied.

The mean squared speed in each of the three independent directions $i = x, y, z$ is given by

$$\left\langle \Delta v_i^2 \right\rangle = \frac{p_j p_k}{m^2} \int_0^t \int_0^t \left\langle \big(\partial_j E_i(\mathbf{x}, t')\big)\big(\partial_k E_i(\mathbf{x}, t'')\big) \right\rangle dt' dt'' \,, \tag{3}$$

which can be conveniently rewritten as

$$\left\langle \Delta v_i^2 \right\rangle = \lim_{\mathbf{x}' \to \mathbf{x}} \frac{p_j p_k}{m^2} \int_0^t \int_0^t \partial_j \partial'_k \left\langle E_i(\mathbf{x}, t') E_i(\mathbf{x}', t'') \right\rangle dt' dt'' \tag{4}$$

where $\partial'_k = \partial/\partial x'_k$ and there is no summation over i. Following Yu and Ford,[27] we assume that the electric field is a sum of classical $\mathbf{E}_c$ and quantum $\mathbf{E}_q$ parts. Because $\mathbf{E}_c$ is not subject to quantum fluctuations and $\langle \mathbf{E}_q \rangle = 0$, the two-point function $\langle E_i(\mathbf{x}, t) E_i(\mathbf{x}', t') \rangle$ in equation (4) involves only the quantum part of the electric field.[27]

In Minkowski spacetime with a topologically nontrivial spatial section, the spatial separation r^2 that enters the electric field correlation functions takes a different form that captures the periodic boundary conditions imposed on the covering space $\mathbb{E}^3$ by the covering group Γ, which characterize the spatial topology. In consonance with Ref. 22, the spatial separations for E_{16} and E_{17} are

$$E_{16}: \qquad r^2 = (x - x' - n_x a)^2 + (y - y')^2 + (z - z')^2, \tag{5}$$

$$E_{17}: \qquad r^2 = (x - x' - n_x a)^2 + (y - (-1)^{n_x} y')^2 + (z - z')^2. \tag{6}$$

2.2. *Orientability indicator*

The orientability indicator that we will consider is defined by replacing the electric field correlation functions in Eq. (4) by their renormalized counterparts.[26] For a dipole oriented along the y-axis the dipole moment is $\mathbf{p} = (0, p, 0)$ and we have

$${}^{(y)}I^{E_{17}}_{v_i^2}(\mathbf{x}, t) = \lim_{\mathbf{x}' \to \mathbf{x}} \frac{p^2}{m^2} \int_0^t \int_0^t \partial_y \partial_{y'} \left\langle E_i(\mathbf{x}, t') E_i(\mathbf{x}', t'') \right\rangle^{E_{17}}_{ren} dt' dt'' \,, \tag{7}$$

where the left superscript within parentheses indicates the dipole's orientation.

The renormalized correlation functions are given by[26]

$$\left\langle E_i(\mathbf{x}, t) E_i(\mathbf{x}', t') \right\rangle_{ren} = \frac{\partial}{\partial x_i} \frac{\partial}{\partial x'_i} D_{ren}(\mathbf{x}, t; \mathbf{x}', t') - \frac{\partial}{\partial t} \frac{\partial}{\partial t'} D_{ren}(\mathbf{x}, t; \mathbf{x}', t') \tag{8}$$

where

$$D_{ren}(\mathbf{x}, t; \mathbf{x}', t') = \sum_{n_x = -\infty}^{\infty}{}' \frac{1}{4\pi^2(\Delta t^2 - r^2)} \tag{9}$$

in which $\sum'$ indicates that the Minkowski contribution term $n_x = 0$ is excluded from the summation, $\Delta t = t - t'$, and the spatial separation for E_{17} is given by Eq. (6). The Hadamard function $D(\mathbf{x}, t; \mathbf{x}', t')$ for the multiply-connected space is

defined by including the term with $n_x = 0$ in the summation (9). Thus, $D_{ren} = D - D_0$, where D_0 is the Hadamard function for the simply-connected space.

Before presenting the results for some components of the orientability indicator (7), we point out that from equations (4) and (7)–(9) a general definition of the orientability indicator reads

$$I^{MC}_{v_i^2} = \left\langle \Delta v_i^2 \right\rangle^{MC} - \left\langle \Delta v_i^2 \right\rangle^{SC}, \tag{10}$$

where $\left\langle \Delta v_i^2 \right\rangle$ is the mean square velocity dispersion, and the superscripts MC and SC stand for multiply- and simply-connected manifolds, respectively. The right-hand side of (10) is defined by first taking the difference of the two terms with $\mathbf{x}' \neq \mathbf{x}$ and then setting $\mathbf{x}' = \mathbf{x}$.

The components of the orientability indicator for the dipole in E_{17} are[26]

$${}^{(y)}I^{E_{17}}_{v_x^2}(\mathbf{x},t) = -\frac{4p^2}{\pi^2 m^2} {\sum_{n_x=-\infty}^{\infty}}' (-1)^{n_x} \left\{ 2I_1 + 3(r^2 - r_x^2 + 6r_y^2)I_2 + 24(r^2 - r_x^2) r_y^2 I_3 \right\}, \tag{11}$$

$${}^{(y)}I^{E_{17}}_{v_y^2}(\mathbf{x},t) = -\frac{2p^2}{\pi^2 m^2} {\sum_{n_x=-\infty}^{\infty}}' (-1)^{n_x} \Big\{ (5 - 3(-1)^{n_x})I_1 + 6[r^2 + (7 - 6(-1)^{n_x}) r_y^2] I_2 + 48[r^2 - (-1)^{n_x} r_y^2] r_y^2 I_3 \Big\} \tag{12}$$

and

$${}^{(y)}I^{E_{17}}_{v_z^2}(\mathbf{x},t) = -\frac{4p^2}{\pi^2 m^2} {\sum_{n_x=-\infty}^{\infty}}' (-1)^{n_x} \left\{ 2I_1 + 3(r^2 + 6r_y^2)I_2 + 24 r^2 r_y^2 I_3 \right\}, \tag{13}$$

where, with $\Delta t = t' - t''$,

$$I_1 = \int_0^t \int_0^t \frac{dt' dt''}{(\Delta t^2 - r^2)^3} = \frac{t}{16} \left[\frac{4t}{r^4 (t^2 - r^2)} + \frac{3}{r^5} \ln \frac{(r-t)^2}{(r+t)^2} \right], \tag{14}$$

$$I_2 = \int_0^t \int_0^t \frac{dt' dt''}{(\Delta t^2 - r^2)^4} = \frac{1}{6r} \frac{\partial I_1}{\partial r} = \frac{t}{96} \left[\frac{4t(9r^2 - 7t^2)}{r^6 (t^2 - r^2)^2} - \frac{15}{r^7} \ln \frac{(r-t)^2}{(r+t)^2} \right], \tag{15}$$

$$\begin{aligned} I_3 &= \int_0^t \int_0^t \frac{dt' dt''}{(\Delta t^2 - r^2)^5} = \frac{1}{8r} \frac{\partial I_2}{\partial r} \\ &= \frac{t}{768} \left[\frac{4t(57t^4 - 136 r^2 t^2 + 87 r^4)}{r^8 (t^2 - r^2)^3} + \frac{105}{r^9} \ln \frac{(r-t)^2}{(r+t)^2} \right]. \end{aligned} \tag{16}$$

In Eqs. (11) to (16) one must put

$$\begin{aligned} r &= \sqrt{n_x^2 a^2 + 2(1 - (-1)^{n_x}) y^2}, \\ r_x^2 &= n_x^2 a^2, \qquad r_y^2 = 2(1 - (-1)^{n_x}) y^2. \end{aligned} \tag{17}$$

For the slab space E_{16} the components of the dipole orientability indicator are obtained from those for E_{17} by setting $r_x^2 = r^2, r_y = 0$, and replacing $(-1)^{n_x}$ by 1 everywhere. Therefore, we have

$$ {}^{(y)}I^{E_{16}}_{v_x^2}(\mathbf{x},t) = -\frac{8p^2}{\pi^2 m^2} \sum_{n_x=-\infty}^{\infty}{}' I_1, \tag{18} $$

$$ {}^{(y)}I^{E_{16}}_{v_y^2}(\mathbf{x},t) = -\frac{4p^2}{\pi^2 m^2} \sum_{n_x=-\infty}^{\infty}{}' (I_1 + 3r^2 I_2), \tag{19} $$

$$ {}^{(y)}I^{E_{16}}_{v_z^2}(\mathbf{x},t) = -\frac{4p^2}{\pi^2 m^2} \sum_{n_x=-\infty}^{\infty}{}' (2I_1 + 3r^2 I_2), \tag{20} $$

in which $r = |n_x|a$.

2.3. *Analysis of the results*

Since equations (11)–(13) and (18)–(20) are too complicated to allow a straightforward interpretation, we plot figures for the components of the orientability indicator. Figures 1 and 2 arise from Eqs. (11)–(13) as well as (18)–(20), with the topological length $a = 1$ and $n_x \neq 0$ ranging from -50 to 50. In both figures the solid lines stand for the orientability indicator curves for the dipole in Minkowski spacetime

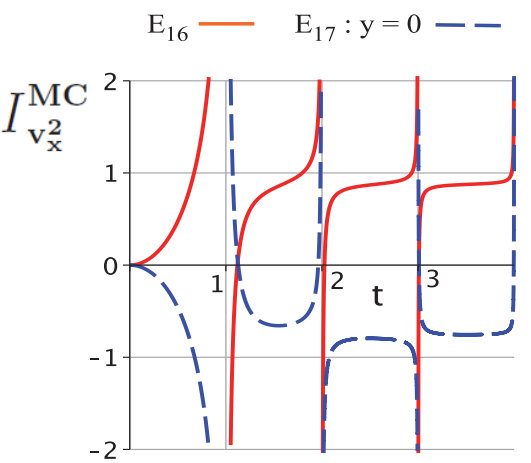

Fig. 1. Time evolution of the x-component of the orientability indicator in units of p^2/m^2 for a point electric dipole oriented in the flip y-direction in Minkowski spacetime with orientable E_{16} and non-orientable E_{17} spatial topologies, both with compact length $a = 1$. The solid and dashed lines stand, respectively, for the indicator curves for a dipole in 3−space with E_{16} and E_{17} topologies. For the globally inhomogeneous topology E_{17} the dipole is at $P_0 = (x, 0, z)$, thus freezing out the topological inhomogeneity. Both orientability indicator curves show a periodicity, but the curve for E_{17} exhibits a different kind of periodicity characterized by a distinctive inversion pattern. Non-orientability is responsible for this pattern of successive inversions, which is absent in the indicator curve for the orientable E_{16}.

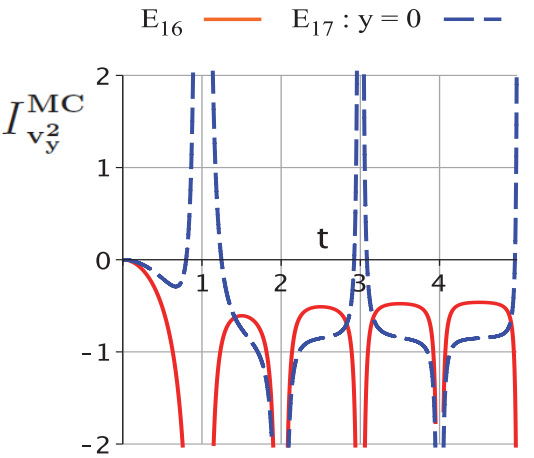

Fig. 2. Time evolution of the y-component of the orientability indicator for a point electric dipole oriented in the y-direction under the same conditions as those of Fig. 1. The orientability indicator curve for E_{17} also displays a characteristic inversion pattern but which is different from the one for the x-component shown in Fig. 1. For the y-component of the orientability indicator the signature of non-orientability can be recognized in the pattern of successive upward and downward "horns" formed by the dashed curve.

with E_{16} orientable spatial topology, whereas the dashed lines represent orientability indicator curves for the dipole located at $P_0 = (x, 0, z)$ in a 3−space with E_{17} non-orientable topology.

In the case of the x-component, the time evolution curves of the orientability indicator for E_{16} and E_{17}, shown in Fig. 1, present a common periodicity but with distinguishable patterns. The orientability indicator curve for E_{17} displays a distinctive sort of periodicity characterized by an inversion pattern. Non-orientability gives rise to this pattern of consecutive inversions, which is not present for the orientable E_{16}.

The differences become more striking when one considers the y-component of the orientability indicator, shown in Fig. 2. The non-orientability of E_{17} is disclosed by an inversion pattern whose structure is more striking than the one for the x-component. The orientability indicator curves for E_{17} form a pattern of alternating upward and downward "horns", making the non-orientability of E_{17} unmistakably identifiable. The z-component of the indicator behaves the same way.[26]

The characteristic inversion pattern exhibited by the dipole indicator curves makes it possible to identify the non-orientability of E_{17} in itself, without having to make a comparison with the indicator curves for its orientable counterpart, which is necessary in the point charge case.[26]

This discussion suggests that it may be possible to unveil a presumed spatial non-orientability by local means, namely by the stochastic motions of charged objects caused by quantum electromagnetic vacuum fluctuations. If the motion of a point

electric dipole is taken as probe, non-orientability can be intrinsically discerned by the inversion pattern of the dipole's orientability indicator curves.

3. Concluding remarks

In general relativity and quantum field theory spacetime is modeled as a differentiable manifold, which is a topological space equipped with a differential structure. It is usually assumed that the spacetime manifold is orientable and, additionally, that it is separately time and space orientable. The theoretical arguments usually offered to assume orientability combine the space-and-time universality of local physical experiments with physically well-defined (thermodynamically, for example) local arrow of time, violation of charge conjugation and parity (CP violation) and CPT invariance.[42–44] One can certainly use such reasonings in support of the standard assumptions on the global structure of spacetime.[b] Nevertheless, it is reasonable to expect that the ultimate answer to questions regarding the orientability of spacetime should rely on cosmological observations or local experiments, or might come from a fundamental theory of physics.

In the physics at daily and even astrophysical length and time scales, we do not find any sign or hint of non-orientability. This being true, the remaining open question is whether the physically well-defined local orientations can be extended continuously to cosmological and/or microscopic scales.

At the cosmological scale, one would think at first sight that to disclose spatial orientability one would have to make a trip around the whole 3−space to check for orientation-reversing paths. Since such a global journey across the Universe is not feasible one might think that spatial orientability cannot be probed globally. However, a determination of the spatial topology through the so-called circles in the sky,[47] for example, would bring out as a bonus an answer to the 3−space orientability problem at the cosmological scale.

We have addressed the question as to whether electromagnetic quantum vacuum fluctuations can be used to bring out the spatial orientability of Minkowski spacetime. We have found that there exists a characteristic inversion pattern exhibited by the orientability indicator curves for a dipole in the case of E_{17}, signaling that the non-orientability of E_{17} might be identified per se. The inversion pattern of the orientability indicator curves for the dipole is a signature of the reflection holonomy, and ought to be present in the orientability indicator curves for the dipole in all remaining seven non-orientable topologies with flip, namely the four Klein spaces (E_7 to E_{10}) and those in the chimney-with-flip class (E_{13} to E_{15}).

Observation of physical phenomena and controlled experiments are essential to our understanding of nature. Our results indicate that it might be possible to locally unveil spatial non-orientability through stochastic motions of point-like objects

[b]See Ref. 45 for a dissenting point of view, and also the related Ref. 46.

under electromagnetic quantum vacuum fluctuations. The present paper may be seen as a hint of a possible way to locally probe the spatial orientability of Minkowski spacetime.

Physical reasoning gives expressions for the hamiltonian of a system of quantum-mechanical particles. These hamiltonians are often differential operators that are symmetric in a densely-defined domain. However, to study the dynamics of the unitary group corresponding to a hamiltonian, it is required that the hamiltonian be self-adjoint or essentially self-adjoint. This study analyzes the effect of the static non-linear electromagnetic-vacuum spacetime of a point nucleus on the self-adjointness and the spectrum of the general–relativistic Dirac hamiltonian for a test electron.

Keywords: Dirac hamiltonian, Reissner–Weyl–Nordström spacetime, self-adjointness

1. Introduction

In non-relativistic physics, whether Newtonian mechanics or quantum mechanics, the gravitational and the electrical attraction between a point electron and a point nucleus obey the same mathematical law and only their coupling strengths differ. Indeed, as the gravitational force is too small compared to the electrical force, it is common to ignore its effect in calculations of realistic hydrogenic spectra.

By contrast, if one models gravity the Newtonian way in the special-relativistic setting, the situation is more subtle. While Coulomb and Newton potential still have the same mathematical form, differing only in their coupling constants, they appear paired up with different Dirac matrices in the Dirac hamiltonian, viz.[a]

$$H := -i\alpha \cdot \nabla + \Big(m - \frac{GmM}{r}\Big)\beta - \frac{Qe}{r}$$

[a] In this note we take $c = \hbar = 1$.

where the hermitian matrices α_j satisfy $\alpha_j\alpha_k + \alpha_k\alpha_j = 2\delta_{jk}1_{\mathbb{C}^4}$, $0 \le j,k \le 3$, with $\alpha_0 = \beta$. Here, (m,e) are the mass and charge of the electron and (M,Q) are the mass and charge of the nucleus. It is known, see [6], that H is essentially self-adjoint if and only if

$$Q^2e^2 - G^2m^2M^2 \le \frac{3}{4}.$$

The self-adjoint extension has $\sigma_{ess}(H) = (-\infty,-m] \cup [m,\infty)$ with $\sigma_{ac}(H) = \sigma_{ess}(H)$ and $\sigma_{sc}(H) = \emptyset$. One can conclude that Newtonian gravity interaction has no significant effect on realistic hydrogenic spectra also in otherwise relativistic settings, as $G^2M^2m^2$ is an exceedingly tiny number[b] compared to Q^2e^2. For instance, one has $\frac{Gmm_p}{e^2} \approx 4.5 \cdot 10^{-40}$, where m_p is the mass of the proton.

On the other hand, the relative contributions of gravitation and electricity to the atomic spectra might be dramatically different, if one considers relativistic gravity. Einstein's gravity refines Newton's law of universal gravitation by providing a unified description of gravity as a geometric property of space and time, and it is formulated by Einstein's field equations. Coupling Einstein's field equations to Maxwell's electromagnetic field equations, we obtain the Einstein-Maxwell system of PDE's

$$\mathbf{R}_{\mu\nu} - \frac{1}{2}R\mathbf{g}_{\mu\nu} = \frac{8\pi G}{c^4}\mathbf{T}_{\mu\nu} \tag{1}$$

$$d\mathbf{F} = 0, \;\; d\mathbf{M} = 0, \tag{2}$$

which describes the geometry of a spacetime endowed with an electromagnetic field. Here, $\mathbf{R}$ is the Ricci curvature tensor, R is the scalar curvature of the metric $\mathbf{g}$, $\mathbf{F}$ is the Faraday tensor and $\mathbf{M}$ is the Maxwell tensor. Furthermore, $\mathbf{T}$ is the electromagnetic energy-momentum-stress tensor associated to $\mathbf{F}$. In order to measure the electrical and gravitational effects on the Dirac spectrum in the relativistic settings, one needs to analyze the relativistic Dirac equation

$$\gamma^\mu(-i\nabla_\mu + eA_\mu)\psi + mI_{4\times4}\psi = 0 \tag{3}$$

in a background that is a solution to (1), (2). Here, ∇_μ is the covariant derivative and A_μ is the electromagnetic 4-potential. In a curved spacetime, $\beta = \gamma^0$, $\beta\alpha^k = \gamma^k$ are related to the metric tensor by $\gamma^\mu\gamma^\nu + \gamma^\nu\gamma^\mu = 2g^{\mu\nu}I_{4\times4}$. Tahvildar-Zadeh[5] showed the following: spherically symmetric, static, asymptotically flat solutions to (1), (2) that are topologically identical to $\mathbb{R}^{1,3}$ minus a timelike line, are covered by a single global chart and have a metric whose line element in spherical coordinates $(t,r,\theta,\phi) \in \mathbb{R}\times\mathbb{R}_+\times[0,\pi]\times[0,2\pi)$ reads

$$ds^2 = -f^2(r)dt^2 + f^{-2}(r)dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2) \tag{4}$$

$$f^2(r) = 1 - 2G\frac{m(r)}{r}, \quad m(r) = M - \mathcal{E}(r). \tag{5}$$

[b]Gravity could be significant for those nuclei satisfying $GM^2 > Q^2$, with mass M and electric charge Q, however, this inequality is not reachable for known nuclei.

Here r is the so-called area radius of a spherical orbit,[c] $m(r)$ is the radial mass function, and $\mathcal{E}(r)$ is the electrostatic field energy outside a ball of surface area $4\pi r^2$. Moreover, M is the ADM mass.

There are well-known examples of such solutions. In particular, $\mathcal{E}(r) = 0$ gives the Schwarzschild metric, and $\mathcal{E}(r) = \frac{Q^2}{2r}$ gives the Reissner–Weyl–Nordström (RWN) metric. In [2], Cohen and Powers considered the relativistic Dirac equation in the RWN spacetime. Note that the structure of the RWN spacetimes depends on the ratio of $\frac{Q^2}{GM^2}$. If $\frac{Q^2}{GM^2} \leq 1$, then $f^2(r)$ has zeros given by

$$r_\pm = GM\left(1 \pm \sqrt{1 - \tfrac{Q^2}{GM^2}}\right). \tag{6}$$

Also, in this case, the RWN spacetime features a dynamical black hole region in $r_- < r < r_+$.[d] Otherwise, $f^2(r)$ is always positive, and the manifold has a naked singularity at $r = 0$. In [2], it was obtained that in the naked singularity sector, the Dirac hamiltonian $\mathcal{H}$ associated with the relativistic Dirac equation is not essentially self-adjoint.

The RWN spacetime of a nucleus has some undesirable features.[7] It has a very strong curvature singularity at its center associated with a negative infinite bare mass, arising from $\mathcal{E}(r)$. In fact, the electrostatic energy density is not integrable about $r = 0$, whereas the system has finite ADM mass, interpreted as the total energy of the spacetime. In Section 2 we answer the question whether a more mildly singular $f^2(r)$, which is compatible with (4), suffices to guarantee an essentially self-adjoint $\mathcal{H}$ for a test electron.

In RWN settings, we say that $f^2(r)$ yields a *subextremal* black hole if $r_- < r_+$; and $f^2(r)$ yields an *extremal* black hole if $r_- = r_+ =: r_0$. In [2], Cohen and Powers also investigated (3) in the static region outside the event horizon of a subextremal (and extremal) RWN black hole, i.e. when $r \geq r_+$. They found that $\mathcal{H}$ is essentially self-adjoint, that its self-adjoint extension has essential spectrum equal to the real line, without a gap, and that it has no eigenvalues at all. Thus, the electron is expected to be swallowed by the black hole unless it escapes to ∞. Therefore, the absence of bound states of an electron outside of the event horizon of a RWN black hole is not a surprising result. In Section 3 we complement this study by considering the static region inside the Cauchy horizon of the subextremal RWN black hole spacetime, i.e., when $0 \leq r \leq r_-$, respectively inside the event horizon of the extremal RWN black hole spacetime, i.e., when $0 \leq r \leq r_0$.

[c]Every point in the stipulated spacetime is an element of a unique orbit under a Killing vector flow corresponding to the $SO(3)$ symmetry, and this orbit is a scaled copy of $\mathbb{S}^2$ with area $4\pi r^2$, *defining* $r > 0$.

[d]Note that $r = r_+$ and $r = r_-$ are the boundaries of the dynamical region and not themselves dynamical. In particular, in the extremal black hole case, there is no dynamical part of the spacetime.

2. Electrostatic spacetimes with negative bare mass and no horizon

Due to the spherical symmetry and static character of the spacetimes, the Dirac operator $\mathcal{H}$ of a test electron in the curved space whose line element ds^2 is given by (4) separates in the spherical coordinates and their default spin frame.[2] More precisely, we study the family of radial Dirac operators H_k, $k \in \mathbb{Z}\backslash\{0\}$, with

$$H_k := \begin{bmatrix} f(r) - e\phi(r) & \frac{k}{r}f(r) - f^2(r)\partial_r \\ \frac{k}{r}f(r) + f^2(r)\partial_r & -f(r) - e\phi(r) \end{bmatrix}, \tag{7}$$

acting on $g(r) := \big(g_1(r), g_2(r)\big)^T$, with a weighted L^2 norm given by
